INSTRUCTIONS TO ABSTRACTORS,

GIVING THE

NOMENCLATURE AND SYSTEM OF NOTATION

ADOPTED IN THE ABSTRACTS.

1. Before beginning to write an abstract, it is desirable to read through the whole of the original paper, in order to form a judgment as to its importance, and as to the scale on which the abstract should accordingly be made.

2. The abstract should mainly consist of the expression, in the abstractor's own words, of the substance of the paper.

3. The abstract should be made as concise as possible, consistently with a clear and accurate statement of the author's results or theories, due regard being paid to their import.

4. If an abstract of a paper on the same subject, either by the author of the paper abstracted, or by some other author, has already appeared, note should as a rule be made of this fact. Important references to the researches of others quoted by an author should be reproduced in the abstract. Always employ figures instead of Roman numerals for references, thus:—*Annalen*, 221, 92, instead of ccxxi, 92.

5. If an abstractor is acquainted with papers previously published by other authors containing statements either practically identical with, or opposed to, those in the paper abstracted, and to which no reference is made, he should notice their agreement or contradiction in a foot-note.

6. As a rule, details of methods of preparation or analysis, or generally speaking of work, may be omitted, unless such details are essential to the understanding of the results, or have some independent value.

Nomenclature.

7. Employ names such as *sodium chloride*, *potassium sulphate*, *ethyl acetate*, and use the terminals *ous* and *ic* only in distinguishing compounds of different orders derived from the same elementary radicle; such, for instance, as mercurous and mercuric chloride, sulphurous and sulphuric acid.

8. Term compounds of metallic and alcoholic radicles with the group OH, *hydroxides* and not hydrates; for example, potassium hydroxide, phenyl hydroxide, the name hydrate being reserved for compounds supposed to contain water of combination or crystallization. Compounds such as CH_3ONa , $\text{C}_2\text{H}_5\text{ONa}$, $\text{C}_7\text{H}_{15}\text{ONa}$, &c., should be termed sodium methoxide, ethoxide, heptyloxide, &c.

9. Apply the term *acid* only to compounds of hydrogen with negative radicles, such as HNO_3 , H_2SO_4 , H_3PO_4 , and denote the oxides which form acids by names such as sulphuric anhydride, carbonic anhydride. Term salts containing an amount of metal equivalent to the displaceable hydrogen of the acid, *normal* and not neutral salts, and assign names such as hydrogen sodium sulphate, hydrogen disodium phosphate, &c., to the acid salts. Basic salts are as a rule best designated merely by their formulae.

10. Use names such as *methane*, *ethane*, &c., for the normal paraffins or hydrocarbons of the $\text{C}_n\text{H}_{2n+2}$ series of the form $\text{CH}_3\cdot[\text{CH}_2]_n\cdot\text{CH}_3$, &c. The isomeric hydrocarbons are usually most conveniently represented by names indicating their relation to methane; for example, $\text{CH}_3\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_3$ = propylmethane; $\text{CH}_3\cdot\text{CH}(\text{CH}_3)_2$ = isopropylmethane or trimethylmethane; or, although less frequently, by names such as diisopropyl.

11. Term the hydrocarbons C_2H_4 and C_2H_2 *ethylene* and *acetylene* respectively (not ethene and ethine). Distinguish the homologues of ethylene, whenever possible, by names indicating their relation to it, such as methylethylene, dimethylethylene, &c., denoting the di-derivatives of the form $\text{C}_n\text{H}_{2n+1}\cdot\text{CH}:\text{CH}\cdot\text{C}_n\text{H}_{2n+1}$ as α -, and those of the form $\text{CH}_2\cdot\text{C}(\text{C}_n\text{H}_{2n+1})_2$ as β -compounds, thus: $\text{CH}_3\cdot\text{CH}:\text{CH}\cdot\text{CH}_3$ = α -dimethylethylene; $\text{CH}_2\cdot\text{C}(\text{CH}_3)_2$ = β -dimethylethylene. Similarly, use names such as methylacetylene and dimethylacetylene for the homologues of acetylene of the form $\text{CH}:\text{C}\cdot\text{C}_n\text{H}_{2n+1}$ and $\text{C}_n\text{H}_{2n+1}\cdot\text{C}:\text{C}\cdot\text{C}_n\text{H}_{2n+1}$. Adopt the same *allene* for the hydrocarbon $\text{CH}_2\cdot\text{C}:\text{CH}_2$, and indicate the relation which its homologues bear to it in the same manner as pointed out for acetylene.

12. Distinguish all alcohols, that is, hydroxyl-derivatives of hydrocarbons, by names ending in *ol*; such as quinol, catechol, resorcinol, saligenol, glycerol, erythrol, mannitol, instead of hydroquinone, pyrocatechin, resorcin, saligenin, glycerin, erythrite, mannite. Compounds which are not alcohols, but which are at present distinguished by names ending in *ol*, may be represented by names ending in *ole*, if a systematic name cannot be given. For example, write indole instead of indol; furfuraldehyde instead of furfural; fucusaldehyde instead of fucsol. Ethers derived from phenols, such as $\text{C}_6\text{H}_5\text{OCH}_3$, &c., hitherto called anisol, anethol, &c., may be distinguished by names ending in *oil*, as anisoil and anethoil.

Alcohols should be spoken of as mono-, di-, tri-, or *n-hydric*, according to the number of OH groups.

13. Compounds analogous to the acids of the lactic series containing the group OH should be termed *hydroxy*-derivatives, and not *oxy*-derivatives; for example, hydroxyacetic and not oxyacetic acid. Compounds containing the analogous groups $\text{C}_2\text{H}_5\text{O}$, $\text{C}_6\text{H}_5\text{O}$, $\text{CH}_3\cdot\text{COO}$, &c., should in like manner be termed *ethoxy*-, *phenoxy*-, *acetoxy*-derivatives. Thus

ethoxypropionic acid instead of ethyl-lactic acid; 3 : 4 diethoxybenzoic acid instead of diethylprotocatechuic acid; and acetoxypropionic acid instead of acetyl-lactic acid. Terms such as diethylprotocatechuic acid should be understood to mean a compound formed by the displacement of hydrogen-atoms in the hydrocarbon radicle of protocatechuic acid by ethyl, viz., $C_6H(C_2H_5)_2(OH)_2COOH$, and not $(C_2H_5(OC_2H_5)_2COOH$, just as dibromoprotocatechuic acid is understood to be the name of a compound of the formula $C_6HBr_2(OH)_2COOH$.

14. The term *ether* should be restricted to the oxides of hydrocarbon radicles, and the so-called compound ethers should be represented by names similar to those given to the analogously constituted metallic salts (comp. 12).

15. Compounds of the radicle SO_3H should, whenever possible, be termed *sulphonic acids*, or failing this, *sulpho-compounds*: as benzenesulphonic acid, sulphobenzoic acid, and not sulfi-compounds. Compounds of the radicle SO_2NH_2 should be termed *sulphonamides*.

16. Basic substances should invariably be indicated by names ending in *ine*, as aniline, instead of anilin, the termination *in* being restricted to certain neutral compounds, viz., glycerides, glucosides, bitter principles, and proteids, such as palmitin, amygdalin, albumin. The compounds of basic substances with hydrogen chloride, bromide, or iodide should always receive names ending in *ide* and not *ate*, as morphine hydrochloride and not morphine hydrochlorate.

Notation.

17. Equations should *be omitted* unless essential to the understanding of the results; they, as a rule, should *not* be written on a separate line, but should "run on" with the text.

18. To economise space, it is desirable: 1, that *dots* should be used *instead of dashes* in connecting contiguous symbols or radicles, whenever this does not interfere with the clearness of the formula; 2, that formulæ should be shortened by the judicious employment of the symbols Me for CH_3 , Et for C_2H_5 , Pr^a for $CH_3\cdot CH_2\cdot CH_3$, Pr^b for $CH(CH_3)_2$, Ph for C_6H_5 , Ac for $CO\cdot CH_3$, and Bz for $CO\cdot C_6H_5$; and 3, that formulæ should be written *in one line* whenever this can be done without obscuring their meaning. For example:

19. In representing the constitution of benzene-derivatives, as a rule, merely indicate the relative positions of the radicles in the symbol of benzene by figures, instead of by means of the hexagon symbol, for example:—

Paradibromobenzenesulphonic acid, $\text{C}_6\text{H}_3\text{Br}_2\cdot\text{SO}_3\text{H}$ [Br : SO₃H : Br =

Relatively to the position 1, the positions 2 and 6 should always be spoken of as *ortho*-positions, 3 and 5 as *meta*-positions, and 4 as the *para*-position. It is better, however, in speaking of the derivatives of benzene, to express their constitution by giving them names such as 1 : 2 dibromobenzene, 1 : 3 dibromobenzene, &c., rather than by terming them *ortho*- or *meta*-dibromobenzene, &c.

20. Moreover, in representing the constitution of derivatives of other "closed-chain" hydrocarbons do not, as a rule, employ graphic formulæ, but merely indicate the position of the radicles introduced in the following manner:—

In the case of *naphthalene*, express the position of the radicles introduced in place of hydrogen relatively to the carbon-atoms common to the two "rings," and number the positions in the one ring 1, 2, 3, 4, and those in the other 1', 2', 3', 4' in the order shown by the annexed symbol:—

The dichloronaphthalenes, for example, are spoken of simply as 1 : 2 dichloronaphthalene, or dichloronaphthalene [Cl : Cl = 1 : 2], &c., thus:—

In the case of *diphenyl*, indicate the position of the radicles relatively to the carbon-atom of one C_6 group which is associated with the other C_6 group, and number the positions in the one group by the figures, 2, 3, 4, 5, 6, and the corresponding positions in the other group by the figures 2', 3', 4', 5', 6'. as shown by the following symbol:

Thus the mono-derivatives, the bromodiphenyls, for example, are represented as

are respectively dibromodiphenyl [Br : Br = 2 : 3]

and dibromodiphenyl [Br : Br = 2 : 6'].

In the case of *anthracene*, employ the following symbol, and indicate the position of the radicles relatively to the central C_2 -group:

Examples:

Alizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 2].

Quinizarin, $C_6H_4 : C_2O_2 : C_6H_2(OH)_2$ [OH : OH = 1 : 4].

Anthraflavic acid, $C_6H_3(OH) : C_2O_2 : C_6H_3(OH)$ [OH : OH = 2 : 3].

Purpurin, $C_6H_4 : C_2O_2 : C_6H(OH)_3$ [OH : OH : OH = 1 : 2 : 4].

In speaking of compounds such as these, their constitution may be represented by the names

1 : 2 Dihydroxyanthraquinone	= Alizarin.
1 : 4 ,,	= Quinizarin.
2 : 3' ,,	= Anthraflavic acid.
1 : 2 : 4 Trihydroxyanthraquinone	= Purpurin.

Always include the letters and figures indicating the constitution of derivatives of closed-chain hydrocarbons in square brackets.

21. In the case of *thiophen*, express the position of the radicles introduced relatively to the sulphur-atom by numbers, as shown by the following symbol:

In the cases of *pyrroline* and *pyridine*, indicate the position relatively to the nitrogen-atoms as shown by the following symbols:

Pyrroline.

Pyridine.

In the case of *indole*, positions should be numbered as shown in the following symbol:—

In the case of quinoline, express the positions relatively to the carbon-atoms common to the two rings, and number the positions in the carbon ring 1, 2, 3, 4, and those in the nitrogen ring 1', 2', 3', 4' in the order shown by the annexed symbol:—

The Editor's decision, in all matters connected with the Abstracts, must be considered final.

ABSTRACTS OF CHEMICAL PAPERS PUBLISHED IN
BRITISH AND FOREIGN JOURNALS.

General and Physical Chemistry.

Some Gaseous Spectra: Hydrogen, Nitrogen. By J. S. AMES (*Phil. Mag.* [5], 30, 48—58).—Exact determinations of the wave-lengths of the line-spectra of hydrogen and nitrogen. The results are tabulated and compared with those of Hasselberg, Cornu, and Deslandres. H. C.

Relations between the Lines of Various Spectra, with special reference to those of Cadmium and Zinc, and a Redetermination of their Wave-lengths. By J. S. AMES (*Phil. Mag.* [5], 30, 33—48).—The author gives an historical and critical survey of the various theories that have been put forward with regard to supposed relations between the lines of the spectra of different elements. Measurements of the wave-lengths and descriptions of the lines of the zinc and cadmium spectra are given from photographs made by Rowland of the arc spectra. The two spectra consist mainly of groups of three lines, which overlap in the cadmium spectrum; but line for line and group by group the two spectra correspond. The differences of the wave-numbers of the last lines in each of the triplets of the two spectra are practically identical. The differences in wave-numbers between the first and second lines in each triplet are all found to be about 39 for zinc and 117 for cadmium; the differences between the second and third lines are 19 for zinc and 54 for cadmium. The first set of differences is therefore in each case about double the second. The spectrum of magnesium has 10 groups of triplets, but these bear no apparent relation to those of zinc and cadmium. There is, however, one broad reversed line common to the three spectra; in magnesium, at wave-length 2852.2; in zinc, at wave-length 2138.3; in cadmium, at wave-length 2288.1. The differences of the wave-numbers in each magnesium triplet are also nearly

constant, being close to 4 and 2. The spectra of calcium, strontium, barium, and mercury also contain triplets, but their number is small in comparison with that of the lines not so included. H. C.

Spark Spectrum of Gadolinium Chloride. By L. DE BOISE-BAUDRAN (*Compt. rend.*, 111, 472—474).—With a spark of low intensity, the spectrum of a hydrochloric acid solution of gadolinium chloride consists of many bands and lines; with a more intense spark, the bands disappear, and the spectrum consists of lines only. With a coil of low intensity, and the poles widely separated, the development of the bands is very remarkable.

The following are the more important wave-lengths in the prismatic spectrum with a spark from a coil of high intensity:—

6223, 5827, and 5698, middle points of somewhat strong bands.

5101, 4888, 4617, and 4467, lines at the edges of bands.

5723, 5705, 5686, 5669, 4929, 4908, 4888, 4793, 4633, 4617, and 4467, lines superposed on the bands, or, in some cases, appearing independently of bands. C. H. B.

The Spectroscopical Properties of Russian Oil of Peppermint. By H. ANDRES (*Chem. Centr.*, 1890, ii, 149; from *Pharm. Zeit. Russ.*, 29, 257—260).—The author has compared the spectroscopical properties of Russian oil of peppermint with those of the English oil, as described by Tichomiroff, and finds that they are almost identical, the only differences being (1) that the black band, which in the case of the English oil appears between 8.5 and 9.5 ($D = 10$), in that of the Russian oil is somewhat wider, extending from 8.5—10.0; (2) the most highly refractive part of the spectrum, from 14.5 to the ultra-violet end, is quite clear in the case of the English oil, whereas in that of the Russian oil, the blue and violet is darkened.

J. W. L.

Measurement of the Quantity of Light that Enters Water. By P. REGNAUD (*Compt. rend. Soc. Biol.* [9], 11, 289).—A line was suspended in the sea by an anchor at the bottom and a buoy at the top. Along this at distances of 2 or 3 metres from one another were placed tubes filled with equal volumes of hydrogen and chlorine. The amount of hydrochloric acid formed by the combination of the two elements is proportional to the amount of light they receive (Bunsen and Roscoe). These preparations are made one night; the light of the day enters the water in inverse proportion to its depth; the next night the tubes, which are graduated, are examined, and the results coincide very closely with those previously obtained with a selenium pile.

W. D. H.

Change of Volume on Mixture of Two Liquids, and its Influence on the Refractive Power. By L. BUCHHEIMER (*Zeit. physikal. Chem.* 6, 161—186).—The author understands by contraction on mixing two substances (dilatation being considered as negative contraction), the expression $\frac{D - D_2}{D}$. D_2 is the calculated density the mixture would possess if no contraction took place; D is

the observed density of the mixture. A similar expression $\frac{N - N_s}{N}$ represents the "contraction" of the refractive power of two substances on mixing. Pulfrich has stated (*Zeit. physikal. Chem.*, 4, 562) the following relations between these two magnitudes:—

$$(1.) \dots\dots\dots \frac{N - N_s}{N} = \alpha \frac{D - D_s}{D},$$

$$(2.) \dots\dots\dots \frac{N - N_s}{N} \text{ and } \frac{D - D_s}{D}, \text{ have always the same sign.}$$

(3.) α is scarcely affected by change of wave-length in feebly dispersive substances. Strongly dispersing media exhibit a continual decrease or increase of α from one end of the spectrum to the other.

The author now tests these relations very fully from the experimental standpoint, and finds in almost every case a confirmation of the rules. His results and those of other investigators are contained in numerous tables and curves. J. W.

Secondary Batteries. By J. H. GLADSTONE and W. HIBBERT (*Phil. Mag.*, [5], 30, 162—170).—The addition of sodium sulphate to the acid solution of an ordinary secondary battery is known to be of considerable advantage to the working of the cell. The authors find that in this case a large proportion of sodium sulphate is formed in close contact with the lead sulphate at the cathode, and they show that this would be favourable to the reduction of the latter substance, as a paste made of equal parts of red lead and lead sulphate is more readily reduced in a solution of normal sodium sulphate than in dilute sulphuric acid. They find also that the presence of sodium sulphate diminishes the local action arising between the acid and different parts of the plates. No indication could be found of the formation of either of Frankland's sub-sulphates of lead on treating litharge with dilute sulphuric acid, and the authors believe the ordinary sulphate of lead to be the substance produced in the voltaic reaction. The high initial E.M.F. observed in a secondary battery when the charging current has just been stopped is shown to be due to inequalities in the acid strength produced by the current. An increase in the strength of the acid surrounding the positive (peroxide) plate is found to take place, and this causes the abnormal E.M.F., which gradually disappears as the strength of the acid is equalised by diffusion. H. C.

Electromotive Force of a Metal in a Series of Electrolytes. By G. MAGNANINI (*Gazz.*, 20, 308—311).—The following table exhibits the average results of a series of experiments undertaken with the view of ascertaining the variation of the E.M.F. of a metal with the nature of the electrolyte in which it is placed.

The measurements were made by Poggendorff's compensation method, using the capillary electrometer.

The difference of potential at the extremity of the measuring

rheostat was maintained at 1 volt, and the metals were successively immersed in each of the series of electrolytes and compared with zinc or cadmium, or lead, in normal sulphuric acid; the E.M.F. was calculated in hundredths of a volt with respect to zinc in sulphuric acid.

(1) Not constant. (2) After a time. (3) A quantity of bromine was used corresponding to $\text{NaOH} = 11$.

It is noticeable that the ordinary salts give values in general not far removed from each other, the more important deviations occurring in electrolytes which may be assumed to have an exceptional action on the metal; oxidising agents, for instance, increase and reducing agents diminish the E.M.F. The differences also depend on the nature of the metal.

S. B. A. A.

Electrical Resistance of Metals. By H. LE CHATELIER (*Compt. rend.*, 111, 454—458).—The author has previously shown that measurements of the electrical resistance of metals may be applied to the study of molecular changes. When a metal undergoes no molecular change below its melting point, the variation in electrical resistance is a linear function of the temperature. The following

numbers give the resistance in ohms of wires 1 mm. in diameter :—platinum, $0.140 + 0.000325t$; platinum + 10 per cent. of rhodium, $0.335 + 0.000350t$; copper, $0.032 + 0.000101t$; copper + 10 per cent. of tin, $0.150 + 0.000109t$; copper + 20 per cent. of nickel, $0.420 + 0.000110t$; silver, $0.023 + 0.000105t$.

Copper, silver, and their alloys with other metals, have practically the same coefficient of variation (approximately 0.000105), that of platinum and its alloys being three times as great. As a general rule, the addition of a small quantity of a foreign metal displaces the curve of resistance parallel with itself.

When silver is heated in oxygen, its curve of resistance remains perfectly rectilinear, and its melting point and mechanical properties are not altered. When, on the other hand, it is heated in hydrogen, all its properties alter above 650° ; the resistance increases more rapidly than in oxygen and the metal after cooling melts at 915° and is so brittle that a wire 0.25 mm. in diameter cannot be bent without breaking. The metal has a dull appearance resembling that of palladium hydride, but the quantity of hydrogen absorbed by the silver at a dull-red heat is not sufficient to form a definite compound, and the metal retains no hydrogen after being cooled.

Metals similar to iron (Abstr., 1890, 549) show variations in the temperature coefficient, but no variations in the absolute value of the resistance similar to those observed at the melting point.

Zinc undergoes a molecular change at 360° ; brass containing 38 per cent. of zinc, at 720° ; and an alloy of copper 70 pts., nickel 18 pts., and iron 11 pts., at 690° . In the case of brass, the molecular change is accompanied by a considerable absorption of heat.

Some alloys show gradual molecular changes recalling the changes in the equilibrium of saline solutions; the change does not take place suddenly, but gradually, between certain limits of temperature. A somewhat siliceous aluminium bronze showed a change between 550° and 650° ; German silver and copper-nickel alloys showed a change between 300° and 500° . In all experiments of this kind, it is essential that the pieces of alloy or metal used should be very carefully annealed. The resistance of German silver resistance coils alters with time, because the coils are in a partially tempered condition, but gradually anneal under the influence of slight variations in temperature, mechanical disturbances, &c.

In the case of iron and nickel alloys, the effect of an increase of temperature is not immediately reversed by cooling; the metal only acquires its original resistance when cooled to the surrounding temperature.

Iron, nickel, and their alloys, at temperatures above the point of transformation, have a temperature coefficient of similar magnitude to that of platinum and the allied metals, whilst below the point of transformation the resistance of iron, nickel, and their alloys increases much more rapidly than that of the platinum metals. C. H. B.

Electrical Conductivity of Salts in the Bunsen Flame. By S. ARRHENIUS (*Sitzungsber. Akad. Wiss., Wien*, 99).—An ordinary Bunsen burner was fed by gas and air, both under constant pressure.

The air current passed through a spray of solution of the salt to be examined. The concentration of this solution determined the amount of salt which passed into the flame. Two platinum plates were introduced into the flame at a distance of 0.56 cm. from each other, and served as electrodes. The circuit contained a battery of 40 Clark elements and a Wiedemann galvanometer. The resistance of the flame was very great compared with that of the remainder of the circuit, so that the deflection of the galvanometer measured the conductivity of the flame.

The relation between E.M.F. e and intensity i was found to be $i = kf(e)$, where k is a constant and f a function which remains the same for all salts at all concentrations.

Only at values below 0.2 Dan. does Ohm's law hold for conduction in the Bunsen flame. The conductivity of the salt in the flame (that is, the total conductivity minus that of the flame itself) is proportional to the square root of the concentration. This was shown to hold good with great approximation for 16 different salts. At extreme dilutions, the conductivity increases somewhat more rapidly. All potassium salts conduct equally well: the same holds true for sodium and for lithium salts.

The conductivity of the chlorides of the alkali metals increases with their molecular weight. Salts of H, NH_4 , Mg, Zn, Cd, Cu, Fe, Ni, Co, Al, Cr, Mn, and Sn do not seem to conduct. Salts of barium, calcium, and strontium conduct by convection of small solid particles, but probably also electrolytically. The difference of potential between two metals in a Bunsen flame containing saline vapours is of the same sign and order of magnitude as when the same metals are immersed in an electrolytic liquid. On the whole, salts in a Bunsen flame behave like a feebly dissociated electrolyte, the chief point of difference being that Ohm's law is not obeyed for large E.M.F.'s.

J. W.

Aqueous Solutions of Double Salts. By W. KISTIAKOWSKY (*Zeit. physikal. Chem.*, 6, 97—121).—It has been proposed by Ostwald to confine the term "double salt" to such compound molecules as are decomposed into their compounds on dissolution, and to use the designation "complex salt" for those which undergo no decomposition. The present paper is a contribution to this classification, the author having investigated a large number of solutions containing salts in molecular proportions. From the electrical conductivity of solutions of given strength, it is possible to obtain information as to the number of ions conducting the electricity, and consequently conclusions may be drawn as to whether the double salts are decomposed into simple salts on dissolution or not. The following substances were found by this means to be (undecomposed) complex salts:— $\text{KAg}(\text{CN})_2$, $\text{K}_2\text{Ni}(\text{CN})_4$, $\text{K}_3\text{Fe}(\text{CN})_6$, $\text{K}_3\text{Co}(\text{CN})_6$, $\text{K}_3\text{Cr}(\text{C}_2\text{O}_4)_3$, $\text{Ag}_3\text{Cr}(\text{C}_2\text{O}_4)_3$, $(\text{NH}_4)_3\text{Fe}(\text{C}_2\text{O}_4)_3$. Double sulphates such as $(\text{NH}_4)_2\text{SO}_4 \cdot \text{CuSO}_4$ and the alums are completely decomposed in solution. If the salt $\text{Ag}_3\text{Cr}(\text{C}_2\text{O}_4)_3$ were a double salt, then the silver and the chromium, on electrolysis, would travel to the same electrode; if, on the other hand, it is a complex salt, the metals will travel in opposite directions. From quantitative experiments, the author finds

that the latter alternative is correct, and that the ions of silver chromoxalate are 3Ag and $\text{Cr}(\text{C}_2\text{O}_4)_3$.

Another mode of attacking the question is given by the depression of the freezing point; and this method is found to yield precisely similar results. The complex salts are found to obey Arrhenius's law of electrolytic dissociation; the double salts, on the contrary, give too large values for the coefficient α .

The author concludes that when a simple salt tends by itself to form compound molecules in solution, it has the power to form compound molecules with other salts. J. W.

Isomerism of the Metaphosphates. By G. TAMMANN (*Zeit. physikal. Chem.*, 6, 122—140).—From an investigation of the electrical conductivity and the freezing point of solutions of the various metaphosphates, the author, by interpreting his results in the light of the dissociation theory, seeks to draw conclusions as to the size of the molecules of these salts.

It would seem that the salts which have hitherto gone by the name of dimetaphosphates in reality have the formula $\text{M}_2\text{P}_2\text{O}_6$, whilst those known as trimetaphosphates correspond with the formula $\text{M}_3\text{P}_3\text{O}_6$.

All the sodium metaphosphates, on being heated, pass into the easily soluble variety known as Graham's salt. This, however, is not a uniform substance, as different specimens exhibit electrical conductivities varying by as much as 20 per cent. On precipitation with silver nitrate, it gives a crystalline silver salt and a heavy liquid. The crystalline salt, treated with sodium chloride, gives a substance of the constitution $\text{Na}_6(\text{P}_3\text{O}_{18})$. Graham's salt is probably a mixture of this with $\text{Na}_4(\text{Na}_2\text{P}_3\text{O}_{18})$ and $\text{Na}_3(\text{NaP}_3\text{O}_{18})$.

The parts of the preceding formulæ within brackets represent the anion formed on solution in water.

There are apparently also salts of the composition $\text{Na}_3(\text{Na}_3\text{P}_3\text{O}_{18})$,

$\text{Na}_2(\text{Na}_1\text{P}_3\text{O}_{18})$, $\text{K}_2(\text{Na}_1\text{P}_3\text{O}_{18})$, $\text{K}_2(\text{Ag}_1\text{P}_3\text{O}_{18})$, $\text{Ag}_3(\text{Na}_3\text{P}_3\text{O}_{18})$,

$\text{Ag}_3(\text{NaP}_3\text{O}_{18})$, $(\text{NH}_4)_3(\text{NaP}_3\text{O}_{18})$, and three different insoluble sodium metaphosphates. J. W.

Electrification of Effluvia from Chemical or from Voltaic Reactions. By J. BROWN (*Phil. Mag.* [5], 30, 21—30).—Experiments are described, showing that when gas is evolved in a chemical or voltaic reaction, the effluvia, that is, the gas or something carried up with it, is usually, as shown by Enright (*Phil. Mag.* [5], 29, 56), electrically charged. No electrification is, however, produced by simple effervescence unaccompanied by chemical change. The sign of the electrification is influenced by the kind of chemical or voltaic action taking place, and does not seem to be due to any contact effect, the conclusion by Enright that nascent hydrogen or other gases become positively electrified by contact with acids, and negatively by contact with salts in solution, being incorrect. When the effluvia is that given off from zinc dissolving in hydrochloric acid (taken as a typical experiment), and consists of hydrogen accompanied by foggy matter, it is not decided whether the charge is given originally to the

gas or the fog particles, although the balance of evidence inclines towards the latter view. The fog in question seems to be formed at, or nearly at, the same time and place as the gas; and the nature of its charge is, therefore, possibly influenced by the voltaic conditions there present. The gas, or effluvium, from the decomposition of a liquid by a current from the poles of a separate battery immersed in it appears also to be electrified. H. C.

Changes of Property in Amalgams by Repeated Fusion. By G. GORE (*Phil. Mag.* [5], 30, 228—230).—It is well known that various alloys undergo a change of properties by repeated melting and cooling. This the author finds to be the case with an amalgam composed of one part by weight of cadmium to four of mercury, for the E.M.F. of a voltaic couple formed by such an amalgam and a strip of platinum in a solution composed of one part by weight of common salt to 100 of distilled water is found to be reduced by repeated fusion, until after about the fifth fusion it becomes constant. At the same time, the amalgam alters in volume, for determinations of the specific gravity after the first and sixth fusions gave 12.5438 and 12.6190 at 14.5°. A similar change was found to take place spontaneously in the freshly-prepared amalgam, a diminution in the E.M.F., measured as above, taking place during the first few days, and clearly indicating a spontaneous molecular change in the amalgam. The author concludes that this amalgam, by the act of fusion and subsequent cooling, and by spontaneous change, suffers a loss of molecular motion, potential heat, chemical activity, and voltaic energy, diminishes in volume, and becomes less corrodible in a solution of sodium chloride. The changes appear to be permanent. H. C.

The Rise of the Zero Point in Thermometers of Jena Glass. By F. ALLIHN (*Zeit. anal. Chem.*, 29, 381—388).—Eight of the thermometers which were under observation a year ago (*Abstr.*, 1889, 1041), and which have not been used in the interval, have again been examined. In some of them no further rise in the zero point has taken place, and in none has it exceeded 0.02°, thus making the total rise only 0.03—0.04° in a period of four years dating from a few weeks after manufacture.

The rise which occurs when a thermometer is for a long time kept at a high temperature is with Jena glass only about half that of ordinary Thuringian glass. It tends to a limit which is practically reached by 30 hours' heating at 300°. The author accordingly recommends that all such thermometers should be so heated before graduating. M. J. S.

The Expansion of Water and other Liquids. By S. U. PICKERING (*Phil. Mag.*, 30, 400).—Some determinations made by the author led him to examine the values for the expansion of water given by Hagen, Jolly, Kopp, Pierre, Rosetti, Mathiessen, and Despretz, with the view of ascertaining whether they indicated any sudden changes in the rate of expansion. Plotting the differential coefficients obtained directly from the experimental values was the method

employed. The results obtained by the majority of these physicists indicated three changes: at 9–11°, at 17–20°, and at 50–60° respectively; but they were not sufficiently marked to afford absolute proof of their existence, especially in the absence of confirmation from a similar study of other properties. Pieme's results with 11 other liquids were examined in the same way: the majority of them showed changes similar to those shown by water, and, as they occurred at different temperatures, the idea that they were due to irregularities in the expansion of glass is precluded. The first differential appears in most cases to be a straight line. S. U. P.

Pressure-variations of certain High Temperature Boiling Points. By C. BARUS (*Phil. Mag.* [5], 29, 141–157).—The author describes a method for the calibration of thermo-couples by aid of boiling points, and then applies it in measuring the vapour tensions of sulphur, zinc, cadmium, and bismuth. It is found that the tensions of saturated vapour from 40 to 760 mm., in terms of temperature, can be expressed by Dupré's equation $\log p = A - B/\theta - C \log \theta$, the best agreement being obtained by keeping C constant throughout, and A variable. The latter step is suggested by assuming that for any two substances S and S', the boiling points θ and θ' , corresponding with a given pressure p , will follow the relation $B/B' = \theta/\theta' = 1/n$, where n is constant for the given pair of substances. This is virtually the principle of Groshans, and postulates a fundamental equation of the form given above, from which all others are derived by substitution as follows:—

$$\begin{aligned}\log p &= A - B/\theta - C \log \theta, \\ &= A - nB/n\theta - C \log n\theta + C \log n, \\ &= A' - B'/\theta' - C \log \theta'.\end{aligned}$$

Making the above assumption, the following values have been obtained for the constants in the cases investigated, and enable the results to be calculated very nearly within the error of experiment. The numbers for water have been added from Dupré and Lertrand's observations.

	A.	B.	C.
Water	19.324	2795	3.865
Sulphur	19.776	4158	3.868
Cadmium	20.63	7443	3.868
Zinc	20.98	8619	3.868
Bismuth	21.51	12862	3.868

H. C.

Raoult's Ebullioscope. By R. LESPIKAU (*Bull. Soc. Chim.* [3], 3, 855–858; compare Abstr., 1889, 7).—When f is the maximum vapour tension of a liquid whose molecular weight is M_1 , f' the maxi-

imum vapour tension of a solution in the given liquid of P grams of a substance whose molecular weight is M , then

$$\frac{100 M}{PM_1} \cdot \frac{f - f'}{j'} = K,$$

K being a constant whose value for water, chloroform, benzene, carbon bisulphide, and ether is 1—1.05. For acetic acid, an abnormal value 1.61 obtains.

If t is the boiling point of the solvent under pressure f_1 , and t' and f_2 the corresponding values for the solution, then the maximum tension of the solvent at t'° is f_1 plus the augmentation of vapour tension suffered by it in passing from t° to t'° , and if the barometer is constant throughout the experiment, f of the formula above given becomes $f = f_1 + n(t' - t)$, where n is the rate of increase in vapour tension for the solvent at temperatures near t ; in the case of water, this is 27 mm. for temperatures near 100° .

To determine the value of $t' - t$, the following apparatus is used by Raoult:—

To ensure a regular heating of the solvent, which is boiled in the vessel shown in the figure, some mercury, covered by 2 cm of coarsely-powdered glass, is placed at the base, and the condensed vapour is returned from the condenser h by a tube g entering the vessel below the glass. The bulb of the thermometer (which is graduated in two hundredths of a degree) is immersed in mercury contained in the tube f , which, after introduction into the apparatus, is read until the heating of the vessel determines a constant temperature. After a slight cooling, the substance M is introduced by the opening e , and the apparatus is further heated to determine t' .

Although this method is less sensitive than the cryoscope process, yet concentrations up to 20 per cent. may be employed, the only condition being that the substance should boil at least 150° higher than the solvent.

T. G. N.

Thermochemistry of Fats and Fatty Acids. By F. STOHMANN and H. LANGHEIN (*J. pr. Chem.* [2], 42, 361—382; compare Abstr., 1885, 857).—The authors have redetermined the heats of combustion of several fats and fatty acids, using the calorimetric bomb and performing the combustions in oxygen at 24 atmospheres pressure.

The mean heat of combustion at constant pressure of 1 gram of various samples of fat is 9500 cal.; that of butter is 9231.3 cal. The heat of combustion is less when the fat is rancid, but the variation differs greatly in different fats; in butter it is almost the same.

In the following table the second column gives the heat of combustion per molecule at constant pressure, and the third column the heat of formation (C = 94, H = 69) :—

	Cal.	Cal.
Erucic acid.....	3297.2	219 8
Brassicic acid.....	3290.1	226 9
Dierucin.....	6979.5	474.5

Behenolic acid.....	3255.1	192.9
Dihydroxybehenic acid....	3235.5	350.5

The formation of glycerides from glycerol and acids is exothermic in the six cases investigated by the authors. A. G. B.

Determination of Specific Gravity of Solids. By O. KLEINSTÜCK (*Chem. Zeit.*, 14, 233—234).—A narrow-necked, pear-shaped glass vessel furnished with a funnel-shaped mouth, a hook below and a mark on the neck, is floated in water: the substance of which the gravity is to be ascertained is attached to the hook, either directly or through the intervention of a pan or wire gauze holder, then by pouring in water the vessel is caused to sink to the mark; the substance is now removed, and the vessel again caused to sink to the mark, this time noting the quantity, by weight or volume, of water required for the purpose; the sp. gr. is calculated from this number. For gravities below unity the weighted vessel is first adjusted to the mark; then the displacement caused by attaching the lighter substance is measured by the water required for the readjustment. D. A. L.

Dissociation of Selenium Chlorides. By W. RAMSAY (*Bull. Soc. Chim.* [3], 3, 783—784; compare Trans., 1884, 62; Abstr., 1890, 558).—The author disputes the statement of Chabrie, that selenium dichloride boils towards 300° without decomposition, and gives experimental proof of its dissociation at 130—170°. In reference to the sublimation of selenium tetrachloride in a sealed tube at 350°,

it is conceivable that the substance is not heated above its normal volatilisation point at the normal pressure (190°) before subliming, and this conception is confirmed by the facts observed by Chabrieu himself, that the tetrachloride dissociates at 300° into dichloride and chlorine, and that this latter is also dissociated into selenium and chlorine, for selenium is always found in the tube after the sublimation of the tetrachloride. T. G. N.

New Periodic Property of the Elements. By W. SUTHERLAND *Phil. Mag.* [5], 30, 318—323).—In solids, the molecules may be assumed to vibrate about a mean position, and at some characteristic temperature each solid to have a period of vibration characteristic of its molecule. The most likely temperature for which this would be the case would be the melting point, when the vibratory motion of the molecule just breaks down. Suppose a molecule of mass M and mean specific heat C , heated up from rest at absolute zero to its melting point T . It receives heat MCT proportional to its kinetic energy $\frac{1}{2}Mv^2$, where v is the velocity of the molecule at the melting point. By Dulong and Petit's law, MC is approximately constant for the elements, so that v is proportional to $\sqrt{T/M}$. Knowing thus the velocity of vibration, from its length L its time or period L/v is obtainable. Let d be the density of the substance, then M/d represents the volume occupied by the molecule; and if a is the mean coefficient of linear expansion of the substance between absolute zero and T , then $aT(M/d)^{\frac{1}{3}}$ represents the increase in the linear dimensions of the space occupied by a molecule when heated from zero to T , and therefore represents the length or amplitude of the vibration just as the molecule is going to leave the vibratory state characteristic of the solid. Hence the periodic time p of the molecule at the melting point is proportional to $aT(M/d)^{\frac{1}{3}}\sqrt{MCT/M}$. The value of a is unknown for many of the elements, but the author has found an empirical equation by means of which it may be determined, namely, $aTM^{\frac{1}{2}} = \text{const.}$, the constant being about 0.015 for all metals except antimony, bismuth, and tin. Substituting this value and dropping all constants from the formula, p becomes proportional to $(M/d)^{\frac{1}{3}}M^{\frac{1}{2}}/\sqrt{T}$.

Taking M as the atomic weight, and calculating the period of vibration by the above formula, we get for the lithium family:—

Li.	Na.	K.	Rb.	Cs.
0.21	0.43	0.66	0.96	1.23

or numbers in the ratio 1, 2, 3, 4.5, 6; and for the next group of the periodic law,

Be.	Mg.	Ca.	Sr.	Ba.
0.35	0.70	1.04	1.62	1.88

numbers in the ratio, 1, 2, 3, 4.5, and 5.3. Copper and silver have periods 0.21 and 0.30, which are nearly as 2 to 3, and involve the same fundamental constant as the main family; and zinc and cadmium have periods 0.32 and 0.47, in which the same peculiarity occurs.

The periods of the other elements do not exhibit such marked relations, but the following series is remarkable:—

Mn.	Fe.	Co.	Ni.	Ru.	Rh.	Pd.	Os.	Ir.	Pt.
0.16	0.16	0.16	0.17	0.21	0.20	0.23	0.23	0.25	0.27

The periods of vibration of compounds are also considered, and it is found that p for each molecule is a sum of parts due to each atom in the molecule.

H. C.

Approximate Algebraic Expression of the Periodic Law.

By T. CARNELLEY (*Phil. Mag.* [5], 29, 97—113).—The atomic weights of the elements, arranged according to the periodic law, may be

represented by the formula $A = c(m + \sqrt{x})$ where A is the atomic weight, c a constant, m a member of an arithmetical progression depending on the series to which the element belongs, and x the maximum valency of the group of which the element is a member. After numerous trials, the best results have been obtained when $x = 2$ and $m = 0, 2\frac{1}{2}, 5, 5 + 3\frac{1}{2}, 5 + 2(3\frac{1}{2}), 5 + 3(3\frac{1}{2}),$ &c., for each series respectively from series ii to xii of Mendeléef's table, so that m is a member of an arithmetical progression in which the common difference is $3\frac{1}{2}$, except in the first two terms, where the common difference is $2\frac{1}{2}$.

The calculated values for c vary from 6.0 (carbon) to 7.2 (selenium), with a mean value of 6.64. The high values of c occur mainly with elements belonging to the higher groups (namely, 5, 6, and 7), whilst low values belong to the lower groups (1, 2, and 3). The greatest extremes occur in group 4, Ti and Ge being high, C and Si low. The equation $A = c(m + \sqrt{x})$ becomes $A = c(m + 1)$ for elements of the first group, so that for potassium $c(m_1 + 1) = 39$, and for silver $c(m_1 + 1) = 107.7$. If x represents the common difference in the arithmetical progression, then $m_1 = m_4 + 3x$, and $107.7 = c(m_1 + 1) + 3xc = 39 + 3xc$, from which $xc = 22.90$. In the same way, by taking different pairs of elements of group 1, different values for xc are obtained, the mean of which is 22.85, or "the difference between the atomic weights of any two elements in group 1 (from series iv upwards), divided by the difference between the number of the series to which each element belongs gives a constant, or $\frac{B - A}{y - x} = \text{const.} = 22.85$ where x and y are the numbers

of the series to which the elements A and B respectively belong." The constant 22.85 is very nearly identical with the atomic weight of sodium (22.99). Atomic weights calculated from the equation $A = c(m + \sqrt{x})$ agree more closely with the observed values than do those determined by Dulong and Petit's law. Specific volumes calculated from the volumes so obtained also agree well with the usual values. The greatest discrepancies occur at the end of series iv, v, and vii, and at the beginning of series xi.

In the equation $A = c(m + \sqrt{x})$, the constant c has a mean value of 6.6, which suggests the constant 6.4 of Dulong and Petit's

law. If c represents the atomic heat, then atomic weight = atomic heat $\times (m + \sqrt{v})$ = atomic weight \times specific heat $\times (m + \sqrt{v})$, or $1 = \text{specific heat} \times (m + \sqrt{v})$, whence specific heat = $\frac{1}{m + \sqrt{v}}$.

Specific heats calculated in this way agree closely with the observed values, especially if specific heats at high temperatures be taken, since in this case the constant 6.4 of Dulong and Petit's law approximates to 6.6.

The value m in the equation $A = c(m + \sqrt{v})$ is the member of an arithmetical progression, and is a whole number for the even series and a number and a half for the odd series, in this way corresponding with the well-known difference between the series. Again, the common difference is $2\frac{1}{2}$ for the first three members, but is $3\frac{1}{2}$ afterwards. This accords with Mendeléeff's statement, that the second and third series are more or less exceptional. H. K. T.

Osmotic Pressure. By M. PLANCK (*Zeit. physikal. Chem.*, 6, 187—189).—The author has in previous memoirs deduced the laws regulating the vapour pressure and freezing point of solutions from thermodynamical principles. In this paper he shows that, given a membrane between a solution and the pure solvent, permeable only to the latter, it is possible, without making any assumptions as to the nature of osmotic pressure, to deduce from the same general conditions of equilibrium the laws discovered by van't Hoff.

The final equation he obtains is $p - p' = n\theta/V$. V is the volume of the solution, θ its absolute temperature, n the number of molecules of the dissolved substance, p the pressure in the solution, and p' the pressure in the solvent; $p' - p$ is thus the osmotic pressure, which, as the equation shows, is inversely proportional to the volume (Boyle's Law), directly proportional to the absolute temperature (Charles' Law), and further proportional to the number of dissolved molecules (Avogadro's Law). J. W.

Inorganic Chemistry.

Properties of Liquid Chlorine. By R. KNIETSCH (*Annalen*, 259, 100—124).—The author has made a series of determinations of the vapour tension of chlorine from -88° to 146° , and of its specific gravity at temperatures ranging from -80° to 77° ; the results are given in tables and as curves, and the methods and apparatus employed are fully described with the aid of various diagrams.

The critical temperature of chlorine was found to be 146° .

F. S. K.

Simple and Rapid Evolution of Pure Gases. By H. BORNTRÄGER (*Zeit. anal. Chem.*, 29, 412; see Abstr., 1890, 849).—The

production of chlorine from a mixture of bleaching powder and sodium hydrogen sulphate was patented by O. Stüber, on April 5th, 1890.

M. J. S.

Atomic Weight of Fluorine. By H. MOISSAN (*Compt. rend.*, **111**, 570—572).—Sodium carbonate, prepared by the ammonia process from carefully purified sodium chloride, was converted into fluoride by the action of hydrofluoric acid from potassium hydrogen fluoride. The sodium fluoride was then converted into sulphate. The results of five determinations varied between $F = 19.04$ and $F = 19.08$ ($Na = 23.05$, $S = 32.074$, and $O = 16$).

Calcium fluoride, obtained in a crystalline form by adding calcium chloride to a boiling dilute solution (0.2 per cent.) of potassium fluoride, was likewise converted into sulphate; $F = 19.02$ to 19.08 .

Barium fluoride, obtained by adding potassium fluoride to a boiling solution of barium chloride, was treated in the same way; $F = 19.05$ — 19.09 .

The action of sulphuric acid on barium fluoride is more difficult to regulate than in the first two cases, and the author regards these results as less trustworthy. Taking the mean of the results with sodium and calcium fluorides, $F = 19.05$.
C. H. B.

Solubility of Oxygen and Hydrogen in Water and in Alcohol. By W. TIMOFÉEFF (*Zeit. physikal. Chem.*, **6**, 141—152).—The author, in his investigation, employs an apparatus devised by Ostwald. It consists of an absorption-chamber which is simply a pipette provided at one end with a stopcock and at the other with a three-way tap, by means of which communication can be effected either with the air or, through a leaden capillary, with a gas burette. The pipette is filled completely with the boiled-out solvent, and a quantity of the gas to be dissolved is introduced into the gas burette and there measured. Communication is then made between the two vessels; a weighed or measured amount of water is run out through the stopcock, which is then closed, and the absorber immersed in a vessel of water at the requisite temperature. From time to time the absorber is taken out of the bath and shaken as vigorously as the flexibility of the lead tube will permit. Mercury is filled into the gas burette as required, in order that the pressure may remain as nearly that of the atmosphere as possible. When no more absorption takes place, pressure and temperature are adjusted, and a fresh measurement made.

The absorption coefficient of hydrogen in water as determined in the above way may be expressed by the formula $\beta = 0.0215286 - 0.00019216t + 0.000001722t^2$. Bunsen found $\beta = 0.01930$ with no temperature coefficient. For oxygen in water, the author obtains $\beta = 0.041408$ at 6.4° , and $\beta = 0.036011$ at 12.6° , numbers which agree well with Winkler's results. The values for hydrogen in alcohol are fairly concordant with those of Carius, β at 0° being 0.0676 (mean of two experiments). An interpolation formula for the absorption coefficient of oxygen in alcohol of 99.7 per cent. strength is $\beta = 0.2337 - 0.0007483t + 0.000003288t^2$. The solubility of nitro-

gen, oxygen, carbon monoxide, and methane in water increases about 30 per cent. between 0° and 20° ; the increase in alcohol is much less.
J. W.

Hydrogen Nitride (Azoimide). By T. CURMUS (*Ber.*, 23, 3023—3033). See p. 56.

Catalytic Decomposition of Ammonium Nitrite. By O. LOWE (*Ber.*, 23, 3018—3019).—On adding platinum black, prepared in the manner described in a previous paper (*Abstr.*, 1890, 453), to a 4 to 5 per cent. solution of ammonium nitrite, an immediate evolution of gas takes place. The first portion consists of a mixture of nitrogen and nitrous oxide, but after a time nitrogen is the sole product. No noticeable alteration in the temperature of the solution occurs.

J. B. T.

Absorption of Carbonic Oxide by Earth. By BERTHELOT (*Compt. rend.*, 111, 469—471).—The volume of carbonic oxide retained by air-dried clay soil is equal to the volume of air which it can retain, and hence the retention of carbonic oxide by the earth, after an explosion in a mine, for example, is not due to any specific action between the soil and the gas.

C. H. B.

Double Chloride and Dithionate of Barium. By A. FOCK and K. KLÜSS (*Ber.*, 23, 3001—3003).—When equivalent quantities of barium dithionate, $\text{BaS}_2\text{O}_6 + 2\text{H}_2\text{O}$, and barium chloride, $\text{BaCl}_2 + 2\text{H}_2\text{O}$, are mixed in aqueous solution and the latter allowed to evaporate, barium dithionate first separates, then, after a time, the double salt, $\text{BaS}_2\text{O}_6 \cdot \text{BaCl}_2 + 4\text{H}_2\text{O}$, and finally barium chloride. The above double salt forms short, colourless prisms, which have been obtained 7 mm. in length and 3.5 mm. in thickness, and belong to the asymmetric system ($a : b : c = 0.6720 : 1 : 0.6398$; $\alpha = 107^{\circ} 12'$, $\beta = 98^{\circ} 11'$, $\gamma = 90^{\circ} 57' 30''$).

H. G. C.

Action of Hydrogen on Potassium Thallium Sulphide. By R. SCHNEIDER (*J. pr. Chem.* [2], 42, 305—327).—When the author first published his work on thio-salts (*Ann. Phys. Chem.*, 136, 138, 139) he showed that when potassium thallium sulphide is heated in hydrogen it is decomposed with formation of hydrogen sulphide, potassium sulphide, and thallium sulphide. KRÜSS and SOLERDER (*Abstr.*, 1887, 111), on the contrary, assert that the thallium is reduced to the metallic state, the potassium remaining as sulphide.

The author has reinvestigated the subject, and his experiments show that the decomposition takes place in two stages, according to the temperature; at a dark-red heat, it is in accordance with the equation which the author first gave, namely:—

at a prolonged, full, red heat, however, a part of the thallium is reduced to the metallic state according to the equation

but at no temperature at which the author has been able to obtain quantitative results is the whole of the thallium so reduced.

Krüss and Schmidt also assert (*loc. cit.*) that the salt of a thio-acid can be reduced by hydrogen when the thio-acid itself can be so reduced. But this is not the case with sodium thioantimonate or Schlippe's salt and potassium indium sulphide, which cannot be reduced by hydrogen notwithstanding that both antimony and indium sulphides are easily reduced. Compare also the behaviour of potassium platinothioplattinate, K_4PtS_4 , and potassium palladothiopalladate, K_4PdS_4 (this Journal, 1871, 317).

The specific gravity of potassium thallium sulphide has been redetermined; it now stands at 4.60.

A. G. B.

Researches on the Gadolinium of Marignac. By L. DE BOISBAUDRAN (*Compt. rend.*, 111, 393—395).—Marignac's gadolinia (Abstr., 1889, 456) was fractionated with dilute ammonia. The absorption spectra showed that there was a concentration of samarium in the head fractions and of didymium in the tail. On the other hand, the fluorescence $Z\beta$ is much stronger in the head fractions, whilst the samarium fluorescence is feeble in these fractions, and is not visible in the others. The spark spectrum shows that all the fractions contain gadolinium.

Cleve finds that the greater part of gadolinia cannot be split up by fractionation. The impurities, which are difficult to eliminate, distribute themselves unequally in the different fractions, without, however, materially affecting the equivalent of the oxide.

The author observed a remarkable temporary solubility of the oxides of the rare earths in ammonium acetate solution containing excess of ammonia. A solution of gadolinium chloride, equivalent to 0.5 gram of the oxide per litre, when mixed with acetic acid and afterwards with ammonia in excess, remained transparent for a long time, but gradually became turbid, and precipitation was practically complete after a day or two. Heat accelerates precipitation, but makes it incomplete. Analogous phenomena are observed with lanthanum, yttrium, and didymium, especially the first, and in a lower degree with cerous chloride.

C. H. B.

Equivalent of Terbia. By L. DE BOISBAUDRAN (*Compt. rend.*, 111, 474—475).—In previous determinations of the equivalent of the earth $Z\beta$ (terbia with a very deep-brown colour), the quantity of oxygen existing in the earth in the form of peroxide, was uncertain. The author has repeated the determinations by the same method, that is, weighing the quantity of the sulphate formed by a given quantity of oxide, but the oxide was previously calcined at a white heat, and the small quantity of peroxide present was determined. The colour of the calcined oxide was much paler, although still very yellow; it contained 0.16 per cent. of oxygen as peroxide. The mean equivalent of the terbia is 122.32, which gives 159.48 for the atomic weight of the metal.

C. H. B.

Ammonium Fluoroxymolybdates. By F. MAURO (*Gazzetta*, 20, 103—121).—*Hexagonal ammonium fluoroxymolybdate*, $3\text{MoO}_3\text{F}_3 \cdot 5\text{NH}_4\text{F} + \text{H}_2\text{O}$, prepared by dissolving the laminar fluoroxymolybdate (Abstr., 1889, 106), or the compound $\text{MoO}_3 \cdot 2\text{NH}_4\text{F}$, in hydrofluoric acid, crystallises in minute, hexagonal prisms, which resemble those of the double salts of molybdenum and niobium of the type $3\text{MOOF}_3 \cdot 5\text{NH}_4\text{F} + \text{H}_2\text{O}$, and are probably isomorphous with the crystals of hexagonal ammonium fluoroxymolybdate. The crystals are colourless and transparent at first, but become opaque after prolonged exposure to the air; they are not dehydrated by heating at 100° ; they dissolve in water, forming an acid solution, which loses hydrogen fluoride on heating, and if the temperature exceeds 100° , ammonia is also evolved.

Monammonium fluoroxymolybdate. $\text{MoO}_3\text{F}_3 \cdot \text{NH}_4\text{F}$, is obtained in monoclinic crystals on allowing a solution of the preceding compound in hydrofluoric acid to evaporate over sulphuric acid;

$$a : b : c = 0.63019 : 1 : 1.42549, \beta = 85^\circ 53'.$$

Faces observed: 010, 001, 110, 111, 337, $33\bar{7}$, $66\bar{7}$. Plane of twinning (307). The crystals, which are generally twinned, are colourless and transparent, but darken and turn green after a short exposure to the air; they dissolve in water, yielding an acid solution. The crystals may be heated to 120° without losing weight, but decompose at a higher temperature.

Delafontaine's acid fluoromolybdate of ammonium appears to be identical with the author's triammonium fluoroxymolybdate, $\text{MoO}_3\text{F}_3 \cdot 3\text{NH}_4\text{F}$, and is not isomorphous with the acid fluoroxymolybdate.
S. B. A. A.

Double Salts of Tungstic and Vanadic Acids. By F. ROTHENBACH (*Ber.*, 23, 3050—3060).—On adding sodium paratungstate to hydrated vanadic anhydride, sodium paratungsto-vanadate is formed, together with a compound which crystallises in dark-red octahedra, and has the formula $3(\text{Na}_2\text{O}, 4\text{WO}_3), \text{Na}_2\text{O}, 3\text{V}_2\text{O}_5 + 38\text{H}_2\text{O}$.

The following salts were prepared from sodium paratungsto-vanadate by double decomposition:—

The *ammonium salt* crystallises in orange-red octahedra of the formula $5[(\text{NH}_4)_2\text{O}, 12\text{WO}_3] \cdot 2[7\text{V}_2\text{O}_5, 3(\text{NH}_4)_2\text{O}] + 58\text{H}_2\text{O}$. The *barium salt* is deposited in light, orange-coloured crystals, which are very sparingly soluble, and have the formula

From the mother liquors cubical crystals are obtained, which contain sodium chloride, barium tungstate, and barium vanadate. The *strontium salt* crystallises in orange-red cubes,

and resembles the barium compound. The *potassium salt* crystallises in aggregates of large, light orange-red plates, which have not yet been analysed. By the action of magnesium sulphate on sodium paratungstovanadate, a compound of the formula

is formed, crystallising in pale orange-yellow prisms. A similar compound is deposited from the mother liquors in lustrous, light orange-coloured plates. With sodium tungstovanadate, aluminium sulphate gives a compound of the formula

crystallising in dark garnet-red cubes. No copper salt could be obtained.

The water of crystallisation in the above compounds was determined by cautious ignition. The vanadic acid and tungstic acid were precipitated together by means of mercuric nitrate and mercuric oxide. The vanadic acid was determined separately by reduction and titration with potassium permanganate, and also by boiling with phosphoric acid, potassium bromide, and hydrochloric acid; the bromine which is evolved is absorbed in potassium iodide solution, and the liberated iodine estimated in the usual manner.

J. B. T.

Bismuth Oxyiodide. By C. ASIRE (*J. Pharm.* [5], 22, 195—200).—Various published methods for the preparation of this oxyiodide yielded products more or less contaminated with sub-nitrate, with oxide, or with both these compounds. To obtain the pure product, 10 grams of bismuth potassium iodide is decomposed by the addition of 4 litres of water, and the product is washed until iodine is no longer removed. The resulting compound contained Bi, 59.38, and I, 36.30 per cent. The double iodide employed is best obtained by triturating normal bismuth nitrate (1 mol.) with potassium iodide (4 mols.), and 50 c.c. of water (*sic*), extracting with ethyl acetate, and submitting the mixture to spontaneous evaporation.

J. T.

Platinum Thiocarbide. By P. SCHUIZENBERGER (*Compt. rend.*, 111, 391—393).—A current of nitrogen or hydrogen charged with the vapour of carbon bisulphide is passed over spongy platinum heated at 400—450°, and when the absorption of the bisulphide ceases, the somewhat finely divided black product is allowed to cool, and is powdered and submitted to the same treatment again. The product is a dense, black powder of the composition Pt_2CS_2 . Under a microscope, it seems homogeneous, and it cannot be separated into different components by levigation. It is not attacked by boiling concentrated nitric or hydrochloric acid, and is almost entirely unaffected by warm aqua regia. It is, therefore, not a mixture of platinum sulphide with carbon, and it probably has the constitution $\text{S}:\text{Pt}:\text{C}:\text{Pt}:\text{S}$. When heated below redness in dry oxygen, it burns with incandescence, and yields carbonic anhydride, sulphuric anhydride, sulphurous anhydride, and a residue of pure platinum.

The formation of this compound may be used for the separation, and even the estimation, of carbon bisulphide in any mixture of gases which is free from oxygen. The gaseous mixture is passed over the heated spongy platinum, and the product is afterwards heated in oxygen, the gases formed being absorbed in some oxidising liquid, and the sulphuric acid estimated in the usual way.

C. H. B.

Mineralogical Chemistry.

Bismuth Minerals from Gladhammar. By G. LINDSTRÖM (*Jahrb. f. Min.*, 1890, ii, Ref. 53; from *Geol. Fören. Förhandl.*, 11, 171).—On examining a series of ores, the author found a lead-grey to tin-white mineral with a brilliant lustre. On analysis, it gave the following results:—

Bi.	Pb.	Ca.	Fe.	Zn.	S.	Insol.	Total.
33.84	48.05	0.69	0.16	0.05	15.92	0.45	99.16

The formula deduced from these results is $3\text{PbS} + \text{Bi}_2\text{S}_3$. The author is unacquainted with a mineral of this composition (compare, however, lillianite, $3\text{Pb}(\text{Ag})\text{S} + \text{Bi}_2\text{S}_3$).

As an assay of another specimen gave 42.15 per cent. of lead, it is possible that bjelkite also occurs at Gladhammar. B. H. B.

Hamlinite, a New Rhombohedral Mineral. By W. E. HIDDEN and S. L. PENFIELD (*Amer. J. Sci.*, 39, 511—513).—Shortly after the discovery of herderite (*Abstr.*, 1884, 827, 1102) at Stoneham, Maine, this mineral was detected occurring as minute, rhombohedral crystals, associated with herderite, margarodite, and the rare glucinum silicate, bertrandite. During the past five years, the authors have kept up a diligent search for the crystals, but without success. The crystals are hexagonal-rhombohedral, and vary from 1 to 2 mm. in diameter. Their hardness is 4.5, and their sp. gr. 3.228. Qualitative analysis indicates that the mineral is a new species—a phosphate, probably of glucinum and aluminium, containing fluorine. The authors propose for it the name of *hamlinite*, in honour of Dr. A. C. Hamlin, who is largely interested in the development of the mineral resources of the district in which the new mineral occurs. B. H. B.

Preparation of Artificial Molybdenite. By A. v. SCHULTEN (*Jahrb. f. Min.*, 1890, ii, Ref. 223; from *Geol. Fören. Förhandl.*, 11, 401).—The author melted 4 grams of potassium carbonate with 6 grams of sulphur in a porcelain crucible, and on cooling added 1 gram of molybdic anhydride. The mass was then heated in a well-closed crucible to a melting heat, and, on cooling, a fresh portion of the anhydride was added. The process was repeated until 5 to 6 gr. of molybdic anhydride had been used. On boiling the melted mass with water, a residue of pure crystallised molybdenite, MoS_2 , was obtained in the form of greyish-violet, opaque, hexagonal crystals with a sp. gr. of 5.06 at 15°. The crystals are very soft, and make grey marks on paper. B. H. B.

Flinkite and Haliophyllite from Harstigen Mine, Sweden. By A. HAMBURG (*Jahrb. f. Min.*, 1890, ii, Ref. 224—228, from *Geol. Fören. Förhandl.*, 11, 212).—Flinkite, a hydrated manganese arsenate, occurs in the Harstigen mine, Pajsberg, Wermland, in greenish-brown crystals with sarkinite on karyopillite. Its sp. gr. is

3·87. It has a hardness of more than 4, and crystallises in the rhombic system, the forms observed being OP , $P\infty$, P , $\infty P\infty$. On analysis, it gave results corresponding with the formula

a composition very similar to that of synadelphite.

An optical examination of the mineral heliophyllite, described by G. Flink as biaxial, showed it to be always composed of biaxial and uniaxial portions. The author distinguishes two types of this mineral as met with at the Harstigen mine: (1) the coarsely laminated variety; and (2) crystals associated with barytes and inesite. The optical properties exhibited are similar to those shown by the mineral ekdemite from Långban, described by Nordenskiöld as optically uniaxial. Further, the minerals appear to be chemically identical, analysis having given the following results:—

	PbO.	FeO + MnO.	CaO.	As ₂ O ₅ .	Sb ₂ O ₃ .	Cl.
I.....	83·45	—	—	10·60	—	8·00
II.....	81·03	0·07	0·08	10·85	0·56	8·05
III.....	80·99	0·16	0·11	10·49	1·38	7·96

I. Ekdemite (Nordenskiöld). II. Heliophyllite, type I. III the same, type II. Nordenskiöld calculates the formula, $Pb_3As_2O_8 + 2PbCl_2$, Flink gives $Pb_4As_2O_7 + 2PbCl_2$. The author, however, is of opinion that the more exact formula $Pb_3As_4O_{15} + 4PbCl_2$ is not improbable.
B. H. B.

Minerals from Styria. By E. HATLE and H. TAUSS (*Jahrb. f. Min.*, 1890, ii., Ref. 17; from *Verhandl. geol. Reichsanst.*, 1887, 226—229).—1. *Pharmacolite* from Völlig. This mineral occurs in white, translucent groups of crystals and crusts with a fibrous texture. Analysis yielded the following results:—

As ₂ O ₅ .	CaO.	H ₂ O.
48·60	27·04	24·49

The mineral is associated with zinc-blende, galena, arsenical pyrites, magnetic pyrites, iron pyrites, quartz, and calcite.

2. *Iron-gymnite* from Kraubath. This mineral occurs, with yellow gymnite, in serpentine. It has a hardness of 3, and a sp. gr. of 1·986. Analysis yielded the following results:—

SiO ₂ .	MgO.	FeO.	H ₂ O.
41·55	30·24	6·60	20·10

Allowance being made for 1·27 per cent. of ferric oxide disseminated in the form of iron mica, the formula is $H_{20}Mg_{13}FeS_{11}O_{46} + 9H_2O$.
B. H. B.

Fluorine and the Synthesis of Minerals. By S. MEUNIER (*Compt. rend.*, lli, 509—511).—The use of aluminium fluoride makes it possible to obtain in a comparatively short time, and at the tempe-

perature of an ordinary coke fire, several minerals, which under ordinary conditions are difficult to synthesise.

32 parts of calcined silica, 8 parts of fused potassium hydroxide, and 44 parts of aluminium fluoride, yield a regulus which is not completely vitreous but gives a fracture with a silky lustre. Under the microscope, it is seen to contain needles of sillimanite and hexagonal lamellæ of tridymite in large quantity, together with inclusions of various kinds and globuliform masses which are almost opaque.

43 parts of silica, 20 of calcium oxide, and 60 of aluminium fluoride yield a product which, although chiefly a glass, has a highly lustrous fracture, and contains needles of sillimanite and lamellæ of tridymite.

26 parts of silica, 12 of calcium oxide, 2 of potassium hydroxide, and 25 of aluminium fluoride yield a decidedly crystalline product containing large quantities of thin plates of labradorite, many of which are macle according to the albite law, whilst the larger have spheroidal inclusions.

22 parts of silica, 17 of alumina, 0.2 of ferric oxide, 8 of sodium hydroxide, 2 of potassium hydroxide, and 1 of lime, in a crucible brasqued with cryolite, yield a deep grey granulo-crystalline product. The mass is vitreous, but is full of inclusions, and contains many crystals of sillimanite, and a large quantity of prismatic crystals of nepheline.

27 parts of silica, 12 of alumina, and 10 of potassium hydroxide in a crucible brasqued with cryolite, yield a partially vitreous product full of crystalline granules. Under the microscope, large numbers of small globules are seen, identical with the leucite of natural amphigenes.

C. H. B.

Sigterite, a New Felspar. By C. RAMMELSBERG (*Jahrb. f. Min.*, 1890, ii, Mem. 71—74).—In an investigation into the properties of eudialyte from Sigterö, the author found that this mineral was associated with two others, white albite and another felspar in the form of grey, granular particles. The new felspar has the cleavage of orthoclase, and, chemically, is a potassium sodium felspar free from lime, and much more basic than albite and orthoclase. In thin sections, inclusions of augite and a small quantity of magnesia-mica were observed. After making corrections for the small quantities of augite present, the mineral gives on analysis the following results: -

SiO_2	Al_2O_3	Na_2O	K_2O	Total.
50.01	30.86	13.90	5.23	100.00

The formula of the felspar is therefore $(\text{NaK})_2\text{AlSi}_3\text{O}_{10}$. In other words, it is a combination of albite and an alkali anorthite. At the same time, it has the composition of an anhydrous natrolite.

B. H. B.

Minerals from Vesuvius. By E. SCACCHI (*Zeit. Krist. Min.*, 18, 99—102; from *B. Accad. di Napoli*, 1888, 12).—1. *Phakellite*, a new mineral. Among the Somma minerals in the museum of the University of Naples there is a substance, hitherto undescribed, which

the author has named from its characteristic combination of transparent, colourless needles to white, silky bundles ($\phi\acute{\alpha}\kappa\epsilon\lambda\lambda\omicron\varsigma$). This rare mineral occurs in a rock consisting of augite with more or less mica, and occasionally in grey, granular calcite. Optically the mineral is uniaxial, with faint negative birefraction, and therefore belongs to the hexagonal system. It has the hardness of orthoclase, and a sp. gr. of 2.49. Analysis gave the following results:—

SiO ₂ .	Al ₂ O ₃ .	K ₂ O.	Na ₂ O.	Total.
37.73	33.33	29.30	0.37	100.73

Formula: $K_2Al_2Si_2O_8$. The analogy with nepheline is remarkable.

2. *Thermonatrite*, from the lava of 1859. This mineral is new for Vesuvius. The Naples museum recently received numerous white, opaque, drusy incrustations from the Fosso grande. On analysis, this mineral, $Na_2CO_3 + H_2O$, yielded 35.44 per cent. of carbonic anhydride.

3. *Soda* from the interior of the same lava in crystalline, colourless, transparent grains. On analysis, the following results were obtained:—

CO ₂ .	Na ₂ O.	K ₂ O.	H ₂ O.	Total.
15.91	22.15	0.41	61.68	100.15

These results correspond with the formula $Na_2CO_3 + 10H_2O$. The mineral cannot have been produced by sublimation, but by the action of carbonic anhydride which has decomposed the lava and taken the soda from it.

4. Altered *comptonite* from the Somma conglomerates. In one variety of conglomerate at Vesuvius, zeolites occur in association with calcite. Among these, small crystals resembling comptonite are occasionally met with, the change in the chemical composition of the zeolites and the variation from that of comptonite consisting chiefly in a loss of water, an absorption of calcium carbonate, and a change in the ratio of the silica to the alumina (compare Abstr., 1887, 17).

B. H. B.

Amphibolite from Habendorf, in Silesia. By E. DATHE (*Jahrb. f. Min.*, 1890, ii, Ref., 243—244; from *Jahrb. preuss. geol. Landesanst.*, 1889, 309—328).—The amphibolite (Analysis I) occurring in the biotite gneiss of Habendorf, consists of hornblende of a greenish-black colour and brilliant lustre. There is a second variety (Analysis II) composed of light greenish-grey hornblende, with a little pyrrhotite and mica. Under the microscope, olivine, diopside, chromite, and rutile could also be detected.

	SiO ₂ .	TiO ₂ .	Fe ₂ O ₃ .	Cr ₂ O ₃ .	Al ₂ O ₃ .	FeO.	MgO.	CaO.

B. H. B.

Chemical Nature of Tourmaline. By C. RAMMELSBERG (*Jahrb. f. Min.*, 1890, ii, Mem., 149—162).—In this paper the author recalculates some 70 analyses of tourmaline, with a view to controvert the formulæ recently arrived at by Riggs (Abstr., 1888, 660), Jannasch and Calb (Abstr., 1889, 472), Scharizer (Abstr., 1889, 764), and Wulffing (Abstr., 1889, 765). He is still of opinion that his interpretation of the tourmaline analyses of 20 years ago was correct, according to which they must be regarded as isomorphous mixtures of three silicates, R'_2SiO_3 , R''_2SiO_3 , and $R'''SiO_3$, in which R' represents H, Na, K, Li; R'' represents Fe, Mn, Mg, Ca; and R''' represents Al_2 , Fe_2 , B_2 , Cr_2 .
B. H. B.

Composition of Tourmaline. By G. W. KALB (*Jahrb. f. Min.*, 1890, ii, Ref. 199—203; from *Inaug. Diss. Göttingen*, 1890).—Ten varieties of tourmaline analysed by the author may be divided into three groups:—(1) Lithium tourmaline, (2) iron magnesium tourmaline, (3) iron tourmaline. From the analyses, the author deduces the general formula $R_3BO_3(SiO_4)_3$. [The analyses given appear to be almost identical with those given in a paper by P. Jannasch and G. Calb (Abstr., 1889, 472).]
B. II. B.

Peridotite from the Harz. By M. KOCH (*Jahrb. f. Min.*, 1890, ii, Ref. 244—245; from *Zeit. deutsch. geol. Ges.*, 41, 163—165).—Peridotite occurring in the gabbro mass of the Kaltenthal, in the Harz, contains olivine in angular grains, as much as $2\frac{1}{2}$ mm. in size, with biotite, spinel, and titaniferous iron ore. Small quantities of augite and plagioclase are present as accessory constituents. The rock is more basic than any of the basic members of the Harzburg gabbro hitherto examined, as is shown by the following analytical results, in which the high percentage of titanium is probably due to the biotite:—

SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO.	MgO.	CaO.	K ₂ O.
34.98	5.18	10.80	1.42	21.33	19.30	0.43	5.42
Na ₂ O.	H ₂ O.	SO ₃ .	Total.	Sp. gr.			
0.17	1.28	trace	100.31	3.27			

B. II. B.

Minerals of the Garnet Group. By W. C. BRÖGGER and H. BÄCKSTRÖM (*Zeit. Kryst. Min.*, 18, 209—276).—Of the 12 silicates crystallising in the regular system, euclite, zunyite, helvine, danalite, garnet, sodalite, nosean, lapis-lazuli, leucite (maskelynite), pollux, analcime, and faujasite, the first eight are orthosilicates, and the last four metasilicates. Three of the metasilicates, maskelynite, pollux, and analcime, belong to one morphological group, whilst faujasite is an isolated species of octahedral type. The orthosilicates are regarded by the author as forming one large group, the garnet group, which may be subdivided into two divisions:—(1) Orthosilicates of tetrahedral character, and (2) orthosilicates of rhombic dodecahedral character. This second division includes holohedral members (the garnet series proper), as well as hemihedral ones (the alkali garnets).

The formulæ of the members of the first division are as follows:—

Eulytine.....	$\text{Bi}_4(\text{SiO}_4)_3$.
Zunyito	$[\text{Al}_6\text{F}_3\text{Cl}(\text{OH})_3]\text{Al}_3(\text{SiO}_4)_3$.
Danalite.....	$(\text{FeZnMn})_3[(\text{ZnFe})_2\text{S}]\text{Be}_3(\text{SiO}_4)_3$.
Helvine	$(\text{MnFeCa})_2(\text{Mn}_2\text{S})\text{Be}_3(\text{SiO}_4)_3$.

In this voluminous paper, the author brings forward a mass of facts to prove the close connection of the regular orthosilicates. The analyses of all the minerals of this garnet group lead to formulæ in which there is 1 mol. of an orthosilicate with 3 mols. of silicic acid. All the members of this group, too, belong to the regular system. A very large number of analyses are discussed. Of these, the following have not previously been published:—

	SiO_2 .	Al_2O_3 .	CaO .	MgO .	Na_2O .	K_2O .	SO_3 .	S.	Cl.	H_2O .

VIII. The same, results calculated from a composition of 76.9 mols. hauyn, 15.7 mols. ultramarine, and 7.4 mols. sodalite. IX. Diopside occurring enclosed in lapis lazuli. X. Results after subtraction of 8 per cent. lazurite. XI. Results corresponding with formula $\text{CaMg}(\text{SiO}_3)_2$. B. H. B.

Minerals and Rocks in the Diamond Fields of South Africa. By A. KNOP (*Jahrb. f. Min.*, ii, Ref. 97—99).—The matrix of the diamonds, the so-called *blue earth*, is found on examination to behave like a serpentine which, after decomposition by acid, leaves microliths of pyroxenic character. The rock may be described as a serpentine-tuff enclosing, at Jagersfontein, the following minerals: garnet, chrome-diopside, enstatite, chromite, zircon, apatite, idocrase, rutile, mica, and diamond. These minerals are described in detail by the author, who gives analyses of the chrome-diopside and chrome-iron ore.

The author regards the Jagersfontein deposit as having been formed

The rock is named *Verite* by the author. It should certainly not be classed as a linburgite. B. H. B.

Meteoric Iron from Magura, Arva, Hungary. By E. WEINSCHENK (*Jahrb. f. Min.*, 1890, ii, Ref. 57—59; from *Ann. k. k. Hof-museums*, 4, 93—101; compare Berthelot and Friedel, *Abstr.*, 1890, 1384).—In an investigation of the meteoric iron from Magura, Arva county, Hungary, the author succeeded in isolating the following constituents:—

1. Tin-white regular crystals, hitherto regarded as schreibersite. These appear to have a cleavage perpendicular to the longitudinal axis; they are strongly magnetic, very brittle, and soluble in hydrochloric acid and copper ammonium chloride, with separation of carbon. The hardness is $5\frac{1}{2}$ to 6, and the sp. gr. 6.977. Analysis (No. I) gave, after subtraction of schreibersite, results corresponding with the formula $O(FeNiCo)_3$. For this new mineral, the author proposes the name of *cohenite*.

2. Thin, silver-white, strongly magnetic lamellæ, which are but slowly soluble in hydrochloric acid, and which may represent Reichenbach's *twinite*. The composition (Analysis II) is in accord with the formula $Fe_3(NiCo)_2$.

3. Fragments of various shapes, which form the principal mass of the iron. They are highly magnetic, sparingly soluble in hydrochloric acid, and give on analysis (No. III) results corresponding with the formula $Fe_3(NiCo)$. The high percentage of cobalt is noteworthy—

	Fe.	Ni.	Co.	C.	Cu.	Sn.	Schreibersite.	Total.
I.	89.83	3.08	0.79	6.43	trace	trace	0.65	100.78
II.	71.04	26.64	1.67	0.30	—	—	—	99.65
III.	87.96	9.19	2.60	0.36	—	—	—	100.11

4. Crystals of rhombic and monoclinic augite.

5. Grains of partly isotropic, partly feebly bi-refractive, diamond proved to be harder than ruby and to burn to carbonic anhydride in a current of oxygen.

Colourless or strongly pleochroic blue grains appear to consist of corundum, whilst small, colourless aggregates may be tridymite.

The author compares the varieties of carbon met with in meteoric iron with those in pig iron. The "hardening-carbon" corresponds with the carbon given off in the form of hydrocarbons when the meteoric iron is dissolved in hydrochloric acid; the ordinary carbide carbon corresponds with cohenite; the graphitic tempering-carbon with the carbon in the residue when meteoric iron is dissolved; and, lastly, graphite is met with in both varieties of iron. This perfect analogy leads to the assumption that the conditions under which meteoric iron was formed are comparable to those under which pig iron is produced, and the presence of the diamond indicates that the carbon dissolved or chemically combined in iron can under certain conditions separate out in the allotropic form of the diamond.

B. H. B.

Organic Chemistry.

Condensation of Acetylene by the Silent Discharge. By BERTHELOT (*Compt. rend.*, 111, 471—472).—If the product of the condensation of acetylene under the influence of the silent discharge is left exposed to the air, it absorbs about one quarter of its weight of oxygen, and can easily be detached from the glass in the form of a yellow, resinous pellicle. It continues to alter spontaneously in the vessel in which it is placed, with formation of a carbonaceous sublimate which is probably the result of a secondary change. When subjected to dry distillation, it undergoes sudden and explosive decomposition, which seems to be exothermic, with production of a considerable quantity of water, together with some acetic acid, and acetonc liquids which have an odour of caramel, and are similar to, if not identical with, the products from sugar or tartaric acid. Neither benzene nor furfuraldehyde is obtained, and distillation with soda-lime yields acetone and other simple products. It is clear therefore that the condensation of acetylene under the influence of the silent discharge is very different from its condensation under the influence of heat. C. H. B.

Combination of Mercuric Cyanide with Lithium Salts. By R. VABET (*Compt. rend.*, 111, 526—527).—A concentrated solution of lithium iodide is added drop by drop to a saturated solution of mercuric cyanide heated at 50—60°. A further quantity of mercuric cyanide is then dissolved in the liquid and more lithium iodide is added. The liquid is concentrated to a syrup, filtered, and allowed to cool, when it deposits the compound $\text{HgCy}_2 \cdot 2\text{LiCy} \cdot \text{HgI}_2 + 7\text{H}_2\text{O}$ in large nacreous lamellæ, which are hygroscopic, very soluble in water, and lose 3 mols. H_2O at 100°, but cannot be completely dehydrated without decomposing. When the salt is carefully heated, it gives off water and becomes yellow, a sublimate of mercuric iodide forming at the same time. At a higher temperature, the salt melts and decomposes into mercuric iodide, mercury, cyanogen, and mercurous iodide. Dilute acids decompose the salt with liberation of hydrocyanic acid and precipitation of mercuric iodide, whilst mercuric cyanide and a lithium salt of the particular acid remain in solution. Copper sulphate, when heated with a solution of the salt, precipitates cuprous cyanide and mercuric iodide, a result which indicates that all the cyanogen is not combined with the mercury. These reactions show that the constitution of the compound is expressed by the formulæ given.

If lithium bromide is added gradually and in small quantity to a saturated solution of mercuric cyanide heated at 80°, the liquid, on cooling, deposits crystals of the compound $\text{HgCy}_2 \cdot \text{LiBr} + 3\frac{1}{2}\text{H}_2\text{O}$. They are hygroscopic and very soluble in water, lose $1\frac{1}{2}$ mols. H_2O at 100°, but cannot be dehydrated without decomposing. When heated gently, it yields no sublimate of mercuric bromide, but at a high temperature it undergoes complex decomposition. When heated with

copper sulphate solution, no cyanogen is evolved, and no precipitate is formed; it follows that all the cyanogen is combined with the mercury.

A mercury lithium cyanochloride is obtained by evaporating a solution of mercuric cyanide containing an excess of lithium chloride. It is so hygroscopic that its composition could not be ascertained.

C. H. B.

Ethylene Dithiocyanate. By C. PARENTI (*Gazzetta*, 20, 178—183).—By treating perthiocyanic acid with alcoholic potash, Fleischer (this Journal, 1871, 391) obtained a compound isomeric with potassium thio- and isothio-cyanate, but differing from these compounds in several respects (*Annalen*, 179, 204). The acid formed by decomposing this salt with sulphuric acid was considered to be a dithiocyanic acid. To prepare the ethylene derivative, perthiocyanic acid and ethylene bromide in molecular proportion are dissolved in the least possible quantity of alcohol, mixed with an alcoholic solution of potassium hydroxide, and boiled for 5 to 6 hours. The filtered liquid, on cooling, deposits a semi-crystalline mass, part of which is insoluble in boiling water, and remains in hard ill-defined crystals which melt at 137—140°. The soluble portion, on recrystallisation from boiling water, is obtained in slightly yellowish prisms which melt at 149—150°, and are readily soluble in hot water and alcohol, but insoluble in ether and benzene. It dissolves in cold concentrated sulphuric acid, and is reprecipitated unaltered on the addition of water. After fusion, it resolidifies at 130°, but this temperature is reduced to 118° after successive fusions. The aqueous solution is not coloured by ferric chloride even after acidification with hydrochloric acid; on heating the alkaline solutions, the respective thio-cyanates are formed. The constitution of this salt is probably

The compound melting at 137—140° has the composition

$\text{C}_4\text{N}_4\text{S}_2(\text{C}_2\text{H}_4)_2$; it is slightly soluble in cold concentrated sulphuric acid, and, on warming, a green liquid with a blue fluorescence is produced from which sulphur separates after a time.

Diacetylcarbinyl Acetate. By A. COMBES (*Compt. rend.*, 111, 421—423).—Chloracetylacetone (Abstr., 1890, 1394), when boiled with potassium acetate in presence of alcohol, yields a pale-yellow liquid which boils at 74.5° under a pressure of 21 mm., also a large quantity of ethyl acetate. The new product has the composition $\text{C}_{11}\text{H}_{14}\text{O}_4$; it has an acid odour, but yields no metallic derivatives, and reduces Fehling's solution and ammoniacal silver nitrate in the cold. It yields a very unstable hydrazone $\text{C}_{11}\text{H}_{14}\text{N}_2\text{O}_2$, which resinifies rapidly when exposed to air and light, and crystallises from ether in large colourless rhomboidal tables which rapidly become red when exposed to light. If this hydrazone is treated with excess of phenylhydrazine in alcoholic solution, it yields an osazone $\text{C}_{19}\text{H}_{18}\text{N}_4$, very soluble in ether, from which it is

precipitated by light petroleum in crystals melting at 143–144°. It is the osazone of acetol, and can also be obtained by the direct action of phenylhydrazine on a hot solution of the compound C_7H_5O , in acetic acid.

The compound C_7H_5O , is in fact the acetate of acetol, formed in accordance with the equations $CHAc_2Cl + AcOK = CHAc_2OAc + KCl$; $CHAc_2OAc + EtOH = CH_2AcOAc + AcOEt$

In order to avoid the secondary action of the alcohol, monochloroacetylacetone was boiled for four or five hours with potassium acetate in presence of glacial acetic acid, and the product was poured into water and mixed with concentrated cupric acetate solution. A green precipitate separates, and is purified by solution in chloroform and precipitation with ether; it forms deep-green crystals of the composition $(C_7H_5O)_2Cu$, and is the cupric salt of diacetylcarbinol, $CHAc_2OAc$, which contains a basic hydrogen atom in the group $-CHOAc$. The copper salt is dissolved in dilute sulphuric acid, and the solution is extracted with ether. After the ether has been expelled, the diacetylcarbinyl acetate is obtained as a colourless liquid boiling at 111° under a pressure of 21 mm. It reduces Fehling's solution and ammoniacal silver nitrate in the cold, has a strongly acid reaction, and decomposes carbonates with formation of crystallisable metallic derivatives. When treated with phenylhydrazine, it yields a viscous liquid which boils without decomposition in a vacuum at 235–240°, and which, when treated with hot sulphuric acid or with oxidising agents, yields a beautiful, blue colouring matter, insoluble in water, but soluble in chloroform or sulphuric acid, and having all the characteristics of a pyrazole-blue.

Attempts to obtain diacetylcarbinol by saponification of the acetate have not yet been successful.

C. H. B.

Indian Geranium Oil: Oxidation of Geraniol. By F. W. SEMMLER (*Ber.*, 23, 2965–2968; see also *Abstr.*, 1890, 951).—For the oxidation of geraniol, potassium dichromate (10 grams) is dissolved in sulphuric acid (12.5 grams) and water (100 grams), and the geraniol added (15 grams all at once), the mixture being at first well cooled, and afterwards allowed to become warm, and vigorously shaken for half an hour. The whole is then made slightly alkaline and distilled in a current of steam. The distillate contains an oil, which has a pleasant odour resembling oranges and lemons, and is a mixture of the oxidation product with ethereal oils formed by the action of the sulphuric acid on geraniol. To separate the latter, the oil is mixed with a saturated solution of sodium hydrogen sulphite, and allowed to remain for 24 hours. The crystalline magma is then collected, pressed between filter-paper, washed with ether, mixed with sodium carbonate, and distilled in a current of steam. A clear, colourless oil, having the composition $C_{10}H_{16}O$ and the above-mentioned characteristic odour, is thus obtained, and appears from its general reactions to be an aldehyde. It is at present being more closely examined.

Alkaline potassium permanganate acts on geraniol in a different

manner, yielding a polyvalent alcohol, which has the closest resemblance to the sugars.

H. G. C.

Dihydric Alcohols derived from Isobutaldehyde. By E. SWOBODA and W. FONSEK (*Monatsh.*, 11, 383—398).—It has been previously shown (compare Abstr., 1894, 37, 832) that when alcoholic potash acts on a mixture of isobutaldehyde and acetaldehyde, *methylisopropylethylene glycol*, $\text{OH}\cdot\text{CHMe}\cdot\text{CHPr}^s\cdot\text{OH}$, boiling at $206\text{--}207^\circ$, is formed. When valeraldehyde and benzaldehyde are substituted for acetaldehyde, *isobutylisopropylethylene glycol*,

which melts at $79\text{--}80^\circ$ and boils at $231\text{--}232^\circ$, and *phenylisopropylethylene glycol*, $\text{OH}\cdot\text{CHPh}\cdot\text{CHPr}^s\cdot\text{OH}$, melting at $81\text{--}82^\circ$ and boiling at $286\text{--}287^\circ$, are formed respectively. In the formation of isobutylisopropylethylene glycol, potassium isobutyrate is the only other product; it must therefore be supposed that a molecule of isobutaldehyde unites with a molecule of valeraldehyde through their aldehydic carbon atoms, which, at the moment of condensation, take up each an atom of hydrogen, furnished by the oxidation of another molecule of isobutaldehyde by a molecule of potassium hydroxide.

The three glycols yield diacetyl derivatives, when heated for 18 hours, in sealed tubes, at 200° , with an excess of acetic anhydride. The compounds thus obtained from methylisopropyl glycol, isopropylisobutylethylene glycol and phenylisopropylethylene glycol, have respectively the formulæ $\text{C}_{10}\text{H}_{18}\text{O}_4$, $\text{C}_{11}\text{H}_{20}\text{O}_4$, and $\text{C}_{15}\text{H}_{26}\text{O}_4$, and the boiling points 220° , $240\text{--}242^\circ$, and $295\text{--}297^\circ$.

On treatment with sulphuric acid, the three glycols behave as pinacones, and lose the elements of a molecule of water; isopropylisobutyl glycol is converted by cold concentrated sulphuric acid into an α -pinacolone, $\text{C}_9\text{H}_{16}\text{O}$, which boils at 150° and has the odour of camphor, and by hot dilute acid into a β -pinacolone, $(\text{C}_9\text{H}_{16}\text{O})_2$, which boils at 274° and is without odour. The other glycols give similar products.

G. T. M.

Sugars derived from Rhamnose. By E. FISCHER and O. PILLOT (*Ber.*, 23, 3102—3110).—Rhamnose (isodulcitol) is methylpentose, has the formula $\text{CH}_2[\text{CH}\cdot\text{OH}]_4\cdot\text{CHO}$, and, like the other heptoses, yields sugars richer in carbon. It is proposed to term these derivatives rhamnohexose, rhamnoheptose, and rhamnooctose.

Rhamnitol, $\text{CH}_2[\text{CH}\cdot\text{OH}]_4\cdot\text{CH}_2\cdot\text{OH}$, is prepared by the reduction of rhamnose with sodium amalgam, and crystallises from alcohol or acetone in triclinic prisms, which melt at 121° , and are insoluble in ether. It is sweet to the taste, is only partially decomposed on distillation, and does not reduce alkaline copper solution. It is readily oxidised by nitric acid, and is reduced by hydriodic acid. The yield is 60 per cent. of the rhamnose.

Rhamnohexonic acid, $\text{CH}_2[\text{CH}\cdot\text{OH}]_5\cdot\text{COOH}$, is already known by the name isodulcitolcarboxylic acid, or rhamnosecarboxylic acid (comp. Abstr., 1888, 806).

Rhamnohexose, $\text{CH}_2[\text{CH}\cdot\text{OH}]_5\cdot\text{CHO}$, is prepared by the reduction of rhamnohexolactone with sodium amalgam at a low temperature;

the yield is 60—65 per cent. of the lactose. The compound crystallises from methyl alcohol in thick plates which melt at 180—181° with decomposition, and exhibit all the characteristic properties of sugar. It does not ferment with yeast. The *phenylhydrazone* is readily soluble in water. The *osazone* is obtained in stellate groups of yellow needles which melt at 200° with evolution of gas, and are readily soluble in alcohol, but nearly insoluble in water.

Rhamnohexitol, $\text{CH}_3[\text{CH}\cdot\text{OH}]_5\text{CH}_2\cdot\text{OH}$, is prepared in a similar manner to rhamnitol, and crystallises from alcohol in small, colourless prisms which melt at 173°, with previous softening at 170°, and have no action on alkaline copper solution.

Rhamnoheptonic acid, $\text{CH}_3[\text{CH}\cdot\text{OH}]_6\text{COOH}$, is formed by the action of hydrogen cyanide on rhamnohexose; on evaporation, it readily passes into the lactone, which crystallises from alcohol in stellate groups of colourless needles melting at 160°, with previous softening at 158°; the yield is 63 per cent. of the sugar.

Rhamnoheptonic hydrazide, $\text{C}_8\text{H}_{15}\text{O}_7\text{N}_2\text{H}_2\text{Ph}$, is formed by the action of phenylhydrazine acetate on the acid or lactone; it crystallises from water in slender, white needles which melt above 215° with evolution of gas, and are very sparingly soluble in alcohol.

Rhamnoheptose, $\text{CH}_3[\text{CH}\cdot\text{OH}]_6\text{CHO}$, is prepared by the reduction of the lactone, and could not be obtained in crystals; it is readily soluble in water or alcohol, but insoluble in ether. The *phenylhydrazones* crystallises from water in colourless, slender needles; on treatment with hydrochloric acid, the sugar is regenerated. The *osazone* is deposited in slender, yellow needles, which are very sparingly soluble in water or alcohol, and melt at about 200° with decomposition.

Rhamnoctonic acid, $\text{CH}_3[\text{CH}\cdot\text{OH}]_7\text{COOH}$, is prepared from rhamnoheptose; on evaporation, the *lactone* is formed, and is best purified by means of the phenylhydrazone; it crystallises from water in colourless, concentric needles which melt at 171—172° without decomposition, and are readily soluble in water or alcohol, but sparingly so in acetone.

The *phenylhydrazide*, $\text{CH}_3[\text{CH}\cdot\text{OH}]_7\text{CO}\cdot\text{N}_2\text{H}_2\text{Ph}$, crystallises from water in slender, white needles melting at 220°. *Rhamnortose* is formed in small quantity by the reduction of the lactone; it readily reacts with alkaline copper solution, and yields an *osazone*, which is insoluble in water, and melts at 216°.

The following table gives the specific rotatory powers of the rhamnose compounds, as far as they are known:—

	Specific rotation.
Rhamnolactone	—
Rhamnose	+ 8° to 9°
Rhamnitol	+10·7
Rhamnohexonolactone	+83·8
Rhamnohexose	—61·1
Rhamnohexitol (approximate) ..	+11·6
Rhamnoheptonolactone	+55·6
Rhamnoheptose (approximate) ..	+ 8·4
Rhamnoctonolactone	—51·20

J. B. T.

Arabinose from Wheat Bran and Rye Bran. By E. STEIGER and E. SCHULZE (*Ber.*, 23, 3110—3113).—It has been previously pointed out by Tollens and his pupils that in all probability the formation of furfuraldehyde from wheat bran and from rye bran by the action of sulphuric acid depends on the previous decomposition of pentaglucofoses (arabinose and xylose); neither of these compounds has, however, hitherto been isolated from the product of the reaction. Wheat bran, freed from starch and albuminous matter, is boiled for several hours with 3 per cent. dilute sulphuric acid; the acid is neutralised with barium carbonate, the solution filtered, concentrated, and extracted with alcohol; on evaporation, arabinose crystallises out; it was identified by its specific rotatory power, and its osazone.

The arabinose is probably formed by the hydrolysis of a compound which the authors term *metaraban*. This is a constituent of the cell membrane, and cannot be prepared quite pure. It gives a cherry-red colour on warming with hydrochloric acid and phloroglucinol, and is insoluble in water, and in cold dilute alkalis or acids. On warming, it readily dissolves, and becomes converted into sugar. Other samples of wheat bran gave similar results, as did also rye bran. No galactose or mannose could be detected in any of the solutions. J. B. T.

Starch. By C. SCHWIBLER and H. MITTELMEIER (*Ber.*, 23, 3060—3075).—The authors give a historical review of the investigation of starch and of the compounds derived from it by hydrolysis, followed by a sketch of the recent work and present theories on the subject.

The experimental part of the present communication is limited to an investigation of dextrin.

Commercial dextrin can be purified by precipitation with alcohol, care being taken that the quantity of alcohol present never exceeds 85 per cent. of the total solution; after precipitating three times, the product ceases to give an insoluble osazone, and after repeating the operation several times the dextrin may be considered to be free from sugar. Good results are also obtained by dialysis and subsequent precipitation with alcohol, but a product free from sugar could not be produced by fermentation.

Pure dextrin becomes yellow or brown on heating with potash, and it readily reduces alkaline copper solution, thus showing that, as it is itself not a definite compound, its constituents must belong wholly, or in great part, to the class of sugars which contain an aldehydic or ketonic group.

This view is supported by the fact that, on digesting solid dextrin with excess of phenylhydrazine at ordinary temperatures, it dissolves, and on heating with alcohol a white precipitate is obtained; this is washed free from phenylhydrazine, and purified by dissolving in water and precipitating with alcohol. This compound contains 1.02 per cent. of nitrogen, corresponding with the formula $C_{60}H_{100}O_{50}.N_2.HPh$, and closely resembles dextrin in its chemical properties and in solubility; it is decomposed by hydrochloric acid in a manner similar to the phenylhydrazones of sugars

with high molecular weights. By heating on the water-bath for two hours with phenylhydrazine acetate, and treating the product with alcohol, a pale-yellow *osazone* is formed, which is less soluble in water than the phenylhydrazone, and may be precipitated by alcohol. The percentage of nitrogen varies somewhat, thus showing that in all probability the body is a mixture of osazone with unaltered phenylhydrazone.

An aqueous solution containing 8 per cent. of dextrin is repeatedly treated with small quantities of sodium amalgam, dilute acetic acid being added from time to time; after several days, alcohol is added to the slightly acid solution, and the insoluble product purified by repeatedly dissolving in water and precipitating with alcohol. The authors propose to call this colourless compound *dextritol*; it does not reduce alkaline copper solution, is insoluble in phenylhydrazine even on warming, and the solution does not become yellow on boiling with potash. By the action of concentrated acids or of diastase on dextritol, a liquid is formed which readily reduces alkaline copper solution.

An 8 per cent. aqueous solution of dextrin is heated with a few drops of bromine and allowed to stand until the colour disappears, a second quantity of bromine is then added, and, as soon as this has reacted, the dextrin is precipitated with alcohol in order to free it from hydrobromic acid; the product is dissolved in water and treated with bromine as before, the process being repeated until the dextrin ceases to reduce alkaline copper solution. After repeated purification, a white powder is obtained which is soluble in phenylhydrazine; an aqueous solution reddens litmus paper, and decomposes calcium carbonate on warming. No precipitate is obtained with lime-water and lead acetate; by the action of diastase, or by heating with a mineral acid, a product is obtained which readily reduces alkaline copper solution.

The above results all point to the presence of an aldehydic group in dextrin, and this view is supported by the fact that the products of hydrolysis are also aldehydes.

By the hydrolysis of starch, the authors have only obtained glucose, but from commercial "starch sugar" they have isolated an unfermentable compound which resembles dextrin, and, from the analysis of its osazone, has the formula $C_{12}H_{22}O_{11}$, being thus isomeric with maltose.

J. B. T.

Stereochemical Isomerides of Nitrogen Compounds. By A. Hantzsch and A. Werner (*Ber.*, 23, 2764—2769; see also *Abstr.*, 1890, 348, 970).—The authors in this paper sum up their views with regard to the isomeric relationships of the oximes as follows:—(1.) The oximes $X:C:N\cdot OH$ behave as tautomeric compounds, and yield two different alkyl derivatives having the structural formulæ $X:C:N\cdot OR$ and $X:\overset{\text{O}}{\underset{\text{O}}{C}}-N\cdot R$, which may be distinguished as "oxygen

ethers" and "nitrogen ethers." (2.) Certain asymmetrical oximes exist in two stereochemically isomeric forms, which, according to the theory proposed by the authors, are represented by the formulæ

$\begin{array}{c} \text{X} \cdot \text{C} \cdot \text{Y} \\ \parallel \\ \text{HO} \cdot \text{N} \end{array}$ and $\begin{array}{c} \text{X} \cdot \text{C} \cdot \text{Y} \\ \parallel \\ \text{N} \cdot \text{OH} \end{array}$ (3.) Each of these isomerides can yield two structurally isomeric ethyl derivatives, and therefore an asymmetrical oxime of the formula $\begin{array}{c} \text{X} \\ \diagup \\ \text{Y} \end{array} > \text{C} : \text{N} \cdot \text{OH}$ should yield four alkyl derivatives, namely:—

In no one case have all four alkyl derivatives been prepared, only three being known in most cases, two of these being "oxygen ethers" and one a "nitrogen ether." In the case of furfuraldoxime, however, the two isomeric "nitrogen ethers" have been prepared, thus giving an indirect proof of this part of the theory.

Auwers and Meyer have suggested that the isomerism of the oximes is due, not to the nitrogen atom, but to the asymmetrical constitution of the hydroxylamine itself, as represented in the

formulae $\begin{array}{c} \text{X} \\ \diagup \\ \text{Y} \end{array} > \text{C} : \text{N} \cdot \text{O} \begin{array}{c} \text{H} \\ \diagup \end{array}$ and $\begin{array}{c} \text{X} \\ \diagup \\ \text{Y} \end{array} > \text{C} : \text{N} \cdot \text{O} \begin{array}{c} \diagdown \\ \text{H} \end{array}$ (Abstr., 1890, 1264). The

authors point out that this hypothesis does not explain the existence of two isomeric nitrogen ethers, and also that the formulae proposed by Auwers and Meyer do not represent distinct isomerides, but only phases of an intermolecular atomic motion, which pass one into the other by the simple rotation of the hydrogen atom of the hydroxyl group around the axis N—O. Further, if, owing to the combined attraction of the nitrogen atom as well as that of the oxygen atom, the hydrogen atom takes up a position intermediate between the two, it must be also supposed that the oxygen atom is attracted out of the plane by the hydrogen atoms of the amido-group; this, however, simply means, in other words, that the hydroxylamine molecule

assumes the tetrahedral configuration $\begin{array}{c} \text{N} \\ \diagup \quad \diagdown \\ \text{H} \quad \text{O} \quad \text{H} \end{array}$, which is simply a

special case of the authors' general hypothesis. According to Behrend's hypothesis (Abstr., 1890, 575), the isomeric benzaldoximes should show very slight differences in their physical properties, but, as a matter of fact, the two compounds are completely distinct. Moreover, the latter hypothesis gives no explanation of the ready formation of benzonitrile from isobenzaldoxime.

In conclusion, the authors state that their hypothesis, like those of Van't Hoff and Wislicenus, is not dependent on any special assumption as to the direction of valencies, &c., but is simply deduced from general symmetrical relations.

H. G. O.

Attempts to prepare Stereochemical Isomerides of Nitrogen Compounds. By A. HANTZSCH (*Ber.*, 23, 2769—2773).—The investigation described in this paper was undertaken to determine, if possible, the conditions under which stereochemical isomerides of

nitrogen compounds are formed. (1.) The study of the question of the existence of an asymmetrical nitrogen atom in derivatives of ammonia and of hydrazine has not yet led to any positive results (see also Kraft, following abstract). (2.) All attempts to obtain stereochemical isomerides of compounds, other than the oximes, with a double linkage between the nitrogen and carbon atom, have been without success. It was found that urethanes do not condense with carbonyl compounds according to the equation

and that isomeric derivatives cannot be obtained from benzylidene-aniline (this vol., p. 50). Further, it was found that nitriles do not form additive compounds in the manner represented by the equation:—

(3.) The compounds which yield isomeric oximes include almost all aromatic aldehydes and asymmetrical ketones, their meta- and para-substitution products, and also diketones of the benzile type and phenylglyoxylic acid. The fatty aldehydes and ketones, and all compounds containing even a single alcohol radicle, C_nH_{2n+1} , in combination with the carbonyl group, yield only a single oxime. This is also the case with all compounds containing a carbonyl group in a closed chain, and in all aromatic aldehydes and ketones in which substitution has taken place in the ortho-position relatively to the carbonyl group. When substitution has taken place in both ortho-positions, the compound does not yield any oxime. This agrees with the results of Kehrman, but the author differs from Kehrman in so far as he regards the configuration of the molecule, rather than the space which it occupies, as determining the possibility of the existence of isomerides.

H. G. C.

Displacement of Halogens by the Amido-group. By E. SHELIG (*Ber.*, 23, 2971—2972).—In the usual process for the displacement of a halogen by the amido-group by treatment with aqueous or alcoholic ammonia, the reaction, as a rule, does not stop with the simple displacement, but proceeds further, with formation of secondary and tertiary bases. If, in place of the solution of ammonia in water or in alcohol, phenol diluted with 15 per cent. of water and saturated with gaseous ammonia is employed, the reaction proceeds much more smoothly. Thus benzyl chloride treated with this reagent gives 24 per cent. of the theoretical yield of benzylamine, whereas with aqueous or alcoholic ammonia, only traces of the amino are obtained. Ethylene bromide, treated in a similar manner, gives a yield of 38 per cent. of ethylenediamine hydrate.

H. G. C.

Isobutylamine. By H. MALHOT (*Compt. rend.*, 111, 528—529). The author has investigated the conditions which give the largest yield of isobutylamine by the reaction of isobutyl chloride with

ammonia. The chloride was heated with different proportions of ammonia in sealed tubes at 100° for various periods of time. Details of the experiments are given. The best results are obtained when 1 mol. of isobutyl chloride is heated with 10 or 15 mols. of ammonia; in the first case the quantity of diisobutylamine formed is twice as great as in the second, but it is easily removed by washing with water. The mixture must be heated for 3 to $3\frac{1}{2}$ days. C. H. B.

Action of Secondary Amines on Imido-ethers. By A. PINNER (*Ber.*, 23, 2927—2933).—*Tetretethylsuccinamidine hydrochloride*, $\text{NH}\cdot\text{C}(\text{NEt}_2)\cdot\text{CH}_2\cdot\text{C}(\text{NH})\cdot\text{NEt}_2\cdot 2\text{HCl}$, is prepared by the action of diethylamine on ethylsuccinimidine hydrochloride; after remaining for about eight days, it separates in lustrous, prismatic crystals. On recrystallisation, ammonia is eliminated, and *tetretethylsuccinimidine hydrochloride*, $\begin{array}{c} \text{CH}\cdot\text{C}(\text{NEt}_2) \\ | \\ \text{CH}_2\cdot\text{C}(\text{NEt}_2) \end{array} \gg \text{N}, \text{HCl}$, is formed, crystallising in large, thin plates. The *platinochloride* is deposited in yellowish-red, lustrous, pointed prisms which melt at 202° .

Tetrapropylsuccinimidine hydrochloride, $\begin{array}{c} (\text{H}\cdot\text{C}(\text{NPt}^{\text{a}}_3) \\ | \\ \text{CH}_2\cdot\text{C}(\text{NPt}^{\text{a}}_3) \end{array} \gg \text{N}, \text{HCl}$, which closely resembles the tetrethyl derivative, is prepared by the action of dipropylamine on phenylsuccinimide hydrochloride; the intermediate succinamidine could not be isolated; the condensation takes place much more readily than with diethylamine. The *nitrate*, $\text{C}_{16}\text{H}_{31}\text{N}_3\cdot 2\text{HNO}_3$, melts at 53° . The *platinochloride* is very sparingly soluble in water, from which it crystallises in large, pale yellow plates melting at 174° .

The constitution of the above compounds cannot be regarded as being definitely proved, but the formulæ assigned to them appear to be the most probable J. B. T.

β -Bromopropaldehyde and β -Bromopropionic Acid. By L. LEDERER (*J. pr. Chem.* [2], 42, 384). *β -Bromopropaldehyde* is obtained by passing dry hydrogen bromide into well-cooled acetaldehyde to saturation, and evaporating the excess of acetaldehyde at a low temperature. It is a thick, yellowish oil, and does not crystallise; it soon decomposes at the ordinary temperature, and, when heated to 45° in absence of air, it evolves hydrogen bromide and chars.

β -Bromopropionic acid, obtained by oxidising the aldehyde with well-cooled nitric acid (sp. gr. 1.48) and extracting with ether, crystallises in large, colourless tables which melt at 62.5° , and dissolve in the usual solvents (Beckurts and Otto, *Abstr.*, 1885, 506). The *ethyl salt* boils at 89° (40—50 mm.). A. G. B.

Action of Hydrocyanic Acid on Unsaturated Aldehydes. By (1. JOHANNY (*Monatsh.*, 11, 399—412; compare Gautier, *Bull. Soc. Chim.*, 25, 481; Lobry de Bruyn, *Abstr.*, 1885, 242; 1886, 224).—When methylethylacetaldehyde is heated with an equal volume of anhydrous hydrocyanic acid in sealed tubes for 50 hours at 45° , the hydrocyanide,

$C_6H_{10}O, HCN$, is formed, but the compound is so unstable that it cannot be isolated in a pure state, although its acetyl derivative $CH_3Et.CMe.CH(CN).OAc$, obtained by heating it with excess of acetic anhydride in a reflux apparatus, may be distilled without decomposition at $110-114^\circ$ under a reduced pressure of 38 mm.

α -Hydroxy- β -propylidenebutyrimide,

is formed when the above-described acetyl compound is treated with five times its weight of fuming hydrochloric acid and the mixture is allowed to remain at ordinary temperatures in a closed flask for three days. From an alcoholic solution, it crystallises in colourless, rhombic plates which melt at $100-101^\circ$, and on heating with milk of lime, ammonia is evolved, and the calcium salt of α -hydroxypropylidenebutyric acid, $(C_7H_{11}O_3)_2Ca + 2H_2O$, obtained; this crystallises from water in needles. G. T. M.

Molecular Weight of Glycocine and its Anhydride. By T. CURTIS and H. SCHULZ (*Ber.*, 23, 3041-3043).—Determinations of the molecular weights of amidoacetic acid and of various derivatives by Raoult's method, with water as the solvent, give results in accordance with the simple formula $NH_2.CH_2.COOH$. Similar experiments with the anhydride point to the formula $CH_2 < \begin{smallmatrix} NH \cdot CO \\ CO \cdot NH \end{smallmatrix} > CH_2$.

The results previously obtained from vapour density determinations by Hofmann's method are thus fully confirmed. J. B. T.

Glycocine. By J. MAUTHNER and W. SUIDA (*Monatsh.*, 11, 373-382; compare *Abstr.*, 1889, 139).—The authors have prepared glycocine by a more satisfactory method than those previously described, in the following way:—To a well-cooled solution of chloroacetic acid (100 grams) in water (100 c.c.) or alcohol, 20-22 per cent. aqueous ammonia (1 litre) was gradually added. After remaining for a week at ordinary temperatures, the solution was heated, first alone, and then with lead oxide, to expel ammonia; after filtering, the lead was precipitated by the addition of freshly prepared ammonium sulphide, the lead sulphide filtered off, the solution evaporated to dryness, and the crystalline mass thus obtained dissolved in a little water and boiled with copper carbonate. On cooling the filtered solution, copper glycocine crystallised out in masses of needles which, when recrystallised from a little water, gave, besides the needles, a number of bluish-violet, glistening scales. These scales have a similar composition, $(C_2H_4NO)_2Cu + H_2O$, to the needles, but give up their water of crystallisation at a much lower temperature. The modification crystallising in scales may be obtained by heating the needles with a quantity of water insufficient to completely dissolve them, rapidly filtering, and allowing the solution to crystallise. The yield of copper glycocine obtained by this method was about 28 per cent. of theory.

Calcium Orthotolylglycocine, $(C_7H_9NO_2)_2Ca + 3H_2O$.—This salt is prepared by a method similar to that used in the preparation of calcium orthophenylglycocine (compare Abstr., 1889, 1068). When crystallised from water, it forms flat, glistening needles which are insoluble in absolute alcohol. On dry distillation with calcium formate, a product was obtained which appears to be orthotolindole (compare Raschen, Abstr., 1887, 956).

Calcium α -naphthylglycocine, $(C_{12}H_9NO_2)_2Ca + 3H_2O$, is obtained by dissolving α -naphthylglycocine in dilute ammonia, and precipitating the warm solution with calcium chloride. When crystallised from dilute alcohol, the salt forms clusters of flat needles. On heating with calcium formate, a substance was obtained which resembles Schlieper's α -naphthindole (*ibid.*, 963) in crystallising in needles, but has a lower melting point, 163° .

Phenylglycocineparacarboxylic acid, $C_6H_5NO_4$, is obtained by boiling for several hours a mixture of paramidobenzoic acid (25 grams), chloracetic acid (20.6 grams), and sodium carbonate (32.8 grams), dissolved in water (1 litre). On acidifying the cooled solution, a yellow powder (yield 30.2 grams) is precipitated, and this, on recrystallisation from water, forms a crystalline mass which melts with decomposition at 219 – 221° . The barium salt, $C_6H_5NO_4Ba + 4H_2O$, and the calcium salt, $C_6H_5NO_4Ca + 3H_2O$, are white, crystalline powders; the copper salt, $C_6H_5NO_4Cu + 3H_2O$, is a dark-green amorphous powder. G. T. M.

Constitution of Diazo-fatty Acids. By T. CURTIUS (*Ber.*, 23, 3036–3037).—*Hydrazine α -hydrazopropionate*,

is obtained from hydrazine hydrate and pyruvic acid as a colourless, crystalline powder melting at 116° .

Methyl α -hydrazopropionate, $\begin{array}{c} \text{NH} \\ | \\ \text{NH} \end{array} > \text{CMe} \cdot \text{COOMe}$, is prepared in a similar manner from methyl pyruvate and hydrazine hydrate; it melts at 52° , and on treatment with mercuric oxide yields a methyl α -diazopropionate, $\text{N}_2\text{CMe} \cdot \text{COOMe}$, which boils at 53 – 55° under a pressure of 32 mm. The same compound has previously been prepared in small quantities from methyl α -amidopropionate and sodium nitrite. This result proves conclusively that in the diazo-fatty acids the two nitrogen atoms are linked to the same carbon atom.

J. B. T.

Action of Bromine on Angelic Acid and Maleic Acid. By R. FITZG (*Annalen*, 259, 1–40).—When Wislicenus was engaged in developing his theory of the rotation of atomic configurations, there were on record various observations made by the author and his pupils which were not in accordance with the new theory; many of the author's experiments were, therefore, repeated by Wislicenus with results which agreed better with his theoretical views, but

which were totally at variance with those previously obtained by the author.

The author has repeated some of the experiments in question with the utmost care, and has shown that his previous statements are absolutely correct in every detail.

One of the most important points of difference which received attention was the investigation of the action of bromine on angelic acid. It had been stated by Fittig and Pagenstecher (*Abstr.*, 1878, 455) that angelic acid combines with bromine, yielding tiglic acid dibromide as principal product; a small quantity of another substance, which could not be obtained in a pure condition, being produced at the same time.

Wislicenus and Pückert (*Abstr.*, 1889, 587) found, on the other hand, that tiglic acid dibromide is not produced by the action of bromine on angelic acid: they obtained a substance with totally different properties, the investigation of which proved to their minds its complete dissimilarity from tiglic acid dibromide.

Now, as the author had obtained 27 grams of pure tiglic acid dibromide from 15 grams of angelic acid, and had proved the identity of the product with the substance obtained directly from tiglic acid, not only by a general, but also by a crystallographic, examination, and as, furthermore, his observations had been confirmed by Schmidt (*Annalen*, 208, 252), Wislicenus' results were received with great astonishment, and the reinvestigation of the subject was commenced.

In the first place, a sample of the so-called angelic acid dibromide, prepared by Wislicenus and Pückert, was examined by the author, and found to be wanting in all the properties of a pure chemical compound; it seemed to consist principally of tiglic acid dibromide, mixed, however, with various substances, amongst others calcium compounds and resinous matters.

The author then began various experiments on the action of bromine on angelic acid. The acid employed melted at 44°, and as it had been kept for 12 years, it would seem that angelic acid does not become converted into tiglic acid on keeping, as is supposed by Schmidt. The acid was very carefully dried, and then distilled; it boiled at 185°, and underwent no change into tiglic acid, either when boiled or when distilled with steam. Wislicenus and Pückert's statement that pure angelic acid is converted into tiglic acid on boiling with water cannot therefore be confirmed. The pure angelic acid was treated with bromine in carbon bisulphide solution at 0° in diffused daylight, moisture being carefully excluded; several experiments were made under various conditions, in some cases the solution of the acid being added to the bromine solution, in others the process being reversed.

In all the experiments, which are described in great detail, a large quantity of tiglic acid dibromide was obtained, and the identity of the product with the dibromide prepared directly from tiglic acid was proved, by direct comparison as well as by a crystallographic examination.

These results show that the statements published by the author more than 12 years ago are absolutely correct in every detail; it may,

therefore, be considered as proved, that when angelic acid is treated with bromine in carbon bisulphide solution at 0° in diffused daylight, it is almost completely converted into tiglic acid dibromide in the course of a few hours.

A number of careful experiments were also made in order to investigate the behaviour of angelic acid with bromine in absence of sunlight; it was found that, whatever the conditions, the principal product is always tiglic acid dibromide, but that another substance, which is not produced from tiglic acid under the same conditions, is also formed in small quantities. Although, then, the formation of tiglic acid dibromide takes place quickly in presence of diffused sunlight at 0° , and the yield is almost quantitative, in the dark the reaction takes place only very slowly, even at the ordinary temperature, and a larger quantity of a more readily soluble compound is produced. The presence of this readily soluble compound has great influence on the behaviour of the tiglic acid dibromide; it makes it much more readily soluble in all ordinary solvents, retards its crystallisation, and causes it to deliquesce with water. The nature of this bye-product could not be determined, but it is probably an isomeride of tiglic acid dibromide; the substance prepared by Wislicenus and Pückert evidently contains both these compounds.

After referring to several minor errors in the statements and results published by Wislicenus, the author criticises Wislicenus' experiments on the action of bromine on maleic acid, and points out that the conclusions drawn therefrom by Wislicenus are directly opposed to the present theories.

In conclusion, the author protests against the way in which Wislicenus is accustomed to trust to his memory alone in referring to the literature of chemistry; in many cases, the author and others are made to state and affirm in their papers, the references to which are all given, just what Wislicenus himself believes at the time, whereas the actual statements are sometimes the exact contrary and sometimes do not appear at all in the articles referred to, but exist solely in Wislicenus' imagination.

F. S. K.

Syntheses of Nitriles and of β -Ketonic Ethers. By L. BOUVEAULT (*Compt. rend.*, **111**, 531—533).—It has previously been shown (*Abstr.*, 1889, 841) that the products of the action of sodium on propionitrile in presence of ether contain the compound

and it follows that the mixed compound obtained by the action of sodium on the two nitriles $\text{R} \cdot \text{CH}_2 \cdot \text{CN}$ and $\text{R}' \cdot \text{CN}$ (*J. prakt. Chem.* [2], **39**, 188, 230, 245) will have the constitution $\text{NH} \cdot \text{CR}' \cdot \text{CRNa} \cdot \text{CN}$. If this derivative is treated with an alkyl iodide, as in the case of propionitrile, it will form the compound $\text{R}' \cdot \text{C}(\text{NH}) \cdot \text{CR}'' \cdot \text{R} \cdot \text{CN}$, which will be converted by hydrochloric acid into a β -ketonic nitrile $\text{R}' \cdot \text{CO} \cdot \text{CR}'' \cdot \text{R} \cdot \text{CN}$. These nitriles can readily be converted into alkyl salts by dissolving them in the corresponding alcohol and saturating the solution with dry hydrogen chloride.

Methylic methylpropionylacetate, $\text{COEt} \cdot \text{CHMe} \cdot \text{COOMe}$, boils at 185° ,

and is identical with Israel's methyl propionylpropionate (*Annalen*, **231**, 197); *methyl dimethylpropionylacetate*, $\text{COEt}\cdot\text{CMe}_2\cdot\text{COOMe}$, is a colourless liquid which has a camphoraceous odour and boils at $188-188.5^\circ$ (corr.) under a pressure of 760 mm.

These changes are quite general, and all the β -ketonic alkyl salts can be obtained from their nitriles.

Methyl methylpropionylacetate shows powers of condensation similar to those of ethyl acetoacetate; it combines with aniline to form amethylethyloxyquinoline melting at 295° , and insoluble in ether; water, methyl alcohol, and carbanilide are formed at the same time.

The β -ketonic nitriles, when heated in sealed tubes with hydrochloric acid, yield ketones, a reaction discovered by E. v. Meyer. The nitrile $\text{COR}\cdot\text{CR}'\text{R}''\cdot\text{CN}$ will yield the ketone $\text{COR}\cdot\text{CHR}'\text{R}''$, and in this way all the ketones can be obtained in which the two atoms of carbon united to the carbonyl are not both tertiary.

C. H. B.

Syntheses with Ethyl Sodiocarbamate. By F. KRAFF (*Der.*, **23**, 2785-2787).—When ethyl carbamate is treated with finely-divided sodium in ethereal solution, it is converted into a white, amorphous sodium compound, $\text{NHNa}\cdot\text{COOEt}$, which is very hygroscopic, has an alkaline reaction, and is reconverted by dilute acids into ethyl carbamate. The displacement of sodium by methyl does not take place very readily, it being necessary to heat the mixture of ethyl sodiocarbamate and methyl iodide diluted with ether, at 110° , in a sealed tube. The product, after separating the sodium iodide and evaporating the ether, is fractionated, and yields regenerated ethyl carbamate and ethyl methylcarbamate, $\text{NHMe}\cdot\text{COOEt}$, boiling at 170° .

Ethyl chlorocarbonate acts on the sodium compound suspended in ether at the ordinary temperature. After the reaction is over, sufficient water is added to dissolve the sodium chloride formed, the solution is extracted with ether, and the extract, after evaporation of the ether, is fractionated. At 110° , a solid substance commences to separate, but at $210-215^\circ$ an oil passes over, leaving a solid residue which consists of cyanuric acid. On refractionating the oil, more cyanuric acid is obtained, but the greater portion passes over at 215° , and solidifies after a time to a crystalline mass closely resembling ethyl carbamate, and having the same melting point of 50° , but it boils 35° higher, and does not volatilise on remaining in the exsiccator. Its analysis agrees with the formula $\text{C}_3\text{H}_3\text{N}_3\text{O}_3$, and it is therefore, as expected, *ethyl imidodicarboxylate*, $\text{NH}(\text{COOEt})_2$.

H. G. C.

Methyl Cyanosuccinate and Cyanotricarballylate. By L. BACTHE (*Compt. rend.*, **111**, 343-345).—Methyl sodiocyanacetate is prepared by the action of sodium methoxide on methyl cyanacetate in presence of excess of methyl alcohol, the product being heated in a water-bath for several hours with methyl monochloracetate. The liquid is then mixed with water, and the reddish oil which separates is dissolved in ether, dried, and distilled.

The fraction which boils at $196-204^\circ$ under a pressure of 45 mm. is *methyl cyanosuccinate*, $\text{COOMe}\cdot\text{CH}_2\cdot\text{CH}(\text{CN})\cdot\text{COOMe}$, an

oily, colourless liquid, insoluble in water, but soluble in methyl and ethyl alcohols and in alkalis. The fraction boiling at 215° under the same pressure solidifies after some hours, and is purified by recrystallisation from methyl alcohol. It is *methyl cyanotricarballylate*, $\text{CN}\cdot\text{C}(\text{CH}_2\cdot\text{COOMe})_2\cdot\text{COOMe}$, and forms white, prismatic crystals which melt at $46.5\text{--}47.5^{\circ}$, and are soluble in ethyl and methyl alcohols and in ether, but insoluble in water and alkalis. It is formed in the same manner as ethyl cyanotricarballylate (Abstr., 1888, p. 937), and can, in fact, be obtained by the direct action of methyl monochloracetate on methyl sodiocyanosuccinate. C. H. B.

Ethyl Allylcyanosuccinate. By L. BARTHE (*Compt. rend.*, 111, 342—343).—20 grams of ethyl cyanosuccinate is mixed with a solution of 2.3 grams of sodium in 60 grams of alcohol, 16 grams of allyl iodide is added, and the liquid is heated in a water-bath for about 30 hours in an apparatus with a reflux condenser. The product, after separation of the alcohol by distillation, is extracted successively with water and ether. The latter dissolves the ethyl allylcyanosuccinate, which is obtained as a colourless, oily liquid boiling at $207\text{--}210^{\circ}$ (corr.) under a pressure of 35 mm. C. H. B.

The so-called "Sulphite Liquor" and the Rotation of Glyconic, Galactonic, and Rhammonic Acids. By F. WELD, J. B. LINDSAY, W. SCHNITZLE, and B. TOLLENS (*Ber.*, 23, 2990—2992).—The so-called "sulphite-liquor" obtained in the cellulose works is a very slightly milky liquid, which, besides calcium sulphate and potassium sulphide, contains much organic matter. On distilling the liquid with sulphuric or hydrochloric acid it yields furfuraldehyde and furfuralamide, showing the presence of pentoses (xylose). The quantity of the latter is small. If the liquid obtained after hydrolysis with sulphuric acid be separated from gummy matters by precipitation with alcohol, it yields, on treatment with phenylhydrazine, considerable quantities of mannosephenylhydrazone. By the action of nitric acid, the evaporated liquor yields mucic acid, showing the presence of galactan or galactose, and the presence of vanillin has also been shown by the phloroglucinol reaction.

The specific rotatory power of certain acids of the sugar group, and of their calcium salts, has also been examined, with the following results (see also Fischer, Abstr., 1890, 1398):—Gluconic acid.—With calcium gluconate, $[\alpha]_D = +7^{\circ}$. If this salt is dissolved in water and an equivalent quantity of hydrochloric acid, it shows, after 10 minutes, a specific rotatory power of $+2\text{--}3^{\circ}$, calculated as free gluconic acid, $\text{C}_6\text{H}_{12}\text{O}_7$; after 5 days, the rotation remains constant, $[\alpha]_D = +9.8\text{--}10.4^{\circ}$. If the mixture of calcium gluconate and hydrochloric acid is heated at first for half an hour at 100° , $[\alpha]_D = +19^{\circ}$, and this rotation is reduced to one half in two to three weeks. Galactonic acid.—Calcium galactonate, and an equivalent of hydrochloric acid, gave, at first, $[\alpha]_D = -10.56^{\circ}$, and after 2—3 weeks, $[\alpha]_D = -46.82^{\circ}$. After heating for half an hour on the water-bath, $[\alpha]_D = -57.84^{\circ}$, which, after remaining for 14 days, sank to -53.36° . Crystallised galactonic lactone gave, at first, $[\alpha]_D = -58.29$, which

scarcely altered on being kept for a time. Rhammonic acid.--With great difficulty, strontium rhammonate, $(C_6H_{11}O_6)_2Sr + 7$ or $7\frac{1}{2}H_2O$, and an ammonium salt were obtained in a crystalline condition. The former, when dissolved in hydrochloric acid, gave, at first, $[\alpha]_D = -7.67^\circ$, and after 5—6 days, the constant number, $[\alpha]_D = -29.21^\circ$, and after heating, -34.30° , which sank in 5—6 days to -30.12° . Rhammonic lactone gave, immediately after solution, the result $[\alpha]_D = -34.26^\circ$, calculated like the foregoing, for rhammonic acid, $C_6H_{11}O_6$. In three days the rotation had scarcely altered. H. G. C.

Constitution of Benzene and Naphthalene. By A. CLAUS (*J. pr. Chem* [2], 42, 458—469).—A reply to the criticisms which Bamberger has recently passed on Claus' formulæ (compare this vol., p. 1299). A. (I. B.)

Substitution in Aromatic Hydrocarbons. By O. NRIPLA (*Monatsh.*, 11, 429—432).—With the object of obtaining parabromobenzyl chloride, bromine (126 grams) was slowly added, in the dark, to a mixture of benzyl chloride (100 grams) and iodine (5 grams). The solid product, after many recrystallisations from alcohol, melted at 59° , and consisted of a mixture of parabromobenzyl bromide, which melts at 61° , with a small quantity of a compound containing chlorine in both the nucleus and the side chain. A similar result was obtained when chlorine acted on parabromotoluene in direct sunlight. The crystalline product obtained melted at 52° , and consisted chiefly of parabromobenzyl bromide. The formation of this compound is easily accounted for if one supposes that chlorobenzyl chloride is simultaneously formed; examination of oily bye-products points to such being the case. G. T. M.

Derivatives of Orthodibromobenzene. By F. SCHIFF (*Monatsh.*, 11, 329—349).—A more satisfactory method of obtaining orthodibromobenzene than those described by Riese (this Journal, 1873, 63), and Korner (*ibid.*, 1876, i, 214), is as follows:—Bromobenzene is added gradually to 6—7 times its weight of well-cooled nitric acid of sp. gr. 1.53, and the resulting nitro-compounds crystallised from alcohol, when the chief product, paranitrobromobenzene, melting at 126 — 127° , first separates (yield 80 per cent. of theory). On heating this compound with the corresponding quantity of bromine and ferric chloride for 50 hours at 85 — 90° (compare Schenfelden, *Abstr.*, 1886, 340), para-orthonitrodibromobenzene, melting at 58 — 59° (yield 90 per cent. of theory), is obtained, and this, on elimination of the nitro-group, is converted into orthodibromobenzene, which, when pure, boils at 224° , solidifies at -5° , and melts at -1° (compare Meyer and Wurster, this Journal, 1874, 757, 758). Pure metadibromobenzene, after being frozen in a mixture of solid carbonic anhydride and ether, melts at 1 — 2° .

When dibromonitrobenzene is treated with ten times its weight of concentrated nitric acid, of sp. gr. 1.53, and the mixture is warmed in a water-bath for 12 hours, two dibromodinitrobenzenes (α - and β -)

are formed, and may be readily separated by fractional crystallisation from acetic acid.

α-Dibromodinitrobenzene is less soluble in acetic acid and in alcohol than the *β*-compound. It crystallises from alcohol in needles melting at 114—115°. On reduction with tin and hydrochloric acid, it is converted into dihydromidamidobenzene, which crystallises from dilute alcohol in needles melting, with decomposition, at 137°. On treatment with alcoholic ammonia at 110—120°, it gives a dibromonitroaniline, crystallising from alcohol in orange-yellow needles melting at 204—205°, and this, by elimination of the amidogen group, is converted into the original nitrodibromobenzene, and seems to be identical with the dibromonitraniline melting at 202°, obtained from dibromaniline, $[\text{Br}_2 : \text{NH}_2 = 1 : 2 : 4]$, by acetylation, nitration, and subsequent elimination of the acetyl group; *α*-dibromodinitrobenzene has, consequently, the constitution $[\text{Br}_2 : (\text{NO}_2)_2 = 1 : 2 : 4 : 5]$.

β-Dibromodinitrobenzene is very soluble in alcohol and in acetic acid, and crystallises from the former in needles, and from the latter and from carbon bisulphide in small, rhombic plates $[a : b : c = 1 : 0.8541 : 0.5700]$. On treatment with alcoholic ammonia, it gives a dinitrobromaniline, which crystallises from alcohol in yellow needles melting at 153°; this is identical with the compound obtained by Leymann (Abstr., 1882, 1057) by the bromination of metadimitraniline $[1 : 3 : 4]$. The compound has, consequently, the constitution $[\text{Br}_2 : (\text{NO}_2)_2 = 1 : 2 : 3 : 5]$.

On diazotising the dibromaniline above-mentioned, dibromophenol, $[\text{Br}_2 : \text{OH} = 1 : 2 : 4]$, which may be readily sublimed, and crystallises from water in needles melting at 79—80°, is obtained.

G. T. M.

Change of Propyl into Isopropyl in the Cumine Series. By O. WIDMAN (*Ber.*, 23, 3080—3088).—*Para-ethylpropylbenzene*, $\text{C}_6\text{H}_4\text{EtPr}^a$, prepared by heating a mixture of parabromopropylbenzene and ethyl bromide with sodium, boils at 202—205° (corr.), and has a specific gravity of 0.867 at 19°. It yields terephthalic acid as sole produce of oxidation with alkaline permanganate solution, whilst with dilute nitric acid, propylbenzoic acid, together with a little ethylbenzoic acid, is formed.

By the action of sulphuric acid on ethylpropylbenzene, a mixture of two sulphonic acids is obtained: these are converted into sulphonamides, and separated by repeated crystallisation from alcohol.

Para-ethylpropylbenzene-α-sulphonamide,

crystallises from dilute alcohol, or from a mixture of benzene and light petroleum, in long, flat needles melting at 112—113°; on oxidation with chromic acid solution, it yields sulphonamidethylbenzoic acid, $[\text{Et} : \text{COOH} : \text{S} = 1 : 4 : 6]$.

Para-ethylpropylbenzene-β-sulphonamide, $[\text{Et} : \text{Pr} : \text{S} = 1 : 4 : 5]$, is deposited in cubical crystals which melt at 108°, and on oxidation give sulphonamidepropylbenzoic acid. The oxidation of an ethyl

group in the para-position does not, therefore, bring about the change of propyl into isopropyl; in this respect the ethyl group resembles the propyl, isopropyl, and acetyl groups; consequently, the rearrangement to isopropyl appears to take place exclusively in the paramethyl derivatives.

J. B. T.

Behaviour of Phenols and Hydroxy-acids towards the Alkali Hydrosulphides. By F. FUCHS (*Monatsh.*, 11, 363—372).—The author has previously shown (*Abstr.*, 1889, 496) that the hydroxylic hydrogen of hydroxy-acids and phenols, derived from aromatic hydrocarbons, is not displaced by metal, on treatment with an alkali hydrosulphide. The hydroxy-acids of the fatty series, such as malic, citric, and tartaric acids, behave in a precisely similar way; tetra- and penta-methylphloroglucinols decompose hydrosulphides as if they were monobasic acids, an action which the presence of carbonyl groups may possibly determine; on the other hand, tetra- and penta-ethylphloroglucinols have no such action, although the substitution of bromine in the β -position brings about decomposition of the hydrosulphide. This difference in the behaviour of methyl and ethyl derivatives appears to depend on the relative weights of the molecules.

Ortho- and meta-nitrophenols have no action on sodium hydrosulphide, whilst paranitrophenol decomposes it. The substitution of a nitro-group in the ortho- or meta-position in a phenol seems, therefore, not to affect the replaceability of the hydroxylic hydrogen, whilst its substitution in the para-position does. This view is confirmed by the behaviour of nitro Eugenol, in which the nitro-group is ortho- to the hydroxyl.

Tribromoresorcinol behaves as a monobasic acid, only one of the hydroxylic hydrogen atoms being displaced by sodium from the hydrosulphide. When one hydroxyl group is displaced by ethoxyl, no such substitution occurs. The action of some other nitro- and halogen-substituted phenols on sodium hydrosulphide has been determined, and the results depend both on the number and the position of the substituted groups, although no general conclusions can yet be drawn.

G. T. M.

Constitution of Thymol and Cymene Derivatives. By G. MAZZARA (*Gazzetta*, 20, 140—149).—*Dinitrothymyl benzoate*,

prepared by heating the corresponding dinitrothymol with benzoic chloride for about two hours at 160° to 180°, crystallises from alcohol in yellow, rhombohedral plates, melts at 127—128°, and dissolves readily in light petroleum and benzene.

the preceding compound with tin and hydrochloric acid, crystallises from alcohol in yellow plates and from light petroleum in prisms, melts at 106—108°, and is tinged faintly violet by light. It is not altered by boiling with hydrochloric acid or with dilute (20 per cent.) sulphuric acid. The *platinochloride* crystallises from alcohol in yellow needles which decompose at 215°.

heating a solution of the preceding compound in benzene with benzoic chloride, crystallises from alcohol in bulky, white needles and melts at 174—175°. It may be boiled with hydrochloric or dilute sulphuric acid without change.

The formation of the above benzenylamido-derivatives is in accordance with the hypothesis that in dinitrothymol one of the nitro-groups is in the ortho position with respect to the hydroxyl. The author is also investigating the action of acetic anhydride on the corresponding amido-derivative with the view of obtaining a further confirmation of this constitution by the formation of an ethenyl derivative.

Dinitrothymyl acetate. $C_6HMePr(NO_2)_2 \cdot OAc$ [1:4:2:6:3], prepared by heating dinitrothymol with acetic chloride, crystallises from alcohol in prismatic tufts, melts at 85°, and dissolves in light petroleum, ether, and chloroform. The author considers that the dinitrocymene melting at 54°, previously described (Abstr., 1890, 753), has the constitution $[Me:NO_2:Pr:NO_2 = 1:2:4:6]$ and that the liquid and solid dinitrobromocymenes prepared by Fleti and Crosa (Abstr., 1889, 493) have respectively the constitutions

S. B. A. A.

Constitution of Thymoquinone and Carvacrol Derivatives.

By G. MAZZARA (*Gazzetta*, 20, 183—190).—*Dinitrocarvacrol*,

prepared by Carstanjen (Abstr., 1877, 614), crystallises from light petroleum in tufts of yellowish needles which turn red even in diffused light and melt at 117°. It dissolves in dilute alcohol. The *benzoyl* derivative, $C_6HMePr(NO_2)_2 \cdot OBz$ [1:4:3:5:2], prepared like the corresponding thymol derivative, crystallises from alcohol in large, yellow, prismatic plates which melt at 98—100°, and turn brown when exposed to the light.

Diamidocarvacrol. $C_6HMePr(NH_2)_2 \cdot OH$, is prepared by heating dinitrocarvacrol (15 grams) for about an hour, with tin (47 grams) and fuming hydrochloric acid (145 grams). The *hydrochloride* forms white plates which are coloured violet by exposure to light; the base is a red powder which softens at about 190°.

Nitroamidocarvacrol benzoate,

is prepared by heating dinitrocarvacrol benzoate (10 grams) for about an hour with tin (22 grams) and fuming hydrochloric acid (70 grams). It crystallises in rose-coloured scales which have a metallic lustre. It forms a white sublimate at 200° , softens at 230° , and melts at $280-283^{\circ}$. The *platinochloride*, $(C_{17}H_{18}N_2O_4)_2H_2PtCl_6$, crystallises in yellow needles which lose part of their acid at $30-40^{\circ}$. The physical properties of this compound and the absence of any nitrobenzoyl derivative, together with the formation of a benzoyl-derivative (not yet described) with benzoic chloride, indicate that the nitro-group in this compound is in the ortho-position with regard to the hydroxyl.

dinitrocarvacrol benzoate with tin and hydrochloric acid for 5 hours. It crystallises from alcohol in violet prisms which soften at 125° and melt at $130-132^{\circ}$. The formation of a benzenyl derivative from dinitrocarvacrol benzoate and of a hydroxythymoquinone by the oxidation of the amido-derivative shows that in dinitrocarvacrol one of the nitro-groups is in the ortho-position and the other in the para-position with respect to the hydroxyl.

Phenylazo- and phenyldisazo-carvacrol (Abstr., 1885, 1132), which respectively yield thymoquinone and hydroxythymoquinone on oxidation, will accordingly have the constitutions $[Me : OH : Pr : N_2Ph = 1 : 2 : 4 : 5]$ and $[Me : OH : N_2Ph : Pr : N_2Ph = 1 : 2 : 3 : 4 : 5]$.

S. B. A. A.

Action of Chloral on Resorcinol and of Aldehyde on Pyrogallol. By H. CAUSSE (*Bull. Soc. Chim.*, [3], 3, 861-867).—Resorcinol (100 grams) and sodium hydrogen sulphate (20 grams) are dissolved in water (1 litre) and chloral hydrate (50 grams) is added to the mixture, which after some time deposits colourless, oily crystals; if warmed at 100° , yellow crystals are deposited resulting from the dehydration of the former. The colourless crystals are insoluble in water and in benzene, but dissolve in alcohol or ether, whilst their solutions in alkaline hydroxides exhibit a remarkable fluorescence. At 250° , they become yellow, and decompose without fusion. With acetic anhydride, this substance yields a crystalline diacetyl derivative, which melts at 252° with decomposition. Analysis gives the formula $C_{14}H_{12}O_8$, and the same compound resulting from the heating at 100° of equal parts of resorcinol and of glyoxylic acid points to its having the constitution $COOH \cdot CH(O \cdot C_2H_5 \cdot OH)_2$.

Pyrogallol (50 grams), sulphuric acid (5 grams), aldehyde (25 c.c. of a 10 per cent. solution) and water, (500 grams) are heated at 100° for several hours and successive quantities of 10 per cent. sulphuric acid are added, when crystals separate out, and by the addition of more aldehyde and acid further crops are obtainable. From the mass of crystals, the colourless are alone separated and recrystallised from alcohol, separating as small, colourless needles having the composition $C_8H_6O_8$, containing 2 mols. H_2O , which are successively lost

at 30° and 80°. The substance is insoluble in water, benzene, and chloroform, slightly soluble in alcohol and ether, but is dissolved easily by alkaline hydroxides. At 260°, it decomposes, and yields pyrogallol at a slightly elevated temperature. It has the constitution $\text{CHMe} \cdot \text{O} \cdot \text{C}_6\text{H}_4 \cdot \text{OH}$; with acetic anhydride, it forms a monacetyl derivative which crystallises in white prisms which melt at 280°.

T. G. N.

Formation of Ethereal Salts and Amides in presence of Water and Alkali. By O. HINSBERG (*Ber.* 23, 2962—2965).—It has been shown by Baumann and his pupils (*Abstr.* 1887, 228; 1888, 1296; 1889, 370) that benzoic chloride may be used for detecting the hydroxyl-, amido-, and imido-groups in certain compounds by acting on them with that reagent in aqueous solution in presence of alkali. This reaction was, however, first employed for the preparation of benzoyl compounds by Schotten (*Abstr.* 1885, 176).

The author has further examined the action of other acid chlorides and of acetic anhydride under similar conditions, and finds that complete acetylation of the primary and secondary amido-bases and the aromatic diamido-bases readily takes place on shaking them with acetic anhydride and iced water. Phenylacetic chloride acts on monhydric alcohols and phenols, and primary and secondary amido-bases belonging to both the fatty and aromatic groups in the same manner as benzoic chloride. Diamines and polyvalent alcohols, such as glucose, can also be readily converted into phenylacetic derivatives.

Phenylsulphonic chloride is without action on tertiary amines, but acts on both secondary and primary amines very readily. The former yield solid or viscous products insoluble in acids and alkalis, whilst the latter form sulphonamides which are readily soluble in alkalis. This reaction may therefore be employed to ascertain whether an amido-compound belongs to the primary, secondary, or tertiary series, and also forms a ready method for the separation of a mixture of members of the three classes.

If the tertiary base is volatile with steam, the mixture of bases after treatment with phenylsulphonic chloride and alkali and approximate neutralisation, may be distilled in a current of steam. The sulphonamide of the secondary compound then remains as an insoluble precipitate in the residue, and may be filtered off, and the primary compound obtained from the filtrate by precipitation with hydrochloric acid. If the tertiary base is not volatile with steam, the mixture is extracted with ether and the tertiary base separated from the sulphonamide of the secondary base by shaking the ethereal solution with dilute hydrochloric acid. The sulphonamide of the primary base is obtained by precipitating with hydrochloric acid the aqueous solution remaining after the extraction with ether. To reconvert the sulphonamides into the bases, they are heated with hydrochloric acid in a sealed tube at 160°.

The reaction with phenylsulphonic chloride is not given by amido-compounds which already contain an acid or other strongly negative radicle, such as the acid amides and halogen and nitro-derivatives of the amido-bases. On the other hand, complicated substances such as

fibrin and peptone yield white products, soluble in alkalis, which have, however, not at present been obtained in the crystalline form.

Polemic. By O. REBUFFAT (*Gazzetta*, 20, 122—123).—A controversial note in reference to the papers published by A. Bischoff (*Ber.*, 22, 1774) and A. Bischoff and A. Hausdorfer (*ibid.*, 1795) on the action of aniline on chloracetic acid.

S. B. A. A.

The Condensation Products of Aromatic Aldehydes with Aromatic Amines. By A. HANTZSCH (*Ber.*, 23, 2773—2776).—These condensation products, of which the best known is benzylidene-aniline, $\text{CHPh}\cdot\text{NPh}$, resemble the oximes, inasmuch as they contain a carbon and a nitrogen atom united together by double linkage, and it seemed, therefore, important to determine, if possible, whether these also exist in isomeric forms. An attempt was first made to convert benzylidene-aniline into an isomeric compound by treating it with bromine, under which conditions the plane symmetrical tolane dibromide is converted into the axial symmetrical isomeride. The reaction was carried out in carbon bisulphide solution, and a yellow, amorphous compound obtained, which was shown by analysis to be *benzylidene-aniline dibromide*, $\text{C}_{11}\text{H}_{11}\text{NBr}_2$. It melts with decomposition at about 142° , is insoluble in water and ether, but dissolves in cold alcohol. It is very readily decomposed, but, instead of re-forming benzylidene-aniline, it splits up into benzaldehyde and parabromaniline. This takes place most readily on heating with pyridine. With reducing agents, it loses hydrogen bromide and not bromine, and is converted by sodium hydrogen sulphite into the additive product $2\text{C}_6\text{H}_5\cdot\text{CHO} + 2\text{C}_6\text{H}_5\cdot\text{Br}\cdot\text{NH}_2 + \text{SO}_2$, corresponding with the aniline compound described by Schiff (*Abstr.*, 1882, 304).

Benzylidene-aniline also yields a *di-iodide*, $\text{C}_{11}\text{H}_{11}\text{NI}_2$, obtained by mixing the former with iodine in benzene solution. It forms well-developed, dark brown needles, which melt at 110° with decomposition, do not yield iodaniline on heating with pyridine, and on reduction re-form benzylidene-aniline. No isomeride of the latter can, therefore, be obtained in this manner.

Attempts were also made to obtain isomeric condensation products from substituted benzaldehydes and substituted anilines, but without success.

H. G. C.

Orthohydroxybenzylamine. By F. TIEMANN (*Ber.*, 23, 3016—3018; compare Goldschmidt and Ernst, *Abstr.*, 1890, 1411).—*Salicyl-metahydrazobenzoic acid*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{N}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ [$\text{OH}:\text{CH} = 1:2$; $\text{NH}:\text{COOH} = 1:3$], is prepared from salicylaldehyde and metahydrazinebenzoic acid; it crystallises from dilute alcohol in needles, melts at 195° , and is insoluble in water. On treatment with zinc-dust and dilute sulphuric acid, *orthohydroxybenzylamine*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{NH}_2$, and *metamidobenzoic acid* are formed; they may be separated by adding a slight excess of sodium carbonate to the acid solution, and extracting with ether; after evaporation, the residual amine is purified by dissolving it in benzene, and precipitating with light petroleum; light yellow crystals separate, which melt at

125°, and sublime at a much lower temperature. It is soluble in water, alcohol, ether, benzene, and alkalis, and gives a deep violet-blue colour with ferric chloride. Characteristic salts are obtained by treatment with acids. The *oxalate* crystallises in lustrous, white plates. The amine may also be prepared by the reduction of salicylic oxime with sodium amalgam in dilute sulphuric acid solution.

J. B. T.

Possibility of Existence of an "Asymmetrical Nitrogen Atom." By F. KRAFT (*Ber.*, 23, 2780—2784).—According to the hypothesis of Hantzsch and Werner, it is possible that nitrogen compounds of the general formula $NXYZ$ may exist in two optically isomeric forms, and the author has, therefore, investigated derivatives of ammonia, hydrazine, and hydroxylamine, with a view to obtaining such isomerides.

For the ammonia derivative, ethylbenzylamine, $NHEt \cdot CH_2Ph$, was chosen, as it yields a crystalline tartrate. It was prepared by heating ethylamine with benzyl chloride and a little alcohol in a sealed tube at 110°, and forms a colourless oil which has an ammoniacal odour, and boils at 194° (corr.). Its *platinochloride*, $(C_8H_{13}N)_2 \cdot H_2PtCl_6$, crystallises in prisms. In addition to the secondary base, a quantity of *ethylidibenzylamine*, $NEt(CH_2Ph)_2$, is also obtained; it is an oily liquid boiling at 306°, whose *platinochloride*, $(C_{16}H_{19}N)_2 \cdot H_2PtCl_6$, is a pale yellow, amorphous precipitate. The attempt to separate ethylbenzylamine tartrate into two isomerides both by addition of conine tartrate and by fractional crystallisation, was without success. Negative results were also obtained in the case of paratolylhydrazine tartrate. The conclusion cannot, however, be drawn from these facts that optical isomerides of these compounds do not exist, for the tartrate method is not always successful even with compounds containing an asymmetrical carbon atom. Thus, the author finds that α -phenylethylamine, $CHMe \cdot Ph \cdot NH_2$, obtained by the reduction of acetophenonoxime, cannot be split up into its optical isomerides by this method.

Finally, it is shown that both benzileoximes, on reduction, yield one and the same diphenylhydroxyethylamine, $NH_2 \cdot CHPh \cdot CHPh \cdot OH$, previously obtained from the α -monoxime by Polonowska (*Abstr.*, 1887, 492).

H. G. C.

Action of Amines of the Benzene Series and of Phenylhydrazine on β -Ketonic Nitriles. By L. BOUVEAULT (*Compt. rend.*, 111, 572—574).—Methylpropionylacetonitrile combines with orthotoluidine to form a well crystallised compound, which melts at 125°, and dissolves in alcohol, but is insoluble in ether or water. With β -naphthylamine, the nitrile yields a compound which crystallises in needles melting at 121°, and dissolves in benzene, but is almost insoluble in ether. Mesidine yields a similar product melting at 114—115°. Methylaniline does not combine with methylpropionylacetonitrile, but, on the other hand, the higher homologue of the latter combines readily with orthotoluidine, forming a liquid boiling at 266°, but analogous to the products already described. From these results, the author concludes that the aniline derivative has the

constitution $\text{Ph}\cdot\text{N}\cdot\text{C}(\text{Et})\cdot\text{CHMe}\cdot\text{CN}$, and he calls it *phenylimidomethylpropionylacetonitrile*. The reaction is general, and the nitriles $\text{R}\cdot\text{CO}\cdot\text{CR}'\text{R}''\cdot\text{CN}$ yield derivatives of the formula $\text{R}'''\text{N}\cdot\text{CR}\cdot\text{CR}'\text{R}''\cdot\text{CN}$.

The action of phenylhydrazine depends on the constitution of the nitrile; if the latter belongs to the type $\text{R}\cdot\text{CO}\cdot\text{CR}'\text{R}''\cdot\text{CN}$, a hydrazone is formed, $\text{NHPh}\cdot\text{N}\cdot\text{CR}\cdot\text{CR}'\text{R}''\cdot\text{CN}$, but if it belongs to the type $\text{R}\cdot\text{CO}\cdot\text{CHR}'\cdot\text{CN}$, a derivative of pyrazole is obtained. Possibly in the second case there is intermediate formation of a hydrazone. Methyl propionylacetonitrile yields *phenylethylmethylamidopyrazole* [1 : 3 : 4 : 5], which crystallises in large, colourless, hexagonal prisms melting at 81° , and boiling at 330° without decomposition. It is very soluble in most of the neutral solvents, but not readily in benzene or petroleum. It is a stronger base than the preceding compounds, and its acetate is only partially decomposed by water. When heated with hydrochloric acid in sealed tubes at 120° , the base undergoes no change. With sodium nitrite and hydrochloric acid, it yields a yellow diazo-derivative, which, when boiled with alcohol, yields the phenylethylmethylpyrazole previously obtained by Claisen and Meyerowitz. If water is used instead of alcohol, the corresponding hydroxypyrazole is obtained, melting at 104° . The diazo-derivative forms crystallisable colouring matters with phenols and amines.

C. H. B.

Carbonylorthamidophenol and Thiocarborthamidophenol.

By S. CHELMICKI (*J. pr. Chem.* [2], **42**, 440—445; compare Abstr., 1887, 477).—When carbonylorthamidophenol is heated with aniline in a sealed tube at 200 — 210° , and the product treated with sulphuric acid, decolorised by animal charcoal, and crystallised from alcohol, white, brittle needles of the formula $\text{C}_{12}\text{H}_{10}\text{N}_2\text{O}$ are obtained. This new substance melts, with decomposition, at 230° , and dissolves in most solvents except water; strong hydrochloric acid at 160° decomposes it into orthamidophenol hydrochloride, aniline hydrochloride, and carbonic anhydride, chloride of lime converts it, in acetic acid solution, into a chloro-derivative, $\text{C}_{12}\text{H}_8\text{Cl}_2\text{N}_2\text{O}$, melting at 276° . This substance is isomeric with Kalkhoff's anilidocarbamidophenol (Abstr., 1883, 1110), and must therefore be $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{NH} \\ \text{O} \end{smallmatrix}\rangle\text{C}\cdot\text{NPh}$.

Nitrocarbonylorthamidophenol, $[\text{NH} : \text{O} : \text{NO}_2 = 1 : 2 : 4]$, crystallises in long, yellow needles melting at 240 — 241° (uncorr.; Bender's nitranhydro-orthamidophenyl carbonate melts at 256° , Abstr., 1887, 38). When this compound is treated with potash, it is converted into nitrocatechol, $[\text{OH} : \text{OH} : \text{NO}_2 = 1 : 2 : 4]$, melting at 170° (166° according to Weselsky and Beredikt, Abstr., 1878, 575).

Orthohydroxyphenylallylthiocarbamide, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{NH}\cdot\text{CS}\cdot\text{NH}\cdot\text{C}_3\text{H}_5$, is obtained by mixing allyl isothiocyanate (1 mol.) with orthamidophenol suspended in alcohol, and leaving the mixture at rest for some time. It forms white crystals which melt at 99° , and are more or less soluble in all the usual solvents. When it is heated with hydrochloric acid at 130° , it is converted into thiocarborthamidophenol.

Thiocarborthamidophenol evolves hydrogen sulphide when heated above its melting point; with ammonia at 200° , it is decomposed into carbamidophenol, carbonic anhydride, and ammonium sulphide. When

an alcoholic solution of iodine is added to thiocarborthamidophenol dissolved in sodium hydroxide as long as the iodine is decolorised, crystals of the bisulphide $S_2(C\langle\overset{N}{\underset{O}{\rangle}}C_6H_5)_2$ (Abstr., 1887, 477) are formed; this substance melts at 110° , and dissolves in most solvents.

A. G. B.

Derivatives of Carbonylorthamidophenol and of Thiocarbonylorthamidophenol. By P. SMIDEL (*J. pr. Chem.* [2], 42, 445–457). --Kalkhoff's anilidocarbamidophenol is more easily obtained than Chelmicki's compound (preceding abstract); this is evidence that carbonylorthamidophenol is $C_6H_5\langle\overset{NH}{\underset{O}{\rangle}}CO$, for the doubly-linked oxygen atom might be expected to be more difficult to displace than the group $-SH$. The ethyl compound, $C_6H_5\langle\overset{NEt}{\underset{O}{\rangle}}CO$, cannot be made to react with aniline. The crystals of carbonylorthamidophenol soon lose their lustre in air, being changed to small needles; the author suggests that the unstable crystals are

and the stable crystals, $C_6H_5\langle\overset{NH}{\underset{O}{\rangle}}CO$. The crystals of thiocarbonylorthamidophenol do not change, and this is in accord with the general belief that the stable form of this compound is $C_6H_5\langle\overset{N}{\underset{O}{\rangle}}C\cdot SH$, a formula supported by the fact that by treatment of orthamidophenol with thiocarbonyl chloride, the same thiocarbonylorthamidophenol is obtained as that obtained by the action of carbon bisulphide on carbonylorthamidophenol.

By the action of ethylorthamidophenol (m. p. 107.5° , not 167.5° as given by Förster, Abstr., 1880, 464) on thiocarbonyl chloride, a *thiocarbonyl ethylamidophenol* is obtained which melts at 112° , and boils undecomposed above 300° ; it is different from Chelmicki's ethyl derivative (Abstr., 1887, 477). This compound is decomposed by strong hydrochloric acid at 170° into ethylorthamidophenolcarboxylic anhydride and hydrogen sulphide, showing that its constitution is $C_6H_5\langle\overset{NEt}{\underset{O}{\rangle}}CN$. By heating this derivative with aniline and lead oxide, an anilide is, with some difficulty, obtained free from sulphur and homologous with Chelmicki's anilide (previous abstract); the difficulty with which it is obtained confirms the double linking of the sulphur to the carbon and, therefore, the above formula.

To obtain methylorthamidophenol, orthamidophenetol was methylated with methyl iodide in the cold, by which means the hydriodides of methylorthamidophenetol, dimethylorthamidophenetol, and orthamidophenetol, and *amidophenetoltrimethylanmonium iodide* were obtained. The last-mentioned crystallises in nacreous, violet-tinted leaflets, freely soluble in hot water. The mixture of the three methylorthamidophenetols was heated with strong hydrochloric acid at 170° , and the mixed methylorthamidophenols thus obtained were

treated with thiocarbonyl chloride. This treatment yields *thiocarbonylmethylorthamidophenol* in colourless needles which melt at 128° , and boil undecomposed above 300° ; strong hydrochloric acid at 170° decomposes it into methylorthamidophenol, carbonic anhydride, and hydrogen sulphide, so that its constitution is similar to that of thiocarbonylethylorthamidophenol (see above).

Methylorthamidophenol crystallises in colourless leaflets which soon oxidise and become brown in air; it melts with decomposition at 80° .

Carborthamidophenol chloride, $C_6H_4\langle\begin{smallmatrix} N \\ O \end{smallmatrix}\rangle CCl$, is obtained when thiocarborthamidophenol and phosphoric chloride are mixed together and the product distilled; thiophosphoryl chloride passes over below 130° , and the portion that distils between 130° and 205° separates after a time into crystals and an oil; the crystals were not investigated. The oil is carborthamidophenol chloride; it boils at $201-202^{\circ}$, solidifies in a freezing mixture, and melts at 7° ; it is a feeble base forming a well-crystallised nitrate and hydrochloride; it is decomposed by water into carborthamidophenol and hydrochloric acid. With phenol, it yields two compounds, one of which is a *carborthamidophenol phenyl ether*, $C_6H_4\langle\begin{smallmatrix} N \\ O \end{smallmatrix}\rangle C \cdot OPh$, melting at 56° and boiling at 310° , whilst the other melts at 190° and boils at a much higher temperature. With aniline, carborthamidophenol chloride yields Kalkhoff's anilide. Carborthamidophenol chloride is also produced when methyl and ethyl thiocarbonylorthamidophenols are heated with phosphoric chloride. A. G. R.

Preparation of Anhydrous Diazo-salts. By E. KNOEVENAGEL (*Ber.*, 23, 2994-2998).—Up to the present time very few diazo-salts have been obtained in the anhydrous condition, the most important exceptions being diazobenzene sulphate and nitrate. The author finds that all the salts may be readily prepared in the anhydrous condition by treating the amido-compound in acid alcoholic solution with amyl nitrite. To prepare diazobenzene sulphate by this method, 15 grams of aniline is dissolved in 9-10 parts of absolute, or at least 95 per cent. alcohol, and 20 grams of concentrated sulphuric acid carefully added; aniline sulphate separates at first, but redissolves on adding the remainder of the acid. When cold, 20 grams of amyl nitrite are added, and the mixture well cooled, ice being preferably employed in the preparation of large quantities. After 10-15 minutes, diazobenzene sulphate usually separates in beautiful needles, the whole mass solidifying to a crystalline magma, which, on filtering and washing with alcohol and ether, yields the compound in an almost pure condition. If the sulphate does not separate after 10-15 minutes, the addition of a few drops of ether causes an immediate crystallisation, and a further quantity of the salt may be obtained by adding ether to the mother liquor. The diazobenzene sulphate thus obtained has all the properties assigned to it by (Iriens, and is more readily prepared in this manner than by his method.

Diazobenzene nitrate is most readily prepared by adding rather

more than the theoretical quantity of amyl nitrite to a cold saturated alcoholic solution of aniline nitrate containing a little free nitric acid, cooling well with ice. On the addition of a small quantity of ether, diazobenzene nitrate separates in beautiful needles, which explode, when dry, very violently, either on heating or by percussion.

Diazobenzene chloride, which has hitherto not been obtained in the solid condition, is easily prepared in a similar manner to the nitrate; very careful cooling is necessary on adding the amyl nitrite, as the diazotisation of aniline chloride proceeds very rapidly. After a short time, the salt separates in almost colourless needles, which are collected, washed with a little alcohol and ether, and dried over sulphuric acid in a vacuum. The yield is almost quantitative; the determination of chlorine and nitrogen gave numbers agreeing closely with the formula $C_6H_5 \cdot N_2Cl$. Diazobenzene chloride decomposes on heating with a slight explosion, but only gives a slight detonation by percussion. It is soluble in alcohol, but insoluble in ether, benzene, and light petroleum; water dissolves it with great avidity, and it deliquesces in moist air, undergoing considerable decomposition, but is fairly stable in dry air, especially in the dark.

The following diazo-compounds have also been obtained in the anhydrous condition by this method:—The *diazo-sulphates* of ortho-toluidine, paratoluidine, paraphenetidine, paranisidine, and metanitr-aniline; the *diazo-nitrates* of ortho- and para-toluidine; the *diazo-chlorides* of paratoluidine, paraphenetidine, and paranisidine.

H. G. C.

Action of Alkalis on Acid Salts of Diazobenzene: Ethyl Diazobenzoate. By T. CURTIUS (*Ber.*, 23, 3033–3036).—By heating diazobenzene sulphate with the calculated quantity of barium hydroxide and extracting with ether, a very volatile, feebly basic compound is obtained which is volatile with steam, melts at -3° , and has an odour resembling that of rose water; although no evolution of nitrogen could be detected, analysis shows that only 2 atoms of nitrogen are combined with 3 benzene nuclei. A corresponding compound may be prepared in the same manner from ethyl meta-diazobenzoate sulphate. No hydrazine could be detected in the mother liquors, and only in one experiment, with aluminium and alkalis, was any formed by the reduction of the compound in either acid or alkaline solutions. Attempts to prepare diazobenzene, by the action of silver nitrite on dry aniline hydrochloride dissolved in some indifferent medium, were unsuccessful, diazoamidobenzene being the sole product, and, in a similar manner, ethyl metamidobenzoate yields ethyl diazoamidobenzoate. Diazoamidobenzene may be prepared by mixing very dilute, cold, aqueous solutions of aniline hydrochloride and sodium nitrite; after washing with cold water, the product is quite pure. The potassium and silver salts of diazobenzene, prepared according to the method described by Griess, were found on analysis to contain only two-thirds the theoretical quantity of nitrogen, the proportion being 6 atoms of carbon to 1 of nitrogen. The quantity of metal present agreed closely with the theory. The author is unable to assign any formula to these compounds.

J. B. T.

Hydrogen Nitride (Azoimide). By T. CURTIUS (*Ber.*, **23**, 3023—3033).—*Hydrogen nitride*, $\begin{smallmatrix} \text{N} \\ || \\ \text{N} \end{smallmatrix} > \text{NH}$, is formed, under certain conditions, by the action of sodium nitrite on hydrazine hydrochloride; the reaction is strictly analogous to the formation of nitrogen from ammonium chloride and sodium nitrite. To obtain it in this manner is, however, a matter of considerable difficulty, and it is best prepared from *hippurylhydrazine* in the manner described below.

Benzoylhydrazine, $\text{NH}_2\cdot\text{NHBz}$, is formed on mixing molecular proportions of ethyl benzoylglycollate and hydrazine hydrate; it crystallises from alcohol in large, lustrous plates, melts at 112° , reduces alkaline copper solution in the cold, and dissolves in cold water, but is only sparingly soluble in ether. It is not changed on boiling with water, but is hydrolysed by the action of dilute alkalis. The same compound is also obtained by the action of hydrazine hydrate on ethyl benzoate.

Benzoylbenzalhydrazine, $\text{NHBz}\cdot\text{N}\cdot\text{CHPh}$, is prepared by adding benzaldehyde to benzoylhydrazine in molecular proportion, and is deposited from alcohol in long, colourless crystals which melt at 203° , are very sparingly soluble in ether, and insoluble in water.

Symmetrical dibenzoylhydrazine, $\text{NHBz}\cdot\text{NHBz}$, is obtained by boiling benzoylhydrazine; it crystallises from alcohol in silky needles melting at 233° , and is hydrolysed by treatment with acids or alkalis.

On heating a cold aqueous solution of benzoylhydrazine with an equal molecular proportion of sodium nitrite, and acidifying with acetic acid, *benzoylazimide (benzoic nitride)*, $\begin{smallmatrix} \text{N} \\ || \\ \text{N} \end{smallmatrix} > \text{NBz}$, separates as an oily liquid which solidifies after some time. It crystallises in colourless prisms which melt at $29\text{--}30^\circ$, explodes on heating, and is volatile with steam. By treatment with alkalis, it is hydrolysed, but undergoes no change on boiling with acids; it reduces ammoniacal silver solution, but has no action on alkaline copper solution; it has a powerful odour resembling that of benzoic chloride, and rapidly attacks the skin.

Hydrazinacetic acid (amidoglycocine), $\text{NH}_2\cdot\text{NH}\cdot\text{CH}_2\cdot\text{COOH}$, is prepared by acting with ethyl benzoylglycollate (1 mol.) on hydrazine hydrate (2 mols.); the benzoylhydrazine which first separates is removed, and after some time the acetic acid derivative is deposited from the mother liquor; it is purified by repeated recrystallisation from alcohol, and forms large, lustrous plates, which melt at 93° , and are insoluble in ether. It has a sweet taste, gives with alkaline copper solution a deep violet colour, and, on warming, a precipitate of cuprous oxide. A red colour is produced with neutral ferric chloride solution, and ammoniacal solution of silver is reduced in the cold. The compound is hydrolysed by warming with acids or alkalis. *Benzalhydrazine-acetic acid*, $\text{CHPh}\cdot\text{N}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{COOH}$, is formed by the action of benzaldehyde on the previous compound, and crystallises from alcohol in silky, lustrous needles melting at $156\cdot5^\circ$. *Hippurylbenzalhydrazine*,

$\text{NHBz}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{NH}_2$, is prepared by adding the calculated quantity of hydrazine hydrate to an alcoholic solution of ethyl hippurate; it crystallises from alcohol in colourless, lustrous needles which melt at $162\cdot5$, and are sparingly soluble in ether; the yield is 90 per cent. The compound reduces ammoniacal silver solution in the cold; with alkalin copper solution, a green colour is produced, and after some time reduction occurs. *Hippurylbenzalhydrazine*,

is formed by the action of benzaldehyde on the previous compound, and crystallises from alcohol in lustrous plates which melt at 182° . By the action of acetic acid and sodium nitrite at 0° on an aqueous solution of hippurylhydrazine, a compound is obtained crystallising from alcohol in colourless needles which melt at 98° ; it is probably either *nitrosohippurylhydrazine*, $\text{NHBz}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{N}(\text{NO})\cdot\text{NH}_2$, or *nitrosohydrazine hippuric acid*, $\text{NO}\cdot\text{NH}\cdot\text{N}\cdot\text{CPh}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{COOH}$; by treatment with acids or alkalis, azoimide and hippuric acid are formed; on boiling with water, an indifferent gas is produced, together with a very insoluble substance that has not yet been investigated. The nitroso-compound readily dissolves in alkalis or ammonia, and the solution exhibits a beautiful blue fluorescence. On adding silver nitrate to the ammoniacal solution, a white, explosive, silver salt is precipitated.

Azoimide may be obtained from benzoylhydrazine or hydrazine-acetic acid, but is best prepared from the hippuryl compound by dissolving it in dilute soda, and decomposing the boiling solution with dilute sulphuric acid; the azoimide distils over with the steam, and is passed into neutral silver nitrate solution, the precipitated silver salt is collected, washed with water, dried at $60\text{--}70^\circ$, and treated with dilute sulphuric acid. By repeating this process, a solution is obtained containing 27 per cent. of azoimide; on bringing the solution into contact with ammonia, thick, white vapours of the ammonium salt are formed. Azoimide itself is a gas, having a particularly nauseous odour, and resembling hydrogen chloride in its general properties. It is very soluble in water, and on distillation a concentrated solution passes over; the distillate gradually becomes weaker until equilibrium is established, a solution of definite strength being obtained which boils constantly. A piece of blue litmus paper held over the solution turns red. Iron, zinc, copper, aluminium, and magnesium readily dissolve in a 7 per cent. solution of the gas, hydrogen being evolved. Gold and silver also appear to be attacked. Azoimide is liberated by the action of dilute sulphuric acid on any of the salts; with concentrated sulphuric acid, the azoimide is itself decomposed, *Barium nitride*, N_2Ba , is obtained in lustrous, hard crystals which are readily soluble in water, and explode with a green flash on heating. *Silver nitride*, N_2Ag , crystallises in prisms which melt at about 250° with a violent explosion.

J. B. T.

Action of Acid Chlorides on Acid Amides. By A. PIOTET (*Ber.*, 23, 3011—3016).—Benzanilide and acetic chloride are formed on heating benzoic chloride and acetanilide at 140° ; the same result is

obtained if the compounds are dissolved in toluene. This reaction is found to be a general one, both for the aromatic and fatty amides and chlorides; and the author explains it by assuming that an additive compound is first formed which then decomposes, the radicles containing the least number of carbon atoms combining with the chlorine, whilst the higher carbon derivatives unite with the amide complex. The production of benzanilide, for example, would be preceded by the formation of the hypothetical compound acetobenzanilide hydrochloride, NHPhBzAcCl . These observations confirm those of Paul and Otten (compare Abstr., 1890, 1415). J. B. T.

Action of Sodium on Acid Amides. By T. CURTIUS (*Ber.*, 23, 3037—3041).—*Sodium benzamide*, $\text{COPh}\cdot\text{NHNa}$ or $\text{ONa}\cdot\text{COPh}\cdot\text{NH}$, is prepared by boiling a benzene solution of benzamide with rather less than the calculated quantity of sodium. The operation takes about 30 hours, the precipitated salt is separated, treated repeatedly with ether in an extraction apparatus, and dried over sulphuric acid and quicklime. It is a white, crystalline powder, insoluble in ether, chloroform, or benzene; it is very readily decomposed by water, or by dissolving in alcohol, but is not hygroscopic, and on distillation, yields benzene, soda, ammonia, and a little benzonitrile.

Sodium dibenzamide, NBz_2Na , is obtained by dissolving dibenzamide in xylene, and boiling the solution for 30 hours with a slight excess of sodium; no evolution of ammonia occurs; the product crystallises from ether in small, white, lustrous plates which melt at 150° and resolidify on heating to 230° , and then do not melt at 300° . The solid is readily soluble in water. On distillation, sodium dibenzamide yields only traces of benzene; it is much more stable than the benzamide salt, and a recently prepared aqueous solution gives precipitates with the salts of many of the heavy metals.

By the action of sodium on acetamide, considerable quantities of ammonia are evolved, and a viscid liquid separates, which after some time becomes crystalline; it contains nitrogen, and is possibly *sodium diacetamide*, NAc_2Na .

By the action of iodine on finely divided sodium benzamide, or sodium dibenzamide suspended in ether, additive compounds are formed which readily crystallise, but do not show a constant composition. Benzamide and iodine give the compound $\text{NH}_2\text{Bz}\cdot\text{I}\cdot\text{NH}\cdot\text{Bz}\cdot\text{I}$ (?), crystallising in long, slender, olive-green prisms, which exhibit pleochroism and melt at 110 — 112° without decomposition. The compound is stable in air, and insoluble in water, but readily dissolves in glacial acetic acid; on shaking with mercury, benzamide and mercuric iodide are formed, whilst by distillation, or on boiling with water or alcohol, it is decomposed into iodine and benzamide. Iodine and dibenzamide give a compound, $\text{NH}_2\text{Bz}_2\cdot\text{I}_2$, which crystallises in large, green prisms melting at 118 — 120° ; it is readily soluble in chloroform, and resembles the preceding substance in properties.

Tribenzamide, NBz_3 , is formed together with dibenzamide by treating benzamide with excess of benzoic chloride; it is very sparingly soluble in alcohol, and is deposited in silky, lustrous needles which

melt at 202° , sublime without decomposition, and yield benzoic acid and ammonia when boiled with soda. J. B. T.

α -Toluamide and its Derivatives. By A. PURGONI (*Gazzetta*, 20, 172—178).—When benzonitrile is treated with concentrated sulphuric acid (sp. gr. = 1.82), an energetic reaction takes place, and α -toluamide (phenylacetamide) is formed. An almost theoretical yield is obtained if the proportion of the acid used contains the quantity of water theoretically necessary for the transformation.

Chloralphenylacetamide, prepared by heating a mixture of anhydrous chloral and phenylacetamide in molecular proportion for half an hour, crystallises from alcohol in minute, nacreous scales which melt at 145° , and dissolve in alcohol and in boiling ether and benzene.

Phenylacetylhydrazine, $\text{CH}_3\text{Ph}\cdot\text{CO}\cdot\text{NH}\cdot\text{NHPh}$.—Phenylacetamide reacts with phenylhydrazine like formamide, acetamide, &c., according to Justus' equation $\text{R}\cdot\text{CONH}_2 + \text{NH}_2\cdot\text{NHPh} = \text{R}\cdot\text{CONH}\cdot\text{NHPh} + \text{NH}_3$. A mixture of the amide and phenylhydrazine in molecular proportion is heated at 120 — 130° ; the product crystallises from alcohol in colourless scales which melt at 175 — 176° , and are moderately soluble in warm alcohol.

When phenylacetamide is heated with aniline in molecular proportion, at about 150° , ammonia is evolved, and the product, after repeated precipitation with water and recrystallisation from alcohol, yields nacreous scales which melt at 116 — 117° , and are readily soluble in alcohol. This compound seems to be identical with Holmann's α -tolnylanilide.

Phenylacetylparatoluidide is obtained by heating the amide with paratoluidine at 160 — 180° until the evolution of ammonia ceases. It crystallises in small, transparent tables which melt at 135 — 136° , and dissolve readily in alcohol and ether. S. B. A. A.

Conversion of Nitriles into Imido-ethers. By A. PINNLE (*Ber.*, 23, 2917—2919).—It has been shown that imido-ethers are formed by the action of hydrogen chloride on a mixture of an alcohol and a nitrile. Further experiments have shown, however, that certain aromatic nitriles, in which a carbon atom, in the ortho-position relative to the CN group, is linked to another carbon atom, are incapable of forming imido-ethers. It is also found that orthodicyanides only form monimido-ethers. The first of these conclusions is formed from a study of orthocyanotoluene, paracyanotoluene, paracyanoxylene, α -cyanonaphthalene, and metacyanoxylene [$\text{Me} : \text{Me} : \text{CN} = 1 : 3 : 4$], whilst the second is deduced from the investigation of metadicyanotoluene [$\text{Me} : \text{CH} : \text{CN} = 1 : 3 : 4$]. J. B. T.

Diphenyloxycyanidine. By A. PINNLE (*Ber.*, 23, 2919—2922; compare *Abstr.*, 1890, 496).—*Ethyl benzamidylcarbamate*,

is prepared by the action of aqueous soda and ethyl chlorocarbonate on benzamidine hydrochloride; it crystallises from alcohol in thick, white prisms which melt at 57 — 58° , and are almost insoluble in water. On heating the compound to about 150° , decomposition takes place,

alcohol and ethyl carbamate are eliminated, and diphenyloxycyanidine (m. p. 239°) is formed. By the action of alcoholic ammonia on the latter substance, it is converted into benzamidine and ethyl carbamate, whilst with aqueous ammonia, benzamide and urethane are formed.

Dibenzamidylcarbamide, $\text{CO}(\text{NH}\cdot\text{CPh}\cdot\text{NH})_2$, is obtained by the action of carbonyl chloride on benzamidine; diphenyloxycyanidine is also produced during the reaction, and the two compounds cannot be completely separated; it crystallises from alcohol in prisms which are soluble in soda, and melt at 229° with evolution of ammonia. The compound is completely converted into diphenyleyanidine on heating above its melting point. Experiments with propionamidine were unsuccessful. By the action of carbonyl chloride on capronamidine *dicapronamidinebiuret*, $\text{NH}(\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_{11}\cdot\text{NH})_2$, is obtained, crystallising from alcohol in stellate groups of slender, white needles melting at 236° . J. B. T.

Amidines. By A. PINNER (*Ber.*, 23, 2923—2927; compare Abstr., 1889, 1004).—*Ethenyldiphenylureid*, $\text{NHPh}\cdot\text{CO}\cdot\text{N}\cdot\text{CMe}\cdot\text{NH}\cdot\text{CO}\cdot\text{N}(\text{HPh})$, is formed by the action of phenyl cyanate on acetamidine; it crystallises from acetone in small, slender needles, melts at 169° , and yields acetylphenylcarbamide on boiling with 6—8 parts of 50 per cent. acetic acid solution.

Propionyldiphenylureid, $\text{NHPh}\cdot\text{CO}\cdot\text{N}\cdot\text{CEt}\cdot\text{NH}\cdot\text{CO}\cdot\text{N}(\text{HPh})$, is prepared from propionamidine in a similar manner to the ethenyl derivatives, and crystallises from acetone in slender, white needles melting at 169 — 170° . On distillation, it yields diphenylcarbamide, whilst on boiling with dilute acetic acid, propionylphenylcarbamide is formed.

Action of Aldehydes on Benzamidine.—Further investigation renders it probable that the compound obtained by the action of benzaldehyde on benzamidine (*loc. cit.*) is *diphenyl dicyanide*, $\text{C}_{14}\text{H}_{10}\text{N}_2$, and not benzylidenebenzamidine, $\text{C}_{14}\text{H}_{12}\text{N}_2$, as stated. Lophine is also formed in a very small quantity during the reaction. A yellow, amorphous product of the formula $\text{C}_{11}\text{H}_{10}\text{N}_2\text{O}_2$ is obtained by the action of acetaldehyde on benzamidine; it melts below 100° , is soluble in alcohol, ether, and chloroform, but insoluble in water or light petroleum. It yields an amorphous *platinochloride*, which melts at about 108° . On heating the base at 130° , and treating the product with hydrochloric acid and platinum chloride solution, an amorphous *platinochloride* is formed which melts at 183° with decomposition, and is probably a purer preparation of the above lower melting compound. J. B. T.

Action of Benzamidine on the Ethereal Salts of Aromatic Orthohydroxy-acids. By A. PINNER (*Ber.*, 23, 2934—2941).—By the action of sodium hydroxide (2 mols.) on ethyl salicylate and benzamidine hydrochloride, crystals are obtained from which *benzamidine salicylate* may be separated by treatment with acetone; it is deposited in large prisms which melt at 202° , and are readily soluble in water or alcohol. The residue remaining after the extraction with acetone forms slender, yellow needles melting at 246° . It is insoluble in organic media or in aqueous soda, and gives a red colour with concentrated sulphuric acid. The same compound may be prepared

in larger quantity by heating an ethereal solution of benzamidine with ethyl salicylate at 40° for 10—12 hours; the ether is evaporated, and the residue boiled out with water. The substance has the formula $C_{21}H_{17}N_3O$, and is formed by the elimination of water, alcohol, and ammonia from 1 mol. of ethyl salicylate and 2 mols. of benzamidine. The *acetyl* compound, $C_{21}H_{17}N_3O \cdot Ac$, is prepared by treatment with acetic anhydride and zinc chloride, and crystallises from alcohol in colourless, lustrous prisms melting at 140 — 141° .

On adding hydrochloric acid to the alkaline filtrate obtained after the separation of the benzamidine salicylate, *benzamidine salicylate* is precipitated; it crystallises from hot water in silky, lustrous plates which melt at 120° . The compound had been previously prepared (compare Abstr., 1889, 1004), but its constitution was unknown.

By the action of benzamidine on the methyl salts of the hydroxytoluic acids, compounds are obtained corresponding in properties and constitution to the above salicylic acid product. The derivative of orthohydroxytoluic acid [$COOH : OH : Me = 1 : 2 : 3$] melts at 214° ; that of metahydroxytoluic acid [$1 : 2 : 4$], at 235° ; whilst the product from parahydroxytoluic acid [$1 : 2 : 5$] melts at 202° . All these compounds are insoluble in acids and alkalis, and are exceedingly difficult to burn. Paradihydroxybenzoic acid [$COOH : OH : OH = 1 : 2 : 5$] also condenses with benzamidine; the compound is deposited from benzene in small, nodular crystals, melting at 261 — 266° , with previous softening at 250° .

The formation of the above compounds probably takes place in two stages; in the case of salicylic acid, the hypothetical intermediate product has one or other of the formulæ

$NH \cdot CPh \cdot NH \cdot C(C_6H_4 \cdot OH) \cdot N \cdot CPh \cdot NH$ or $C_6H_4 \cdot \begin{smallmatrix} NH \cdot CPh : NH \\ CO \cdot NH \cdot CPh : NH \end{smallmatrix}$; ammonia is then eliminated, the constitution of the final product being represented by the formulæ

On heating ethylphloroglucinoltricarboxylic acid with benzamidine for two hours at 130° , 2 mols. of carbonic anhydride are eliminated, and a compound is formed to which the formula

is given.

J. B. T.

Imido-ethers. By A. PINNER (*Ber.*, 23, 2942—2956).—**IMIDO-ETHERS FROM TRIMETHYLENE CYANIDE.**—Trimethylene cyanide is prepared by mixing trimethylene bromide with 2.5 parts of 85 per cent. alcohol, and adding $\frac{2}{3}$ part of finely divided potassium cyanide; after boiling for 5—6 hours, the product is filtered, the greater part of the alcohol removed, the residue dissolved in water, and extracted with ether; after distilling off the ether, the crude product is fractionated; the yield is 85 per cent. of theory. The *hydrochlorides* of *glutaramidyl ethyl ether* and *glutaramidyl methyl ether* are unstable. *Glutar-*

amidyl isobutyl ether hydrochloride, $C_4H_9[C(NH) \cdot O \cdot CH_2 \cdot CHMe_2 \cdot HCl]_2$, is readily soluble in water or alcohol and crystallises in plates. By the action of water, ammonia is eliminated, and *isobutyl glutarate*, $C_7H_{14}(COO \cdot CH_2 \cdot CHMe_2)_2$, is formed; it is a viscid liquid boiling at 270° . On heating the imido-ether hydrochloride, it softens at 110° , and at higher temperatures decomposes into glutarimide, isobutyl chloride, and isobutylamine hydrochloride. By the action of aqueous ammonia, it is converted into *glutaramide*, $C_5H_8(CO \cdot NH_2)_2$, which is soluble in water or alcohol, and melts at 176° with evolution of ammonia. On treatment with alcoholic ammonia, isobutyl alcohol and ammonium chloride are eliminated, and an additive compound is formed consisting of the hydrochlorides of glutaramidine and glutarimidine in molecular proportion; on dissolving it in water, the imidine is formed, but it could not be isolated on account of its great solubility. On evaporating the mother liquor from the above additive compound, large rhombic crystals of *glutaramidine hydrochloride*, $C_5H_8[C(NH)NH_2 \cdot HCl]_2 + 2H_2O$, are obtained, which are readily soluble in water or alcohol but cannot be recrystallised; the hydrated salt melts at 79° , and the anhydrous compound at 189° . The *platinochloride* is deposited in flat, yellow prisms which melt at 214° with decomposition. *Glutaramidyl acetate*, $C_5H_8[C(NH)OAc]_2$, is prepared by the action of acetic anhydride and sodium acetate on glutaramidine hydrochloride, and crystallises in small, lustrous needles melting at $210-211^\circ$.

By the action of primary amines on the hydrochlorides of glutarimido-ethers, substituted glutaramidines are formed, the hydrochlorides and platinochlorides of which are excessively unstable. *Diethylglutaramidine platinochloride* ($C_5H_7N_3Et_2$) $_2$, H_2PtCl_6 , is obtained in yellowish-red crystals which melt at 179° . Secondary amines yield tetra-substituted glutaramidines; neither the free bases nor the hydrochlorides could be obtained in a pure state.

Tetramethylglutaramidine platinochloride,

is deposited in dark-red, cubical crystals which darken at 190° , and melt at 210° with decomposition. The corresponding *tetraethyl* compound crystallises in long, dark red needles, melting at 141° . The *tetrapropyl* derivative forms reddish-yellow crystals melting at 178° . *Dibromotetrapropylglutaramidine hydrobromide*,

is prepared by the action of bromine on the hydrochloride, and crystallises in long, reddish-yellow needles which melt at 86° , and are very sparingly soluble in water.

IMIDO-ETHERS OF HYDROXYPROPIONITRILE AND PHENYLHYDROXYACETO-NITRILE.—The *methyl* and *ethyl* ethers of hydroxypropionide are very unstable; the *hydrochloride* of the *propyl ether*,

forms long, colourless needles which melt at $68-69^\circ$ with decomposi-

tion. The corresponding *amyl* derivative is deposited in slender needles melting at 69°. By the action of alcoholic ammonia, *hydroxypropamidine hydrochloride*, $\text{OH}\cdot\text{CHMe}\cdot\text{C}(\text{NH})\cdot\text{NH}_2\cdot\text{HCl}$, is formed, crystallising from alcohol in flat needles which melt at 171°. The *nitrate* softens at 78°, and melts at 84°.

Dimethylactamidine hydrochloride, $\text{OH}\cdot\text{CHMe}\cdot\text{C}(\text{NMe})\cdot\text{NHMe}\cdot\text{HCl}$, is prepared by the action of methylamine on the imido-amyl ether, and is deposited in colourless, rhombic crystals, melting at 215°. Attempts to prepare an asymmetrical dimethyl derivative by the action of dimethylamine were unsuccessful.

Diacetylphenylactamidine, $\text{OAc}\cdot\text{CHPh}\cdot\text{C}(\text{NH})\cdot\text{NHAc}$, is obtained on treating phenylhydroxyacetamidine with acetic anhydride and sodium acetate, and melts at 210°.

Hydroxybenzylmethylhydrocypyrimidine,

is formed on mixing phenylhydroxyacetamidine, ethyl acetoacetate, and sodium hydroxide in molecular proportion; it crystallises from amyl alcohol in long needles which melt at 216°, and are sparingly soluble in water, alcohol, ether, or benzene, but readily dissolve in dilute alcohol, alkalis, and acids. The *hydrochloride* crystallises in needles melting at 217° with previous softening at 212°. The *picrate* forms slender, yellow needles melting at 175°. The *silver* salt is white and sparingly soluble.

The *acetyl* derivative, $\text{OAc}\cdot\text{CHPh}\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CH}$, is formed by the action of acetic anhydride; it melts at 170°, and yields a white, amorphous *silver* salt. The *picrate* forms slender, yellow needles which melt at 160° with decomposition; the *hydrochloride* melts at 188°.

The *benzoyl* derivative, $\text{OBz}\cdot\text{CHPh}\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CH}$, is formed by the action of benzoic chloride on the pyrimidine, and melts at 205–208°. The *hydrochloride* crystallises from glacial acetic acid in stellate groups of small needles melting at 240°. *Hydroxybenzylphenylhydrocypyrimidine*, $\text{OH}\cdot\text{CHPh}\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CPh} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CH}$, is prepared from the amidine and ethyl benzoylacetate; it crystallises in fine needles which melt at 218°, with previous softening at 212°. *Hydroxybenzylmethylhydrocypyrimidine* is formed from ethyl methylacetoacetate and melts at 155°. It yields a white, amorphous *silver* salt. The *acetate* crystallises in stellate groups of lustrous needles, which decompose at 100°. *Hydroxybenzylmethyl ethylhydrocypyrimidine*, $\text{OH}\cdot\text{CHPh}\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CEt}$, from ethyl ethylacetoacetate, crystallises in small needles which melt at 148–152°.

IMIDO-ETHERS FROM ORTHO- AND PARA-ETHOXYBENZONITRILE.—*Ortho-ethoxybenzonitrile*, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{CN}$, is a yellow, viscid, bitter liquid, which boils at 258°, is volatile with steam, and miscible with alcohol, ether, or light petroleum. The preparation of the pure imido-ether is a matter of some difficulty; the nitrile is therefore treated with alcohol

and hydrogen chloride, and the product converted into *ortho*-ethoxybenzimidine hydrochloride, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH})\cdot\text{NH}_2\cdot\text{HCl}$, by the action of alcoholic ammonia; it is deposited in short, colourless, hexagonal crystals melting at 218° . *Ortho*-ethoxyphenylmethylhydroxypyrimidine, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CH}_2$, is formed from the amidine and ethyl acetoacetate, and melts at 146° .

Para-ethoxybenzonitrile is deposited in long, yellow, rhombic crystals which melt at 69° , boil at 258° , and resemble the *ortho*-compound in properties; the preparation was not quite pure. *Para*-ethoxybenzimidooethyl ether hydrochloride, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH})\cdot\text{OEt}\cdot\text{HC}\cdot\text{Cl}$, crystallises in white needles which decompose on heating into ethyl chloride and *para*-ethoxybenzamide, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\cdot\text{O}\cdot\text{NH}_2$; this same compound is also formed by the action of soda on the amidine hydrochloride, and is deposited in long crystals melting at 206° . *Para*-ethoxybenzamidine hydrochloride, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH})\cdot\text{NH}_2\cdot\text{HCl}$, is prepared by the action of alcoholic ammonia on the crude imido-ether, and is deposited from alcohol in long, hexagonal crystals melting at 260° . On treating the free base with ethyl acetoacetate, *para*-ethoxyphenylmethylhydroxypyrimidine, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CH}_2$, is obtained, crystallising from alcohol in short, white prisms which melt at 204° . The same compound is formed by the action of ethyl acetomalonate on the amidine, carbonic anhydride being eliminated. *Para*-ethoxyphenylmethylhydroxypyrimidine, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CMe}$, is prepared from ethyl methylacetoacetate, and crystallises from alcohol in small prisms melting at 216° . Ethyl ethylacetoacetate yields the corresponding ethylmethyl derivative, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{CEt}$, crystallising from alcohol in long needles which melt at 194° . *Para*-ethoxyphenylmethylbenzylhydroxypyrimidine, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CMe} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{C}\cdot\text{C}_6\text{H}_5$, is formed from ethyl benzylacetoacetate, and crystallises from alcohol, in which it is very soluble, in lustrous needles melting at 212° . *Para*-ethoxydiphenylhydroxypyrimidine, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}=\text{CPh} \\ \text{N}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{OH}$, from ethyl benzoylacetate, crystallises from alcohol in broad needles which melt at 214° . *Para*-ethoxybenzamidine *para*-ethoxyphenylhydroxypyrimidinecarboxylate, $\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}\begin{smallmatrix} \text{N}\cdot\text{C}(\text{COOH}) \\ \text{N}\text{---}\text{C}(\text{OH}) \end{smallmatrix}\text{CH}_2\cdot\text{OEt}\cdot\text{C}_6\text{H}_4\cdot\text{C}(\text{NH})\cdot\text{NH}_2$,

is formed by the action of ethyl oxalate on the amidine, and is deposited from alcohol in long, white, lustrous crystals melting at 280° , with previous softening at 275° . The free acid crystallises from alcohol in short needles which melt at 248° with decomposition.

J. B. T.

Compounds containing the Group $\text{C}_2\text{N}_2\text{O}_2$. By A. F. HOLLMAN (Ber., 23, 2998—3001).—In the hope of obtaining compounds related to the dinitiosacys (Abstr., 1889, 50), the author has

the action of benzoic chloride on mercuric fulminate. The results are, however, not so simple as was expected, two crystalline compounds of quite a different constitution being formed. Mercuric fulminate, obtained according to de Bruyn's method (*Ber.*, 19, 1370), and well washed with water, alcohol, and ether, was allowed to remain quietly in a cool place with an equal weight of benzoic chloride for 5—7 days; after that time, the fulminate had disappeared, and was replaced by a hard, greyish-white mass. On adding water to the latter, carbonic anhydride is evolved, and mercuric chloride passes into solution. The insoluble matter, after washing with cold water, is extracted with hot water, which takes up a white, crystalline compound, free from mercury, but containing nitrogen and melting at 107° . The residue is for the most part soluble in acetic acid, and crystallises out on cooling in beautiful needles which melt at 197° , and have the composition $C_{11}H_{12}N_2O_3$, as shown by the results of the analysis and molecular weight determination by Raoult's method. On boiling with alkalis, it is converted into benzoic acid, ammonia, and carbonic anhydride, and it is therefore probably *dibenzoylcarbamide*, but whether it is the symmetrical or asymmetrical compound has not yet been proved. The compound melting at 107° is also being more closely investigated, and it is hoped that the formation of these substances may throw some light on the constitution of fulminic acid.

By the action of benzoic chloride on potassium fulminate, a compound was obtained which also melts at 197° , but is not identical with dibenzoylcarbamide. It appears to be a mixed anhydride of benzoic and fulminuric acids.

H. G. C.

Compounds of Phthalimide with Phenols. By O. ÖSTERSETZER (*Monatsh.*, 11, 424—428).—The author has prepared the so called "resorcinolphthalimidesulphonic acid" of Reese (German Patent No. 44,268, 1887) by the action of sulphuric acid on a mixture of phthalimide (1 mol.) and resorcinol (2 mols.). The compound has the formula $C_{20}H_{12}O_7NS$, but does not appear to be a sulphonic acid. It yields a sodium derivative, $C_{20}H_{12}NO_7SNa + 7H_2O$, which, when precipitated from its aqueous solution by means of alcohol, forms dark-coloured crystals; and a diacetyl compound, $C_{20}H_{11}O_7NSAc_2$, which is soluble in alcohol and chloroform, and may be obtained as a yellowish-green, crystalline powder, by cooling a saturated solution in acetic acid.

G. T. M.

Dihydrobenzaldehyde. By A. EICHENGRÜN and A. EINHORN (*Ber.*, 23, 2870—2887; compare Abstr., 1887, 741).—The compound formed by the action of alkaline carbonates on the salts of anhydroecgonine dibromide proves not to be the analogue of orthobromocinnamene, as stated, but is a mixture of methyl tetrahydropyridylacetylene and dihydrobenzaldehyde; the small quantity of bromine previously found is due to the presence of unaltered anhydroecgonine dibromide. Methylamine is also formed in some quantity during the reaction.

Dibromanhydroecgonine dibromide hydrobromide,

is prepared by heating anhydroecgonine hydrochloride with 2 parts of

bromine on the water-bath for 3—4 hours. It crystallises in well-developed, red, rhombic prisms, which melt at 145° with decomposition, and exhibit strong pleochroism. After remaining for a few hours, the compound gives up bromine, and it is also decomposed by dissolving in alcohol, glacial acetic acid, or ethyl acetate. It is insoluble in water, ether, chloroform, and light petroleum.

Anhydroecgonine dibromide hydrobromide,

is obtained by the decomposition of the previous compound in a current of steam; it is deposited from alcohol, glacial acetic acid, or water in long, monoclinic prisms melting at 187 — 188° with decomposition. From dilute aqueous solution, tetragonal double pyramids are deposited, which contain 3 mols. H_2O and melt at 181 — 182° with decomposition. On exposure to air, these crystals become converted into the anhydrous modification.

Anhydroecgonine dibromide hydrochloride,

is formed by the action of silver chloride on the hydrobromide. It crystallises in long, monoclinic prisms melting at 173 — 174° with decomposition, and also in tetragonal octahedra, which contain water of crystallisation and melt at 169 — 170° . By the action of alkalis or alkaline carbonates on the salts of anhydroecgonine dibromide, methylamine, carbonic anhydride, and hydrogen bromide are eliminated, and dihydrobenzaldehyde is obtained. If, however, the action is allowed to proceed in the cold, several intermediate products may be isolated.

α -Bromecgonine lactone, $CH \begin{smallmatrix} \text{CH}_2 \cdot \text{CH}_2 \\ \text{CH} \cdot \text{NMe} \end{smallmatrix} CH \cdot CH \begin{smallmatrix} \text{CHBr} \\ \text{O} \end{smallmatrix} CO$, is

prepared by treating a salt of the dibromide with 2 parts of a saturated solution of potassium carbonate, or by the action of ammonium hydroxide or sodium hydroxide at 0° . It is extremely soluble in water, insoluble in absolute alcohol, and crystallises from acetone in small, cubical crystals which melt at about 150° with evolution of carbonic anhydride. The *hydrochloride* is deposited from dilute aqueous solution in tetragonal octahedra which contain 3 mols. H_2O , and melt at 197 — 198° with decomposition; the compound crystallises from alcohol, from glacial acetic acid, or from concentrated aqueous solution in anhydrous, monoclinic prisms which melt at 203 — 204° with decomposition. The *hydrobromide* is also dimorphous; the anhydrous, monoclinic modification melts at 179° , and the tetragonal form melts at 174° . The *hydrochloride*, $C_8H_{13}NO_2Br \cdot HAuCl_4 + 1\frac{1}{2}H_2O$, crystallises from water in tufts of long, golden-yellow needles which melt at 211° ; on exposure to air, the crystals become anhydrous and melt at 216° . The lactone does not yield a methyl salt; on boiling with water, carbonic anhydride is eliminated, and a compound of the formula $C_8NH_7Me \cdot C_3H_5O_3, HBr$ is formed in very small quantity; it crystallises from dilute alcohol in monoclinic prisms melting at 175° .

ω -Bromo-1-3-4-methyltetrahydropyridylethylene,

is prepared by heating a glacial acetic acid solution of the lactone in

a sealed tube for 5 to 6 hours at 170° ; the product is poured into water, and the solution neutralised with sodium carbonate and extracted with ether; on treating the ethereal solution with hydrochloric acid and auric chloride, the *aurochloride* is formed; it crystallises in short, yellow needles which melt at 174° . On boiling with water, the auric salt of methyltetrahydropyridylacetylene is formed (see below). The same base is also obtained by the fusion of the lactone, or by boiling it for some time with glacial acetic acid or acetic anhydride.

On boiling dibromoeconine dibromide hydrobromide with aqueous potassium carbonate, and distilling the solution in a current of steam, a yellow, oily liquid is obtained; this is dissolved in ether and the solution washed with hydrochloric acid; the acid liquid is neutralised with soda and extracted with ether; on evaporation, *methyltetrahydropyridylacetylene*, $C_5NH_7Me \cdot C:CH$ remains as a colourless, basic, viscid liquid. The *aurochloride* crystallises from dilute alcohol in brownish-yellow cubes or flat, yellow needles which melt at 177.5 — 178.5° .

Dihydrobenzaldehyde, $CH_2 \begin{smallmatrix} CH_2 \cdot CH \\ CH:CH \end{smallmatrix} > C \cdot CHO$, is formed, together with the previous compound, from which it is separated in the manner described. It is best prepared by heating an aqueous solution of anhydroeconine dibromide hydrobromide with 0.5 part of sodium carbonate at 60° ; the product is distilled in a current of steam and the distillate extracted with ether. After washing with a few drops of hydrochloric acid, the ether is distilled, and the residue fractionated in a vacuum; the yield is 20 per cent. of the dibromide employed. Methylamine and anhydroeconine hydrobromide are also formed. The aldehyde is obtained as a colourless oil which darkens on exposure to light, and has an intensely nauseous odour; it boils at 121 — 122° under a pressure of 120 mm., and is partly decomposed on distillation at ordinary pressures; sp. gr. = 1.0202 at 14.5° , and 1.0327 at 0° . It forms a crystalline compound with ammonia, reduces ammoniacal silver solution and potassium permanganate solution in the cold, and also reduces Fehling's solution on warming; it is not oxidised on exposure to air or oxygen, but becomes slowly converted into a resinous mass; concentrated sulphuric acid decomposes it in the cold. The formation of the aldehyde is explained by assuming that hydroxyl is substituted for the bromine in *m*-bromomethyltetrahydropyridylethylene; the unstable group $CH:CH \cdot OH$ then changes into the more stable complex $CH_2 \cdot CHO$, and, by the elimination of methylamine, the hypothetical compound

is formed; this gives up the elements of water and yields dihydrobenzaldehyde. The aldehyde forms a crystalline compound on treatment with hydrogen sodium sulphite in the cold, which is readily soluble in water, but insoluble in alcohol or ether; on boiling with an alkaline carbonate, it is converted into benzaldehyde. *Dihydrobenzylidene phenylhydrazine* is prepared by the action of phenylhydrazine on dihydrobenzaldehyde, and is deposited from alcohol in small, yellow plates melting at 127 — 128° ; the crystals exhibit strong pleochroism. *Dihydrobenzoxime* is obtained by the action of hydroxyl-

amine on the aldehyde. The oily liquid which is formed consists of two isomeric compounds, which may be separated by treatment with light petroleum (b. p. 40—50°); the soluble compound, which is termed the β -oxime, crystallises on cooling, and melts constantly at 43—44°; the α -hydroxime is insoluble in light petroleum, and does not crystallise.

Dihydrobenzoic acid, $\text{CH}_2 < \begin{smallmatrix} \text{CH}_2 \cdot \text{CH} \\ \text{CH} : \text{CH} \end{smallmatrix} > \text{C} \cdot \text{COOH}$, is prepared by the oxidation of the aldehyde with an ammoniacal solution of silver oxide; it is volatile with steam. On cooling an aqueous solution, it is deposited in feathery crystals which melt at 94—95°, and are more sparingly soluble in water than benzoic acid. The compound has an agreeable odour, and reduces ammoniacal silver solution, but does not react with Fehling's solution: it is converted into benzoic acid on strongly heating. The *silver salt* readily decomposes on exposure to light; like the *lead salt*, it is sparingly soluble in water. The salts of *barium*, *ammonium*, and the *alkali metals* readily dissolve in water, and crystallise from dilute alcohol, on the addition of ether, in silky, lustrous needles. The *copper salt* is soluble in ammonia with a green colour, and is deposited in green, nodular crystals. On treating dihydrobenzaldehyde with almost any other oxidising agent, it either remains unaltered, or is completely decomposed; with potassium permanganate, it yields benzoic acid. J. B. T.

The Stereochemical Isomerides of Paratolyl Phenyl Ketone. By A. HANTZSCH (*Ber.*, 23, 2776—2780).—The further investigation of the oximes of paratolyl phenyl ketone (*Abstr.*, 1890, 1273) has shown that the α -oxime may be converted into the β -compound simply by heating its alcoholic solution. The transformation is, however, very incomplete, and a large amount of the ketone is re-formed. Better results are obtained when the oxime is mixed with an equal weight of hydroxylamine hydrochloride, but even under these conditions a mixture of the two oximes is always obtained. As previously mentioned, the β -oxime is only slowly and incompletely converted into the benzyl ether on treatment with benzyl chloride; if, however, the bromide is employed, the reaction proceeds much more readily, and a purer product is obtained, which, after recrystallisation from amyl alcohol, melts at 51°. It also crystallises from ether in slender, silky needles, and if pure is not acted on by hot water or alcohol, or when hydrogen chloride is passed into its ethereal solution.

The acetyl derivative of the α -oxime has already been described by Auwers (*Abstr.*, 1890, 503). If the β -oxime is dissolved in acetic anhydride at the ordinary temperature, and the solution allowed to evaporate spontaneously, β -acetylparatolyl phenyl ketoxime, $\text{CPh}(\text{N} \cdot \text{OAc}) \cdot \text{C}_6\text{H}_4$, crystallises out. The crystals resemble those of the α -compound, but are somewhat more acute. It cannot be obtained quite pure, as it readily passes into the α -acetyl derivative in the course of the usual processes of purification, especially in alcoholic solution; if the latter be warmed, the transformation is almost instantaneous and complete. This fact explains why Auwers (*loc. cit.*) was unable to obtain the β -oxime, for he adopted this method of purification, and

therefore only obtained the α -compound. Phenyl isocyanate acts on both oximes, but with formation of one and the same additive compound, corresponding with the α -oxime and melting at 180° . The isomeric acetyl derivatives and phenyl isocyanate additive compounds of parabromobenzophenone are much more stable than the above; this, according to the author, is probably due to the influence of the methyl group.

H. G. C.

Constitution of Cumenylpropionic Acid. By O. WIDMAN (*Ber.*, 23, 3076–3080; compare Abstr., 1889).—*Orthobromocumenylacrylic acid*, $\text{CHMe}_2\cdot\text{C}_6\text{H}_4\cdot\text{Br}\cdot\text{CH}:\text{CH}\cdot\text{COOH}$ [$\text{CH}:\text{CHMe}:\text{Br}=1:2:4$], is prepared from the corresponding amidic-acid, but could not be obtained in a pure condition; it crystallises from dilute acetic acid in long, colourless needles melting at 134° . On reduction with hydriodic acid and phosphorus, it yields *orthobromocumenylpropionic acid*, $\text{CHMe}_2\cdot\text{C}_6\text{H}_4\cdot\text{Br}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, crystallising from light petroleum in long, slender needles which melt at 55.5° , and yield cumenyl propionic acid by the action of sodium amalgam.

Orthochlorocumenylacrylic acid, $\text{CHMe}_2\cdot\text{C}_6\text{H}_4\cdot\text{Cl}\cdot\text{CH}:\text{CH}\cdot\text{COOH}$, crystallises from acetic acid in lustrous plates melting at 133 – 134° .

By the action of sodium nitrite and hydrobromic acid on amidopropylcinnamic acid, a compound is obtained which melts at 128° , and on reduction with phosphorus and hydriodic acid, yields the above described orthobromocumenylpropionic acid (m. p. 55.5°). An investigation of the orthamidopropylcinnamic acid showed it to be a mixture of two-thirds orthamidocumenylacrylic acid (m. p. 161°) and one-third metamidocumenylacrylic acid. It follows, therefore, that the so-called orthonitropropylcinnamic acid is also a mixture of ortho- and meta-nitrocumenylacrylic acids. Cumenylpropionic acid (m. p. 75.59°) is thus finally proved to be an isopropyl derivative.

J. B. T.

Perkin's Reaction. By O. RERUFFAT (*Gazzetta*, 20, 158–162).—The condensation of aldehydes with organic sodium salts is generally supposed to take place without the acetic anhydride used taking any part in the reaction. The author finds that in his synthesis of phenylcinnamylacrylic acid (Abstr., 1885, 1137) from cinnamaldehyde, sodium phenylacetate and acetic anhydride, if the reaction is interrupted as soon as the solution has been raised to the boiling point, and the product is thrown into cold water, an insoluble oil remains, which has the composition of *cinnamylidene diacetate*, $\text{CHPh}:\text{CH}\cdot\text{CH}(\text{OAc})_2$, whilst the aqueous solution contains the whole of the phenylacetic acid used. The acetate crystallises from alcohol in large, colourless, nacreous plates, and melts at 84 – 85° . It is decomposed into cinnamaldehyde and acetic acid by distillation in steam, or by boiling with alkaline carbonates. It takes up 2 atoms of bromine forming an unstable compound, which, on steam distillation, yields Zincke's phenyl- β -bromacetaldehyde (Abstr., 1884, 1343). If left for a long time, it is converted into a yellow syrup, which smells of cinnamaldehyde and acetic acid. The foregoing experiment renders it probable that the first step in Perkin's reaction is the formation of an acetate of the aldehydic radicle.

S. B. A. A.

Methylresorcinolphthaloylic Acid. By E. QUELIDA (*Gazzetta*, 20, 127—132).—*Methylresorcinolphthaloylic acid*,

is obtained like the corresponding anisoil and phenetoil derivatives (see Grande, Abstr., 1890, 1128). A mixture of phthalic anhydride (12 grams), dimethylresorcinol (24 grams), and aluminium chloride (16 grams) is heated for about three hours on the water-bath, the product thrown into excess of cold water, and the precipitated acid extracted with ammonium carbonate, and reprecipitated with hydrochloric acid. It is then purified by repeated crystallisation from toluene and from water. The pure acid crystallises in light, columnless scales, dissolves sparingly in boiling water, but readily in hot toluene and in ether. It melts at 164—165°, forming a clear, yellowish-red liquid, and at a higher temperature dense, white, irritating fumes are evolved. A neutral solution of the ammonium salt gives precipitates with soluble salts of copper, zinc, mercury, lead, &c. The silver salt, $\text{C}_{13}\text{H}_{11}\text{O}_3\text{Ag}$, is obtained as a heavy, white precipitate, which is soon blackened and decomposed by light. The barium salt crystallises in anhydrous, yellowish nodules. S. B. A. A.

Gallic Acid, Tannin, and Oak Tannic Acids. By C. BÖTTINGER (*Annalen*, 259, 132—136).—The author's attempts to prepare cyanhydrins and oximes from gallic acid and various tannins were unsuccessful, and no definite results were obtained. F. S. K.

Action of Phenylhydrazine on Tannin Extracts. By C. BÖTTINGER (*Annalen*, 259, 125—132).—The true tannins combine with phenylhydrazine, yielding amorphous compounds, which have not been prepared in a pure condition, and which consequently have not been analysed; in their behaviour with acids, they show a certain resemblance to the osazones of the sugars.

On boiling an aqueous solution of a tannin extract with phenylhydrazine, carbonic anhydride is evolved, probably also nitrogen, and the phenylhydrazine is partially decomposed into ammonia and azobenzene, so that ammonia derivatives, as well as phenylhydrazine derivatives of the tannins, are formed. The following extracts were examined:—Sumach, vallonina, algarobilla, divi-divi, oak-wood, oak-bark, and pine-bark. F. S. K.

Manufacture of Decolorised Tannins: Zinc Tannate. By A. VILLON (*Bull. Soc. Chim.* [3], 3, 784—786).—The liquor obtained by exhausting the crude material in the ordinary way is cooled at 2° for half an hour, and after filtering off extractives and tannins insoluble in the cold, 0.5 per cent. of zinc sulphate is added. The tannin of the liquor is now titrated, and for each kilo. present in the solution, 2.5 kilos. of zinc sulphate, dissolved in 12.5 litres of water, is added, and the whole is placed in a closed vat, furnished with a mechanical stirrer and steam coil, into which is passed the ammonia resulting from the decomposition of 2.5 kilos. of ammonium sulphate per kilo. of tannin present. After separation by a filter press of the precipitated zinc tannate, it is decomposed by dilute sulphuric acid, and to the liquor barium

sulphide is added, until the zinc sulphate is completely precipitated as zinc sulphide and barium sulphate. On filtration, a liquor containing 20—30 per cent. of tannin, and almost free from colour, is obtained. The process is economical, since all the bye-products are capable of easy regeneration. T. G. N.

Diphenylsuccinic Acids. By R. ANSCHÜTZ and P. BENDIX (*Annalen*, 259, 61—100).—Diphenylmaleic anhydride, prepared from benzyl cyanide by Reimer's method (Abstr., 1882, 169), separates from ether in well-defined rhombic crystals, $a : b : c = 0.69287 : 1 : 1.35838$, boils at 236° (15 mm.), and is readily soluble in chloroform and benzene, but only sparingly in alcohol and ether. Attempts to convert this anhydride into diphenylfumaric acid were unsuccessful; when it is treated with hydrogen chloride in methyl or ethyl alcoholic solution, it is partially converted into an alkyl salt identical with that obtained from the silver salt of diphenylmaleic acid, but a considerable quantity of the anhydride remains unchanged.

Diphenylmaleinil, $C_{22}H_{13}NO_2$, is easily obtained by heating the preceding compound with aniline at 120° ; it crystallises from alcoholic chloroform in slender needles, melts at 174 — 175° , and boils at 293° (14 mm.). On hydrolysis with boiling potash, it is decomposed into diphenylmaleic acid and aniline; the same change is brought about by boiling hydrochloric acid, but only very slowly. These experiments show that diphenylmaleic anhydride is not converted into diphenylfumaric acid under conditions which lead to the transformation of maleic into fumaric acid; it is doubtful whether the compound described by Rügheimer (Abstr., 1882, 1298) as diphenylfumaric acid is in reality this substance.

Both α - and β -diphenylsuccinic acids are formed when diphenylmaleic anhydride is reduced with sodium amalgam in alkaline solution, as described by Reimer (*loc. cit.*), or with zinc and hydrochloric acid in alcoholic solution; the relative yield of the β -acid is greater when the reduction is carried out with zinc and hydrochloric acid. The two acids are most conveniently separated by means of their barium salts.

Barium α -diphenylsuccinate, $C_{16}H_{12}O_4Ba + 2H_2O$, is obtained by precipitating a solution of the ammonium salt with barium chloride; it is soluble in 312 parts of water at 17 — 18° . A sparingly soluble salt containing 4 mols. of water is formed when barium hydroxide is added to a dilute solution of the ammonium salt.

Barium β -diphenylsuccinate, $C_{16}H_{12}O_4Ba + 7H_2O$, separates in well-defined crystals when a solution of the barium salt of the β -acid is evaporated at 100° ; it is soluble in 4742 parts of water at the ordinary temperature.

Both α - and β -diphenylsuccinic acid form colourless silver salts, which, when dried at 100° , have the composition $C_{16}H_{12}O_4Ag_2$; when these silver salts are treated with ethyl iodide at 100° , they are converted into ethyl salts, identical with the compounds obtained by Reimer (*loc. cit.*), by treating the corresponding acids with alcohol and sulphuric acid. The ethyl salt of the α -acid melts at 84° , that of the β -acid at 140 — 141° .

α -Diphenylsuccinic acid dissolves in cold acetic chloride with evolution of hydrogen chloride, and, after evaporating the solution at 100°, there remains an oily mixture of the anhydrides of the α - and β -acids, which gradually becomes crystalline; this product separates from ether in well-defined crystals, melts at 115–116°, and boils at 240° (about 15 mm.), the distillate gradually solidifying. When boiled with water, it yields about 96.5 per cent. of the α -acid, and 3.5 per cent. of the β -acid, even when in its preparation from the acid the temperature is kept below 36° throughout the various operations; when treated with potash, it gives 85.8 per cent. of the α -acid, and 14.8 per cent. of the β -acid. The same mixture of anhydrides is obtained from the barium salt of the α -acid in like manner.

β -Diphenylsuccinic acid is not acted on by acetic chloride in the cold, but at 100° it yields a mixture of anhydrides which has the same melting point and other physical properties as that obtained from the α -acid, but which, on boiling with water, gives 74.81 per cent. of the α -acid, and 18.5 to 26.1 per cent. of the β -acid. When silver or barium β -diphenylsuccinate is treated with acetic chloride, a mixture of the anhydrides is formed which melts at 110–111°, and on boiling with water, gives 65–70 per cent. of the β -acid, and 25–40 per cent. of the α -acid.

The mixture of anhydrides obtained by distilling α - or β -diphenylsuccinic acid under reduced pressure (14 mm.) melts at 112–113° and in its behaviour with solvents, &c., it resembles that produced by treating the acids with acetic chloride; when boiled with water, it yields about 90 per cent. of the α -acid, and 10 per cent. of the β -compound.

When the α -acid is heated at temperatures ranging from 150 to 185°, about 50 per cent. is converted into anhydride, and about 50 per cent. into the β -acid; the β -acid, on the other hand, does not lose water below 185°. These experiments prove the existence of two isomeric diphenylsuccinic anhydrides, but owing to the great similarity in properties, the two compounds cannot be separated; the existence of two anhydrides proves, however, that the isomerism of the two acids cannot be explained by assuming, as Roser has done, that they have the constitution $\begin{array}{c} \text{CHPh}\cdot\text{C}(\text{OH})_2 \\ \text{CHPh}-\text{CO} \end{array}$ and $\begin{array}{c} \text{CHPh}\cdot\text{COOH} \\ \text{CHPh}\cdot\text{COOH} \end{array}$ respectively, and it seems more probable that the relationship between them is the same as that which exists between the two hydrobenzoins.

Diphenylsuccinanil, $\text{C}_{22}\text{H}_{17}\text{NO}_3$, is obtained when the anhydride, prepared either from α - or β -diphenylsuccinic acid by means of acetic chloride, is heated with aniline; it can also be obtained by reducing diphenylmaleanil. It crystallises from hot benzene in colourless needles melting at 226–227°, and from glacial acetic acid in larger needles melting at 230–231°.

Diphenylsuccinanilic acid, $\text{C}_{22}\text{H}_{19}\text{NO}_3$, is produced when the preceding compound is boiled with barium hydroxide; it crystallises from dilute alcohol in colourless needles, and melts at 220°. It is not changed by warm concentrated alcoholic potash, but it is reconverted into the anil by glacial acetic acid, hydrogen chloride, and alcoholic sulphuric acid.

F. S. K.

Crystallographic Proof of the Identity of Pyranilpyroinlactone and Citraconanil. By R. ANSCHÜTZ (*Ber.*, 23, 2979—2981; see also Abstr., 1890, 1102).—By the slow evaporation of the ethereal solution of citraconanil obtained in different ways, the author has succeeded in obtaining it in well developed crystals. Hintze and Jennsen have examined crystallographically preparations obtained (1) from β -anilidopyrotartaric acid (Reissert's pyranilpyroinlactone), (2) from aniline and citraconic acid, (3) from pseudoitaconanilic acid. The measurements show conclusively that the substances obtained by all three methods are identical, the crystals belonging to the monosymmetric system ($a : b : c = 2.7575 : 1 : 1.8152$, $\beta = 51^\circ 17'$). The optical properties of all three were also found to be almost identical, three corresponding plates giving the following numbers :—

	No. 1.	No. 2.	No. 3.
2H α	11° 6'	11° 22'	11° 35'

H. G. C.

Paranitro-orthotoluenesulphonic Acid. By J. HAUNNER (*Bull. Soc. Chim.* [3], 3, 797—799).—Paranitrotoluene (200 grams) is slowly added to sulphuric acid containing 44 per cent. sulphuric anhydride (260 grams), the energetic reaction being modified by cooling with ice, and then completed by heating the mixture at 150° . The product is added to water (1500 grams), and after removing the excess of sulphuric acid by calcium carbonate, the solution is concentrated until the sulphonic acid crystallises out, the yield being 64 per cent. The author confirms Jennsen's researches (this Journal, 1874, 479), and finds that the acid decomposes the sulphates of zinc and copper forming nitrosulphonates and liberating sulphuric acid. Nitrotoluenemetasulphonic acid, which may be prepared in a similar manner, is an analogous substance.

T. G. N.

Iodometylenesulphonic Acid. By C. BAUCH (*Ber.*, 23, 3117—3119).—The iodometylenesulphonic acid prepared by Hamerlich (Abstr., 1890, 1106) has the formula $[Me_2 : I : SO_3H = 1 : 3 : 4 : 6]$, since, on fusion with potash, it yields a dihydroxy-derivative which melts at 146° and is identical with the compound obtained by Wischin (compare following abstract). The sulphonamide, prepared after elimination of the iodine, melts at 137° , and therefore has the formula $[Me_2 : SO_2NH_2 = 1 : 3 : 4]$.

J. B. T.

Metaxylenedisulphonic Acid. By R. WISCHIN (*Ber.*, 23, 3113—3117).—*Metaxylenedisulphonic acid*, $[Me_2 : (HSO_3)_2 = 1 : 3 : 2 : 4]$, is prepared by heating metaxylene with 4 parts of fuming sulphuric acid at 150° ; on pouring into water, small crystals separate which cannot be purified by crystallisation from dilute sulphuric acid. The *disulphochloride* crystallises from ether in needles melting at 129° . The constitution of the compound is proved by the production of dichlorometaxylene (b. p. 228°), on heating with phosphorus pentachloride at 180° . The *sodium salt* is readily soluble in water. On oxidation with potassium permanganate, it yields a *disulphisophthalic acid*, which is deposited from alcohol in small,

granular crystals melting at 250°. The *barium sulphonate* crystallises from water in plates. The *sulphonamide* is deposited from water in silky, lustrous needles which melt at 249°.

Dihydroxyxylene [$\text{Me}_2 : (\text{OH})_2 = 1 : 3 : 2 : 4$] is obtained by fusing the sulphochloride with potassium hydroxide, and may be purified by sublimation; it is deposited in slender, white needles melting at 146°, and is very readily soluble in water, alcohol, or ether; an intense violet colour is produced with ferric chloride; on heating with phthalic anhydride and dissolving the product in soda, a green fluorescence is observed. *Disulphamine-isophthalic anhydride*,

is prepared by heating the disulphonamide with potassium permanganate solution, and decomposing the resulting potassium salt with sulphuric acid; the anhydride crystallises from alcohol, melts at 225°, is very sparingly soluble in water, and exceedingly bitter to the taste.

M-tarylenedisulphonethylamide, from the disulphochloride and ethylamine, crystallises from water in silky, lustrous needles which melt at 135°.

Bromoxylenedisulphonic acid [$\text{Me}_2 : \text{Br} : (\text{HSO}_3)_2 = 1 : 3 : 4 : 2 : 6$] is prepared by the action of fuming sulphuric acid on bromo-xylene [$\text{Me}_2 : \text{Br} = 1 : 3 : 4$]; both the acid and its salts crystallise with great difficulty. The *sulphochloride* is obtained from ether in long, white crystals melting at 160°. The *sulphonamide* is deposited from water in needles melting at 265°.

Bromodihydroxyxylene, obtained by the fusion of the acid with potassium hydroxide, forms white crystals, melts at 126°, and gives a violet colour with ferric chloride.

Chloroxylenedisulphonic acid resembles the bromo-derivative in properties and constitution. The *sulphochloride* crystallises from ether in white needles melting at 155°. The *sulphonamide* is deposited from water in silky, lustrous needles which melt at 270°.

Chlorodihydroxyxylene is obtained by sublimation in white needles which melt at 106°, and give a violet colour with ferric chloride.

J. B. T.

Action of Thionyl Chloride on Secondary Aromatic Amines. By A. MICHAELIS and E. GODCHAUX (*Ber.*, 23, 3019—3023; compare Abstr., 1890, 610).—*Thionylmethylaniline*, $\text{SO}(\text{C}_6\text{H}_4\cdot\text{N}(\text{Me})_2)_2$, is prepared by adding an ethereal solution of thionyl chloride to a mixture of aluminium chloride and methylaniline, dissolved in the same medium; the solution is well cooled and poured into cold water, the ether separated, and the aqueous solution filtered and treated with excess of soda; the precipitate thus obtained is boiled with alcohol, and the alcohol evaporated; the residue is dissolved in chloroform, and, on adding light petroleum, it crystallises out in stellate groups of colourless needles which melt at 154° and readily assume a blue tint. *Nitrosothionylmethylaniline*, $\text{SO}(\text{C}_6\text{H}_4\cdot\text{N}(\text{Me})\cdot\text{NO})_2$, is obtained by the action of sodium nitrite and hydrochloric acid on the preceding com-

ground, and is deposited from alcohol in colourless needles melting at 171° .

Thiomethylaniline, $S(C_6H_5.NHMe)_2$, is formed by the reduction of the thionyl derivative with sodium in alcoholic solution; it crystallises from a mixture of ether and light petroleum in long, yellow, transparent needles which melt at 60° , and are readily soluble in chloroform, ether, or alcohol. *Nitrosothiomethylaniline*, $S(C_6H_5.NMe.NO)_2$, from sodium nitrite and thiomethylaniline, crystallises in yellow, lustrous plates which melt at 133° , and are very sparingly soluble in cold alcohol.

J. B. T.

New Synthesis of Indigo. By L. LEDERER (*J. pr. Chem.* [2], 42, 383).—2 grams of phenylglycocine are stirred into 8–10 grams of fused sodium hydroxide, and the fusion maintained until the colour becomes pure orange, when the reaction is over. The melt is dissolved in much water, when pure indigo-blue is separated.

A. G. B.

Synthesis of Indigo and Allied Dyes. By K. HEUMANN (*Ber.*, 23, 3043–3045).—Phenylglycocine is heated in absence of air with 2 parts of potassium hydroxide at 260° ; the fused mass becomes brownish-orange; it is allowed to cool, dissolved in water, and a stream of air drawn through the solution; an immediate precipitation of indigo occurs. Care must be taken not to continue the fusion too long, or decomposition takes place; small portions are therefore withdrawn from time to time and dissolved in water, the heating being immediately stopped as soon as the formation of indigo is observed. Sodium hydroxide may be substituted for potassium hydroxide, but the reaction takes place at a much higher temperature. Experiments with other dehydrating agents were unsuccessful. The reaction may be explained by assuming that, by the elimination of water from phenylglycocine, pseudindioxy, $C_6H_4 < \begin{smallmatrix} CO \\ NH \end{smallmatrix} > CH_2$, is formed, and that this yields indigo on oxidation.

J. B. T.

Desmotropy in Phenols. By J. HERZIG and S. ZEISEL (*Monatsh.*, 11, 413–420; compare Abstr., 1888, 822; 1889, 247 and 966).—On heating diresorcinol (1 mol.) in alcoholic solution with potash (8 mols.) and ethyl iodide (8 mols.) in a reflux apparatus for several hours, the authors obtained, as the chief product, a viscid, brownish oil, insoluble in potash. When shaken with cold alcohol, a portion of this substance dissolves, and may be obtained on evaporation of the solvent. After several recrystallisations from hot alcohol, it is obtained in scales melting constantly at 90 – 92° , and is shown by analysis to be *ethyl diresorciny l tetrethyl ether*, $C_{12}H_8Et(OEt)_4$. On heating this compound with hydriodic acid, *ethyl diresorcinol*, $C_{12}H_8Et(OH)_4$, is formed, but, owing to its instability, it cannot be obtained in a pure state. *Tetracetyl ethyl diresorcinol*, $C_{12}H_8EtAc_4$, is readily prepared by heating the product of the action of hydriodic acid on ethyl diresorciny l tetrethyl ether with acetic anhydride. It crystallises from alcohol in needles which melt at 135 – 138° .

That portion of the oil which is insoluble in alcohol consists of *dirosorcinyl tetrethyl ether*, $C_{12}H_8(OEt)_4$, and crystallises from hot alcohol in scales which melt at $112-114^\circ$ (compare Pukall, Abstr., 1887, 660—661).

These results show that in dirosorcinol two hydroxyl groups of a benzene nucleus occupy, relatively to each other, the meta-position, and that ethylation is induced by the mobility of their hydrogen atoms, in the same way as the authors have previously shown (*loc. cit.*) obtains in the case of other metaphenols. G. T. M.

Diphenyldiethylene Derivatives. By O. REBUFFAT (*Gazzetta*, 20, 154—157).—*Diphenyldiethylene*, $CHPh:CH:CH:CHPh$, synthetically prepared by the author (Abstr., 1885, 1137), crystallises from alcohol in large, colourless, micaceous plates, melts at $147-148^\circ$, and distils unaltered at 250° . It is sparingly soluble in ether, but readily in alcohol and carbon bisulphide.

Tetrabromodiphenyldiethylene, prepared by treating an ethereal solution of the hydrocarbon with excess of an ethereal solution of bromine, crystallises in white scales which are unaffected by prolonged exposure to air and light; it blackens and melts at 230° .

The *dibromo-derivative*, $CHPhBr:CHBr:CH:CHPh$, is prepared by mixing the theoretical quantities of its constituents in ethereal solution in the cold, and allowing the mixture to remain. It forms tufts of colourless, acicular crystals, and melts at $147-148^\circ$, decomposing if not quite pure. It combines with some difficulty with two atoms of bromine forming the tetrabrominated derivative.

When a solution of diphenyldiethylene in carbon bisulphide is treated with a solution of bromine in the same solvent in the proportion required for the formation of a tetrabromide, the liquid is decolorised after some time, a small quantity of the hydrocarbon being deposited; on distillation, the dibromo-derivative passes over together with a brominated compound, intermediate in composition between the di- and tetra-bromo-derivatives. This substance crystallises from carbon bisulphide in long prisms, and melts at 198° , previously softening at 190° . S. B. A. A.

Synthesis of Benzylcinnamic Acid. By A. OGIALORO (*Gazzetta*, 20, 162—164).—*Benzylcinnamic Acid*, $C_{11}H_{10}O_2$.—A mixture of sodium hydrocinnamate and benzaldehyde in molecular proportion is heated with an excess of acetic anhydride for six hours at 160° , and the unaltered anhydride and the phenylpropionic acid are then removed by treating the product with ether and hot water respectively. The residue, after being purified by extraction with boiling light petroleum, crystallises from absolute alcohol in large, white needles which melt at 158° . The most probable constitution for this compound is that of a benzylcinnamic acid, $CHPh:C(CH_2Ph):COOH$.

S. B. A. A.

Naphthyl Sulphides. By F. KRAFFT and E. BOURGEOIS (*Ber.*, 23, 3045—3049; compare Abstr., 1890, 1311).—*aa-Dinaphthyl sulphide* may be prepared from bromonaphthalene and the lead salt of α -naphthyl mercaptan in the manner previously described. *Phenyl-*

α-naphthyl sulphide, $C_{10}H_7 \cdot SPh$, is obtained in the same way by heating *α*-bromonaphthalene with the lead salt of phenyl mercaptan, at 240° for 2—3 hours; it crystallises from alcohol in hard, colourless, lustrous prisms which melt at 41.5° , and boil at 218° under a pressure of 14 mm. The yield is over 50 per cent. of the lead salt employed; on oxidation, the corresponding sulphone is obtained.

Phenyl-β-naphthyl sulphide, $C_{10}H_7 \cdot SPh$, is formed, together with diphenyl sulphide and *ββ*-dinaphthyl sulphide, from monobromobenzene and the lead salt of *β*-naphthyl mercaptan; it crystallises from alcohol in stellate groups of small, white needles, or in lustrous plates, which melt at 51.5° , and boil at 224° under a pressure of 14 mm. The yield is 25 per cent. of theory, and the corresponding sulphone is obtained on oxidation. J. B. T.

Action of Aromatic Bases on Naphthol Violet. By R. HIRSCH and F. KALCKHOFF (*Der.*, 23, 2992—2994).—A new colouring matter related to naphthol violet has recently been described by Witt (*Abstr.*, 1890, 1307), who regards it as being formed simply by the action of heat on the last-named colouring matter. The authors had also previously observed that, under certain circumstances, preparations of naphthol violet have an unusually blue shade. According to present ideas, the colouring matter has the constitution $C_{10}H_6 < \underset{O}{\overset{N}{\text{O}}} > C_6H_4 \cdot NMe_2 \cdot HCl$, and is formed from nitrosodimethylaniline and *β*-naphthol according to the equation

The hydrogen thus set free reduces another portion of nitrosodimethylaniline to amidodimethylaniline, and the authors regarded it as probable that the blue colouring matter was formed by the further action of the latter on naphthol violet, and they, in fact, succeeded in thus obtaining a colouring matter identical in every respect with that described by Witt. In place of amidodimethylaniline, other aromatic bases, and even ammonia, may be employed, well-defined colouring matters being thus obtained. The compound from aniline crystallises in brown needles which melt at 256° and dissolve in concentrated sulphuric acid with a violet coloration. The base from paratoluidine resembles it very closely, but melts at 250° , whilst that from *α*-naphthylamine has a yellowish-brown colour in sulphuric acid solution. The yield does not, as a rule, amount to more than 50 per cent.

The constitution of these colouring matters has not yet been ascertained, but they are probably formed in a similar manner to the quinoneanilides. H. G. C.

Naphthoic Acids. By Å. G. EKSTRAND (*J. pr. Chem.* [2], 42, 273—304; compare *Abstr.*, 1889, 52, 152).—This paper is largely a reprint of what has already appeared. The nitro-*β*-naphthoic acids are best obtained as follows:—*β*-Naphthoic acid is gently warmed with nitric acid of sp. gr. 1.42 (two parts) until red fumes cease to appear, and the product is washed with water, dissolved in soda, and the sodium salt

crystallised; the acids are then liberated from the recrystallised salts by hydrochloric acid, dissolved in alcohol, and converted into their ethyl salts by dry hydrogen chloride; the ethyl salts are separated by light petroleum, in which that of the acid of m. p. 288° is sparingly soluble, the residue from the mother liquor being recrystallised from benzene, and the mixed tables (ethyl salt of acid of m. p. 288°) and needles (ethyl salt of acid of m. p. 293°) separated by hand.

Nitro- β -naphthoic acid (m. p. 293° , Abstr., 1885, 905) dissolves in 660 parts of alcohol at the ordinary temperature. The barium salt crystallises with 4 mols. H_2O ; the calcium salt (with $3\frac{1}{2}$ mols. H_2O) dissolves in 930 parts of water at the ordinary temperature. When the acid is oxidised by potassium permanganate, a non-nitrogenous acid is obtained which crystallises in slender needles and melts at 200° ; it has not been identified, but its formation is a strong indication that the nitro- and carboxyl-groups are not in the same benzene nucleus. Nitro- β -naphthoic acid gives no dinitronaphthalene when treated with nitric acid, whereas nitro- α -naphthoic acid does. When amido- β -naphthoic acid (m. p. 232° , *loc. cit.*) is heated with barium oxide, α -naphthylamine is obtained; thus the constitution of the nitro- acid is $[NO_2 : COOH = 1' : 2 \text{ or } 4' : 2]$. *Acetamido- β -naphthoic acid* crystallises in small tables melting at 291° .

By the action of chlorine on amido- β -naphthoic acid (m. p. 232°) in hot glacial acetic acid in the presence of iodine, a substance insoluble in water and alcohol is obtained, which crystallises from glacial acetic acid in orange needles melting with intumescence at 235° ; the analysis of this substance agrees fairly well with the formula $OH \cdot C_{10}H_7Cl_2 \cdot COOH$; if the treatment with chlorine is continued, the product crystallises in pale-red needles which melt with intumescence at 238° . By chlorinating the amido-acid in the cold, and treating the product with sulphurous anhydride, a substance containing less chlorine is obtained; it crystallises in brownish tables which melt about 234° ; when further chlorinated, it melts at 237° ; its formula is uncertain, but a calcium salt (with 5 mols. H_2O) has been obtained in yellow needles. Two other chlorine derivatives, the one crystallising in orange-red tables and melting at 220° , and the other, a brick-red powder melting at 277° , have also been obtained.

Dinitro- β -naphthoic acid (m. p. 248° , Abstr., 1884, 1361) dissolves in 61 parts of alcohol at the ordinary temperature. The *ammonium* (with 1 mol. H_2O), *sodium* (with 4 mols. H_2O), *barium* (with 8 mols. H_2O), and *calcium* (with 5 mols. H_2O) salts are described. By treating this acid with a large excess of hydrogen sulphide in ammoniacal solution, a dark-brown, infusible powder is obtained; it cannot be freed from sulphur, but it appears to be a diimido- β -naphthoic acid, $COOH \cdot C_{10}H_5(NH)_2$ (compare Abstr., 1889, 153; 1886, 948; 1887, 373). From analogy with the dinitro- α -naphthoic acid (m. p. 265°), the author ascribes the constitution $[(NO_2)_2 : COOH = 1' : 1 : 2 \text{ or } 4' : 4 : 2]$ to this acid.

Diamido- β -naphthoic acid, obtained by reducing the above dinitro-acid with ferrous sulphate in ammonia, crystallises in greenish-yellow needles which melt at 202° , and partially sublime; the *calcium salt* and the *monohydrochloride*, melting above 285° , were obtained.

Nitro- β -naphthoic acid (m. p. 288, Abstr., 1885, 905) dissolves in 390 parts of alcohol at the ordinary temperature. The ethyl salt melts at 121° , not 122° . The *ammonium*, *barium* (with 8 mols. H_2O), and *calcium* (with $4\frac{1}{2}$ mols. H_2O) salts are described. Oxidation with permanganate and treatment of the amido-acid with calcium oxide lead to the same conclusion as in the case of the β -nitro-acid (see above). *Calcium amido- β -naphthoate* crystallises with 4 mols. H_2O . *Acetamido- β -naphthoic acid* crystallises in slender needles which melt at 258° ; the *diacetyl derivative* melts at 181° . *Nitruacetamido- β -naphthoic acid* forms slender needles melting at 270° . When the amido acid is treated with chlorine in glacial acetic acid in presence of iodine, a product is obtained which crystallises in colourless needles and melts with intumescence at 258° ; it would appear from its formula, $\text{OH}\cdot\text{C}_{10}\text{H}_7\text{Cl}_4\cdot\text{COOH}$, to be a dichloride of a dichloroxy- β -naphthoic acid. In another experiment, colourless tables of the formula $\text{OH}\cdot\text{C}_{10}\text{H}_7\text{Cl}_3\cdot\text{COOH}$, and melting at 237° , were obtained.

Dinitro- β -naphthoic acid (m. p. 226° , Abstr., 1884, 1361) dissolves in 57 parts of alcohol at the ordinary temperature; the *ammonium salt* (with 1 mol. H_2O) dissolves in 285 parts, and the *calcium salt* (with 4 mols. H_2O) in 1740 parts of water at the ordinary temperature; the *barium salt* (with 6 mols. H_2O) is described.

Nitramido- β -naphthoic acid is obtained by treating an ammoniacal solution of the dinitro-acid (m. p. 226°) with hydrogen sulphide, adding acetic acid, digesting the precipitate with hydrochloric acid, and decomposing the solution thus obtained by ammonia; it forms stellate needles and melts at 235° ; its *hydrochloride* forms slender, red needles.

Diamido- β -naphthoic acid is obtained by reducing the dinitro-acid (m. p. 226°) with ferrous sulphate in ammonia; it melts about 230° , but with blackening, and forms small, six-sided crystals. The *calcium salt* (with $4\frac{1}{2}$ mols. H_2O) and the *dihydrochloride* are described.

The ethyl salt of a third nitro-acid remains in the mother liquor of the benzene solution in the preparation of the above nitro-acid (see beginning of the abstract). The *nitro- β -naphthoic acid* corresponding with this ethyl salt crystallises in stellate needles which melt, although not sharply, at 285° ; the *ethyl salt* melts at 75° .

Dry Distillation of Terpenylic Acid. By C. AMTHOR and G. MÜLLER (*J. pr. Chem.* [2], 42, 385—399).—By the dry distillation of terpenylic acid, Amthor (Abstr., 1882, 44) obtained a syrupy acid, tetracrylic acid, a lactone boiling at 202 — 204° , and a lactone, $\text{C}_7\text{H}_{12}\text{O}_3$, boiling at 210 — 212° ; but Fittig and Kraft (Abstr., 1882, 42) obtained no lactone. The authors have, therefore, reinvestigated the subject.

100 parts of boiling ether dissolve 3.856 parts of terebic acid, and the same quantity of cold ether dissolves 1.698 parts; the following is therefore a better method for separating this acid from terpenylic acid than that previously adopted (*loc. cit.*):—The mixed acids are heated to 80 — 90° , at which temperature most of the terebic acid remains unmelted, and is separated from the molten terpenylic acid by filtration through cotton-wool in a hot water funnel; the terpenylic

acid is then crystallised from hot water, and again heated until most of it is melted, when warm water is added and the solution filtered through cotton-wool; some of the crystals which separate on cooling are then dried on a micro-scope slide, heated to 80–90°, and examined under the microscope for any still solid particles of terebic acid. The melting and solution in water are repeated until no more terebic acid is detected in the crystals examined in this way.

Barium diterpenylate crystallises with 2 mols. H_2O (Abstr., 1882, 43), one of which is lost over sulphuric acid, and both at a high temperature, although not without partial decomposition.

The investigation of the products of the distillation of terpenylic acid was carried out on much the same lines as previously (Abstr., 1882, 44); the acid was not perfectly dry when distilled, still containing its water of crystallisation (1 mol.). The products isolated were teracrylic acid (b. p. 218°), a syrupy acid, and a very small quantity of other acids; a very little heptalactone (?) (b. p. 210–213°); and various neutral oils, soluble and insoluble in water, among which was an oxetone, $C_{12}H_{22}O_2$.

Fittig and Kraft probably overlooked the lactone produced in the distillation, having used too little terpenylic acid.

Heptalactone boils at 218° (Fittig and Kraft, 220°; Anthor, 202–204°).
A. G. B.

Methyldipyridyls. By A. HEUSER and C. STOEHR (*J. pr. Chem.* [2], 42, 429–440).—Anderson (*Annalen*, 105, 344) obtained a substance, which he called parapicoline, by the action of sodium on (impure) picoline. More recently Ahrens, (Abstr., 1889, 59) obtained a base which he called dipicolyl by the same process, but his picoline was not free from higher homologues. The authors have obtained a pure product and designate it as α -dimethyldipyridyl.

α -Dimethyldipyridyl, $C_{12}H_{12}N_2$, is prepared by adding thin strips of sodium (10 grams) to α -picoline (b. p. 128°, 20 grams) in a flask and gently warming the mixture, after 7–8 days, in a reflux apparatus. Water is then added to the reaction mass, an operation requiring great care as unaltered sodium is liable to remain enclosed in the mass and to cause an explosion, and the separated oil is distilled; ammonia and unaltered picoline come off below 150°, and then practically nothing distils until 300°. All that distils above 300° is redistilled, when the greater portion comes over at 303–306°; this portion is dissolved in absolute alcohol and converted into hydrochloride by a current of dry hydrogen chloride; the hydrochloride is recrystallised, decomposed by aqueous sodium carbonate, and the free base extracted with ether. This base crystallises from water in large, lustrous, white leaves, with 4 mols. H_2O , which are lost over sulphuric acid; the crystals melt at 37–38°, and the anhydrous substance at 84°. It dissolves in most solvents; like other pyridine bases, it is less soluble in hot than in cold water, and is separated from its aqueous solution by alkalis; it is specifically heavier than water, and has a characteristic odour. Its solutions give a yellow colour with potassium ferrocyanide, and brown-red fables gradually separate from the solution. The hydrochloride crystallises in colourless leaves, and dissolves easily in water

and sparingly in alcohol; the *pirrate* crystallises in sparingly soluble yellow tables, and melts with decomposition at 240° ; the *stannochloride* forms prismatic, yellow needles which melt at $179-180^{\circ}$; the *zinc salt* and the *platinochloride* are described; the latter is sparingly soluble; the *aurochloride* forms needles, darkens at 200° , and melts at $209-210^{\circ}$ (compare Ahrens, *loc. cit.*); the *mercuriochloride* crystallises in serrated leaves which darken at 210° and melt at 220° .

α -Methyldipyridyl- α -carboxylic acid, $C_5NH_5Me \cdot C_5NH_5 \cdot COOH$, obtained by oxidising *aa*-dimethyldipyridyl with potassium permanganate, crystallises in pale yellow needles (with 5 mols. H_2O); it is freely soluble in hot water and alcohol, and its solutions give a reddish-yellow colour with ferrous sulphate; the anhydrous acid melts at 193° giving off carbonic anhydride.

α -Methyldipyridyl, $C_5NH_5Me \cdot C_5NH_5$, is formed when the above mentioned carboxylic acid is heated with glacial acetic acid in a sealed tube at $180-190^{\circ}$ for 2—3 hours; the acetic acid is evaporated, and the base liberated by sodium carbonate and extracted with ether. It is more soluble in water than dimethyldipyridyl, and melts at 94° ; it will be treated of in a future communication. A. G. B.

α -Picoline and α -Isobutylene-pyridine. By C. STOEHR (*J. pr. Chem.* [2], 42, 420—428).— *α -Picoline* was obtained from animal oil by treating the hydrochloric acid solution of the fraction $128-133^{\circ}$ with mercuric chloride and recrystallising the mercuriochloride formed. It boils at 128° . The platinochloride never contains any water of crystallisation, whatever the circumstances under which it is crystallised (compare Weidel, *Abstr.*, 1880, 269; Seyffert, *J. pr. Chem.* [2], 34, 248); it crystallises in monoclinic tables, $a : b : c = 0.6636 : 1 : 0.9078$; $\beta = 72^{\circ} 46'$; it melts with decomposition at 195° , not 178° (Lange, *Abstr.*, 1886, 256; and others), and is more soluble in water than β -picoline platinochloride. Impure *α -picoline* (b. p. $128-134^{\circ}$) gives a platinochloride which crystallises with 1 mol. H_2O , melts at 195° , and is nearly similar in crystalline form [$a : b : c = 0.9758 : 1 : 1.3270$; $\beta = 76^{\circ} 47'$] to the platinochloride previously described as that of *α -picoline* (*loc. cit.*).

α -Isobutylene-pyridine, $C_6H_{11}N$, is obtained by heating *α -picoline* (8 grams) with acetone (5 grams) and some zinc chloride in a sealed tube at $250-260^{\circ}$ for 10 hours; the product is acidified with hydrochloric acid, extracted with ether, and, after heating to expel ether, distilled with steam; solid sodium hydroxide is then added and the liberated bases distilled, dried by potassium hydroxide, and redistilled. The greater part of the distillate, boiling below 140° , is unaltered *α -picoline*; the rest is twice fractionated, and the portion boiling between $190-210^{\circ}$ converted into mercuriochloride, from which the isobutylene-pyridine is liberated by potassium hydroxide. It boils at 200° , is very sparingly soluble in water, has a blue fluorescence and peculiar odour; its aqueous solution becomes turbid from separation of the base at the temperature of the hand, and it is volatile with steam. Its sp. gr. at $0^{\circ}/4$ is 0.9715. The *hydrochloride* crystallises in prisms melting at $140-141^{\circ}$, and soluble in alcohol and water; the *platinochloride* forms needles or prisms (with 2 mols. H_2O), and melts, when anhydrous, at

163—164° with decomposition; the *aurochloride* is unstable, and melts at 135—137°; the *mercurochloride* is sparingly soluble, and crystallises in long, slender, lustrous needles which melt at 144—145°; the *picrate* forms small, yellow needles, melts at 177°, and is sparingly soluble. A. G. B.

Diethylmuscarinepyridine. By H. LOCHERT (*Bull. Soc. Chim.* [3], 3, 858—861).—*Diethylmuscarinepyridine bromide*

is obtained by heating a mixture of bromoacetal and pyridine, in molecular proportion, at 80° for 10 days; on cooling, the compound crystallises out in deliquescent, nacreous scales which are very soluble in water and in alcohol. With platinum tetrabromide, it forms a red, amorphous precipitate, which is almost insoluble in water, completely insoluble in alcohol.

On treating diethylmuscarinepyridine bromide in aqueous solution with moist silver oxide, a colourless, strongly alkaline liquid is obtained, which neither crystallises on concentration nor forms crystalline salts, concentration of the solutions yielding syrupy liquids. *Diethylmuscarinepyridine*, $\text{OH}\cdot\text{C}_5\text{NH}_5\cdot\text{CH}_2\cdot\text{CH}(\text{OEt})_2$, as thus obtained, precipitates the hydroxides of silver and of copper from solutions of their salts.

Further communications on other muscarine derivatives are promised, as also on the synthesis of muscarine itself by means of bromoacetal and trimethylamine. T. G. N.

Tribromoquinolines. By A. CLAUS and P. HEERMANN (*J. pr. Chem.* [2], 42, 327—346).—The generic similarity between 3 : 4'-dibromoquinoline and the tribromoquinoline described by Claus and Welter (Abstr., 1890, 1320), and the fact that the latter can be obtained by brominating 4'-bromoquinoline, settles the orientation of two of the bromine atoms in this tribromoquinoline. The position of the third bromine atom is now settled, for the authors have succeeded in obtaining the same tribromoquinoline by heating 1 : 3-dibromoquinoline hydrobromide dibromide according to Claus' and Collischonn's method (Abstr., 1887, 158); this is therefore 1 : 3 : 4'-tribromoquinoline. This conclusion is supported by the fact that quinoline-3-sulphonic acid and quinoline-1-sulphonic acid both give this tribromoquinoline when they are brominated, for it is known that the first bromine atom enters into the 4'-position. It is to be noted that Claus and Küttner (Abstr., 1887, 278) were not working with pure quinoline-1-sulphonic acid when they obtained a tribromoquinoline of melting point 198°, but with a mixture of this and quinoline-4-sulphonic acid, which by their method yielded only 3 : 4 : 4'-tribromoquinoline; that the tribromoquinoline obtained by Claus and Zuschlag (Abstr., 1890, 267), melting at 185°, is a mixture of 1 : 3 : 4'- and 3 : 4 : 4'-tribromoquinolines; and that Lohavins' (*Beilstein*, 3, 749) tribromoquinoline (m. p. 173—175°) is impure 1 : 3 : 4'-tribromoquinoline.

1 : 4 : 4'-*Tribromoquinoline* is obtained by heating the hydrobromide dibromide of 1 : 4-dibromoquinoline (m. p. 127°, Abstr., 1890, 172), and fractionally precipitating the acetic acid solution of the residue by the method already given. It forms small needles when crystallised and large needles when sublimed; it melts at 168—168·5° (uncorr.), and dissolves in most organic solvents. Its salts with the stronger mineral acids crystallise well, but are dissociated by water. The *platinochloride* forms orange-red crystals, which are dissociated by water and alcohol. No methiodide has been obtained. Two *nitro*-derivatives, melting at 197° (uncorr.) and 157° (uncorr.) respectively, and soluble and insoluble in alcohol, respectively, have been obtained. This tribromoquinoline is also obtained by brominating 4 : 1-bromoquinolinesulphonic acid (Abstr., 1890, 267); if too much bromine (above 2 mols.) is used, a tetrabromoquinoline melting at 198° is also formed, and the constitution of this is evidently 1 : 3 : 4 : 4'-*tetrabromoquinoline*. It is identical with the tetrabromoquinoline obtained by Claus and Welter (Abstr., 1890, 1320), and is perhaps the compound (m. p. 198°) obtained by Claus and Küttner, and described by them as a tribromoquinoline (see above).

Claus and Posselt (Abstr., 1890, 522) studied the action of phosphorus pentabromide on 1 : 4-hydroxyquinolinesulphonic acid at 130° and 160°, and obtained substances which they described as a bromoquinolinesulphonic bromide and a tribromoquinoline, respectively. Closer investigation has now shown that both these substances still contain the hydroxyl group, being 1-hydroxy-2 : 4-bromoquinolinesulphonic bromide and 1-hydroxy-3 : 4 : 4'-tribromoquinoline respectively, and not the aforesaid compounds.

1-hydroxy-3 : 4 : 4'-*tribromoquinoline* crystallises in long, brilliant, lustrous, colourless needles, and melts at 172—173°, not 168°; its basic properties are inappreciable, for it forms no platinochloride or methiodide, but yields metallic derivatives with the alkalis and the heavy metals.

When 1-hydroxy-2 : 4-bromoquinolinesulphonic acid is treated with tin and hydrochloric acid, the hydroxyl group is reduced, and the hydroquinoline-4-sulphonic acid, $C_8NH_{10}SO_3H$, described by Lellmann, is obtained; it crystallises with 1 mol. H_2O , and melts at 315° (uncorr.); its *potassium salt* was obtained. A. G. B.

2'-*Quinolylacetaldehyde*. By E. CARLIER and A. EINHORN (Ber., 23, 2894—2897).—2'-Quinolylacetaldehyde may be prepared by the electrolysis of 2'-quinolyl- α -hydroxypropionic acid, or by the action of concentrated sulphuric acid. On treating quinolylhydroxypropionic acid with a glacial acetic acid solution of bromine, *dibromoquinolylacetaldehyde* is formed, melting at 180°. The *phenylhydrazone* crystallises from alcohol in prisms which melt at 168—169°. The *oxime* crystallises in white needles melting at 235—237°. By the action of phosphorus pentachloride on the aldehyde, 2'-*w*-*dichloroethylquinoline*, $C_8NH_7CH_2CHCl_2$, is formed, crystallising from ether or alcohol in white needles which melt at 80°.

2'-3'-*Di*quinolyl is prepared from orthamidobenzaldehyde and quinolylacetaldehyde; it crystallises from alcohol in white plates,

melting at 175.5° , and is identical with the compound obtained by Weidel by the action of sodium on quinoline.

2'-Quinolylacetic acid is formed by the oxidation of the aldehyde, or by fusion with potassium hydroxide; it crystallises from alcohol in white needles which melt at 275° , and may be sublimed without decomposition. The *hydrochloride* melts at 243° . The *calcium salt* forms a white, crystalline powder; the *silver salt* decomposes on exposure to light, and yields quinaldine on distillation in an atmosphere of hydrogen; it is also formed by heating the calcium salt with calcium oxide.

2'-Quinolylpropionic acid, $C_9H_7 \cdot CH_2 \cdot CH_2 \cdot COOH$, is prepared by the reduction of quinolylacrylic acid with sodium amalgam; it crystallises from water or alcohol in needles which melt at $115-116^{\circ}$. The *ethyl salt* crystallises from light petroleum in needles which melt at 116° . No other salts could be obtained.

2'-Quinolyl dibromopropionic acid, $C_9H_7 \cdot CHBr \cdot CHBr \cdot COOH$, is formed by the action of bromine on quinolylacrylic acid; it crystallises from glacial acetic acid in white prisms which melt at $180-181^{\circ}$. If this compound is dissolved in an alkaline carbonate solution, and distilled in a current of steam, *2'-quinolylacetylene*, $C_9H_7 \cdot C \equiv CH$, is formed; this is an oily liquid, and yields *2'-quinolyl dibromomethylene*, $C_9H_7 \cdot CBr \cdot CHBr$, which is deposited from ether in nodular crystals melting at $63-64^{\circ}$. By the action of excess of bromine on this compound, a *perbromide* is obtained, which crystallises in prisms, and melts at $195-196^{\circ}$.

2'-Quinolyl dihydroxypropionic acid, $C_9H_7 \cdot CH(OH) \cdot CH(OH) \cdot COOH$, is prepared by the oxidation of quinolylacrylic acid with a dilute solution of potassium permanganate at low temperatures; it crystallises from water or alcohol in prisms which melt at 113° ; the *ethyl salt* forms prisms melting at 110.5° .

J. B. T.

Nitro- and Chloro-derivatives of β -Methyl- δ -oxyquinazoline (Anhydroacetylorthamidobenzamide). By L. H. DEHOFF (*J. pr. Chem.* [2], 42, 346-360; compare Abstr., 1887, 1043).—*Nitro- β -methyl- δ -oxyquinazoline* is obtained by nitrating β -methyl- δ -oxyquinazoline with nitric acid (sp. gr. 1.5) at the boiling point, and evaporating. It crystallises from hot water as a white powder; it begins to darken at 230° , but is not further changed till 280° ; when heated on platinum foil, it explodes feebly; it dissolves in aqueous alcohol and alkalis, but not in ether or benzene. Its solution in ammonia gives a white *silver compound* when precipitated with silver nitrate, but is not precipitated by the salts of other heavy metals. It crystallises unchanged from hot strong hydrochloric acid. The *methyl compound* forms small, slender, white needles melting at 165° .

No monochloro-derivative has been obtained.

Tetrachloro- β -methyl- δ -oxyquinazoline is produced by mixing the oxyquinazoline (8 grams) with phosphoric chloride (25 grams), dissolving the mixture in phosphorous chloride (10 grams), and heating for 12 hours at 170° ; the excess of the phosphorus chlorides is distilled off, and the residue washed with soda solution, and crystallised from alcohol; the yield is 53 per cent. It crystallises in white

needles which melt at 124—125°, and are insoluble in water, but soluble in most other solvents.

When the tetrachloro-derivative is evaporated with alcoholic potash, and the residue dissolved in water, filtered, and treated with dilute sulphuric acid, a precipitate is obtained which crystallises from alcohol in yellowish prisms melting at 206—207°; the formula of this substance is $C_6H_4Cl_2N_2 \cdot OH$. The *ethyl* compound, $C_6H_4Cl_2N_2 \cdot OEt$, is obtained at the same time, being left undissolved by the water; it crystallises from alcohol in soft, lustrous, white needles melting at 75—76°. The *amide*, $C_6H_4Cl_2N_2 \cdot NH_2$, is obtained by heating the tetrachloro-derivative with alcoholic ammonia at 150—160° for 2—3 hours; the reaction mass is washed with water, and heated with alcohol and animal charcoal; the alcoholic solution is then precipitated with water. The amide crystallises in needles which blacken at 178°, and melt at 183—184°; it dissolves in dilute alcohol and benzene, but not in ether, light petroleum, or water; its *hydrochloride* blackens and decomposes about 200°. A *methylamine* derivative, $C_6H_4Cl_2N_2 \cdot NHMe$, was obtained by heating the tetrachloro-derivative with methylamine at 110°; it forms white, microscopic needles (with 1 mol. H_2O), which soften at 149°, and melt at 155°. An *anilide*, $C_6H_4Cl_2N_2 \cdot NHPh$, was also obtained; it crystallises (with 1 mol. alcohol) in thick, white, rhombic tables.

A consideration of the above compounds leads to the conclusion that tetrachloro- β -methyl- δ -oxyquinazoline contains one atom of chlorine situated differently from the other three, and as this atom is easily replaced, it cannot be in the benzene nucleus; the author, therefore, ascribes the formula $C_6HCl_3 \begin{smallmatrix} CO \cdot N \\ | \\ N = OMe \end{smallmatrix}$ to the tetrachloro-derivative. The above-described ethyl and amido-compounds will thus be trichloro- β -methyl- δ -ethoxyquinazoline and trichloro- β -methyl- δ -amidoquinazoline, respectively. It is, however, still an open question whether β -methyl- δ -oxyquinazoline is really a hydroxy- or an oxy-derivative (Abstr., 1887, 1043). When the tetrachloro-derivative is reduced with hydriodic acid, β -methyl- δ -oxyquinazoline is obtained; β -methylquinazoline is probably formed, but oxidises at once to the oxy-compound.

A. G. B.

Papaveroline. By K. KRAUSS (*Monatsh.*, 11, 350—362; compare Abstr., 1869, 166, 167; 1887, 1116).—The hydriodide of this base has been prepared by Goldschmiedt by the action of concentrated hydriodic acid on papaverine, in presence of amorphous phosphorus. When a solution of sodium hydrogen carbonate, saturated with carbonic anhydride, is added to the hydriodide, the free base, $C_{16}H_{13}NO_4 \cdot 2H_2O$, is precipitated as an almost colourless, crystalline powder, which, when dried in a vacuum, is perfectly stable, and contains 2 mols. H_2O , which are given up at 100°. Heated to 150°, it darkens in colour, and, on raising the temperature to 210°, becomes quite black, without having previously melted. The base dissolves readily in mineral acids, in oxalic acid, and in alcohol, and is very soluble in acetic acid and in glycerol. Dilute potash turns an alcoholic solution blue; strong potash produces a dark-violet coloration.

The hydrochloride, $C_{16}H_{13}NO_4 \cdot HCl + H_2O$, crystallises in white needles, soluble in hot water; the sulphate, $(C_{16}H_{13}NO_4)_2 \cdot H_2SO_4 + 8\frac{1}{2}H_2O$, is only slightly soluble in water; the oxalate,

crystallises from water in spherical aggregates of needles.

On distillation with zinc-dust in a stream of hydrogen, the author expected to obtain α -benzylisoquinoline. Instead of this, dibenzylidisoquinoline, $(C_{16}H_{13}N)_2$, and α -methylisoquinoline were formed. The former is insoluble in dilute hydrochloric acid, dissolves readily in ether, light petroleum, acetic acid, and benzene, and when crystallised from alcohol, melts constantly at $234-235^\circ$; the latter is an oil, which dissolves in dilute hydrochloric acid, and furnishes a platinum-chloride, $(C_{16}H_{13}N)_2 \cdot H_2PtCl_6 + 1\frac{1}{2}H_2O$, which, after recrystallisation from water, melts at 229° , and a crystalline picrate which commences to sinter at 198° , and melts at $209-210^\circ$. G. T. M.

Strychnine. By C. STOEHR (*J. pr. Chem.* [2], 42, 399-415).—Most of the analyses of strychnine which have been made agree with the formula $C_{21}H_{22}N_2O_2$. The author has prepared and analysed strychnine hydrochloride (with $1\frac{1}{2}$ mols. H_2O), of which he gives crystallographical measurements, and its platinumchloride; also strychnine hydrobromide (with 1 mol. H_2O) and hydriodide (with 1 mol. H_2O); his analyses confirm the above formula for strychnine and the generally accepted formulæ for these salts. Pure commercial strychnine melted at $265-266^\circ$; by converting this into the hydrochloride, reconvertng the latter into strychnine, crystallising from alcohol, and pulverising the crystals, a light powder was obtained which darkened at 260° , and was a dark brownish-yellow liquid at 269° . Claus and Glassner give the melting point of strychnine as 284° (Abstr., 1881, 747); Beckurts as 285° (uncorr., Abstr., 1885, 675); Loebish and Schoop as 268° (*Monatsh.*, 6, 558); Beckurts as 265° (Abstr., 1890, 1328); and Garzarolli-Thurnlackh as 262° (*Monatsh.*, 10, 1).

The author has again investigated the distillation of strychnine with lime (compare Abstr., 1887, 604, 682; 1888, 63), and has again found that hydrogen, ethylene, ammonia, ethylamine, scatole, β -picoline, and, probably, ethylpyridine are produced. As the β -picoline thus obtained seems to be identical with that obtained from other sources, it may be allowed that all β -picolines at present known are identical, whatever their source (compare Ladenburg, Abstr., 1890, 1432).

To obtain trichlorostychnine (Abstr., 1887, 604) dry, powdered strychnine hydrochloride is heated with phosphoric chloride (4-5 parts) and chloroform in a reflux apparatus on the water-bath as long as hydrogen chloride is evolved; water is then added, and the chloroform distilled off; ammonia is added, the liquid extracted with ether, and the ether residue crystallised from alcohol containing hydrochloric acid. It gives much the same reaction as strychnine with potassium dichromate and sulphuric acid, and a similar colour with nitric and sulphuric acids.

When an excess of phosphoric chloride (7-8 parts) is used, a

higher chlorinated derivative is obtained; after distilling off the chloroform, an insoluble mass is left which is extracted with benzene. This derivative crystallises in long, slender, colourless needles when absolute alcohol is added to the hot benzene solution; its composition is in approximate agreement with a pentachlorostrychnine; it darkens and melts at 224° ; it does not give the same reaction as trichlorostrychnine with nitric and sulphuric acids. A. G. B.

Brucine. By L. BEREND and C. STOEHR (*J. pr. Chem.*, **42**, 415—420).—De Coninck (Abstr., 1882, 739) distilled brucine with potash, but obtained no homologues lower than lutidine.

The gaseous products of the distillation of brucine with slaked lime were hydrogen, ammonia, and ethylene. The distillate was at first a colourless liquid with a yellow oil suspended in it, but it rapidly became brownish-red in air; it was acidified with hydrochloric acid and distilled in steam, whereby a few drops of scatole were obtained, but the bulk of the liquid did not distil. The liquid was shaken with ether, and then solid potash was added to it until all the oily bases had separated; these were then dissolved in ether. The aqueous liquid contained ammonia and methylamine, while the bases in the ethereal solution were found to be mainly β -picoline and a lutidine, probably β -ethylpyridine, together with smaller quantities of other pyridine bases; quinoline bases were absent. The β -picoline boiled at 142 — 143° , and was identical with that obtained from strychnine (previous abstract); its sp. gr. at $0^{\circ}/4^{\circ}$ was 0.9756 (Zanoni, 0.9771).

A. G. B.

Alkaloids of Veratrum album. By C. PEHKSCHEN (*J. Pharm.* [5], **22**, 265—269; from *Pharm. Zeit. Russ.*, **29**, 339).—The rhizome of the wild plant gives 0.57 to 0.66 per cent. of mixed alkaloids, whilst the cultivated rhizome yields only 0.29 per cent. The powdered root is macerated with alcohol during six days at the ordinary temperature, and this repeated a second and third time, the last time with the addition of acetic acid. The first alcoholic extract is faintly acid from the presence of jervic acid. The alcoholic solutions are united, and the major portion of the alcohol is removed by distillation under reduced pressure; on the addition of 3 to 4 vols. of boiling water, resinous substances are precipitated, which are removed by filtration. The remaining resinous and colouring matters are removed by agitation with ether. Hydrogen sodium carbonate is then added to alkaline reaction, then ether, and subsequently chloroform. When the ether and chloroform solutions are evaporated, the mixed alkaloids are left, and these on being treated with absolute ether, give veratrodine and a minute amount of jervine in solution, whilst the insoluble portion contains jervine and a third alkaloid, pseudojervine. *Veratrodine*, $C_{22}H_{33}NO_9$, melts about 149° , and chars about 172° . It is optically inactive. At 22.5° , 1 part dissolves in 13 parts of benzene, 5.9 of chloroform, and 9.09 of absolute ether. It dissolves in alcohol in almost all proportions. Veratrodine yields amorphous salts with hydrochloric, hydrobromic, sulphuric, nitric, oxalic, and acetic acids. Most of the general reagents for alkaloids give with this base more or less of a precipitate, according to the

state of concentration. A hydrochloric solution of 1 : 5000 gives a faint turbidity with mercury potassium iodide, and a solution of 1 : 3500 a turbidity with phosphomolybdic acid. With concentrated sulphuric acid, veratroidine gives a yellow liquid which passes through orange-red to cherry-red, with a green fluorescence, whilst concentrated nitric acid produces a transient rose colour which soon passes to citron-yellow. Hydrochloric acid (11.0 per cent. is best) gives a beautiful rose coloration; this serves to distinguish veratroidine from veratrine. Veratroidine, when heated at 120° with ethyl iodide in a sealed tube for 40 hours, yields the compound $C_{25}H_{33}NO_3 \cdot 2EtI$. *Pseudo-jervine*, $C_{25}H_{33}NO_3$, forms large, rhombic crystals. The root does not contain more than 0.006 per cent. The alkaloid begins to turn yellow at 215° , and melts at 259° with blackening. It is optically inactive. At 22° , 1 part of this base dissolves in 10.876 parts of light petroleum, in 372 parts of benzene, 1021 parts of absolute ether, 4.1 of chloroform, and 184.8 of absolute alcohol. With phosphomolybdic acid, a solution of 1 : 10,000 gives a perceptible turbidity; but with mercury potassium iodide, the dilution should not exceed 1 : 6000. The pure base gives no colour with either hydrochloric, nitric, or sulphuric acids, the latter mixed with sugar or with other reagent. When mixed with minute quantities of jervine, it gives the coloration reactions described as characteristic of it by Wright and Luff. *Jervine*, $C_{14}H_{22}NO_3$, crystallises from a boiling alcoholic solution in beautiful white needles. It melts at 237.7° , and is slightly levorotary. At 25° , 1 part of the base dissolves in 1658 parts of benzene, in 268 parts of absolute ether, in 60 of chloroform, and 16.8 parts of absolute alcohol. The base is insoluble in light petroleum, and very slightly soluble in ethyl acetate, water, and carbon bisulphide. Beautiful rhombic crystals of the normal hydrochloride, with 2 mols. H_2O , are obtained by mixing an alcoholic solution of the base with an alcoholic solution of hydrogen chloride; sulphuric acid gives an acid salt under the like conditions. Jervine is characterised by the violet coloration, passing to blue, which it gives with sulphuric acid and sugar; veratroidine, with this test, gives a brown coloration.

J. T.

Benzyl Derivatives of Piperidine, Tetrahydroquinoline, and Pyridine. A New Method of Formation of Benzyleneimides. By E. LELLMANN and H. PEKRUN (*Annalen*, 259, 40—61).—*Paranitrobenzylpiperidine*, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot C_5NH_{10}$, is obtained when piperidine is gradually treated with paranitrobenzyl chloride in well-cooled alcoholic solution, the mixture then boiled for about an hour, and the hydrochloride thus produced decomposed with water. It crystallises from light petroleum in large, amber-coloured plates, melts at 34° , and is very readily soluble in mineral acids and most organic solvents, but only sparingly in water. The *hydrochloride*, $C_{12}H_{18}N_2O_2 \cdot HCl$, crystallises from hot alcohol in light-brown prisms, melts at 236° , and is readily soluble in water, but insoluble in ether, benzene, and light petroleum. The *platinochloride*, $(C_{12}H_{18}N_2O_2)_2 \cdot H_2PtCl_6$, is a yellow, amorphous, unstable compound.

Paramidobenzylpiperidine, $C_{12}H_{18}N_3$, is formed when the preceding

compound is reduced with tin and hydrochloric acid; the product is distilled with steam and recrystallised from hot light petroleum, from which it separates in colourless needles melting at 87° . It is readily soluble in most ordinary solvents except water. The *hydrochloride*, $C_{12}H_{18}N_2 \cdot 2HCl$, crystallises in yellow needles and is very readily soluble in water.

Dimethylanilineazobenzylpiperidine, $NMe_2 \cdot C_6H_4 \cdot N_2 \cdot C_6H_4 \cdot CH_2 \cdot C_5NH_{10}$, is produced when a solution of paramidobenzylpiperidine in well-cooled concentrated hydrochloric acid is treated first with sodium nitrite, and then with dimethylaniline. It crystallises from alcohol in golden needles, melts at 109° , and dissolves in dilute acids, yielding a dark-violet solution, the colour of which changes to yellow on the addition of water; it is readily soluble in the ordinary organic solvents, but only sparingly soluble in water. The *hydrochloride* crystallises from alcohol in small, bluish-black needles, and its aqueous solution imparts to silk and wool a yellow coloration.

Paramidochlorobenzylpiperidine, $NH_2 \cdot C_6H_3Cl \cdot CH_2 \cdot C_5NH_{10}$, is obtained, mixed, however, with paramidobenzylpiperidine, when the brown light petroleum mother liquors obtained in the purification of the last-named compound are evaporated; it can be purified by converting it into the *hydrochloride*. It crystallises from light petroleum in colourless needles melting at $76-76.5^{\circ}$. The *hydrochloride*, $C_{12}H_{17}ClN_2 \cdot 2HCl$, forms yellow, well-defined, transparent crystals.

Orthonitrobenzylpiperidine, $C_{12}H_{16}N_2O_2$, prepared as described in the case of the corresponding para-compound, is a thick, yellow oil having an odour recalling that of piperidine; it is soluble in mineral acids and most ordinary organic solvents. The *hydrochloride*, $C_{12}H_{16}N_2O_2 \cdot HCl$, separates from hot alcohol in well-defined, yellowish-green, transparent crystals, sinters together at 124° , and melts completely at 209° . The *platinochloride*, $(C_{12}H_{16}N_2O_2)_2 \cdot H_2PtCl_6$, is a yellow, amorphous compound.

Orthamidobenzylpiperidine, $C_{12}H_{18}N_2$, crystallises from hot light petroleum in almost colourless, rhombic plates, melts at 82.5° , and is readily soluble in mineral acids, alcohol, benzene, &c., but more sparingly in water.

Metanitrobenzylpiperidine, $C_{12}H_{16}N_2O_2$, is an oil, and resembles the isomerides described above in its behaviour with solvents. The *hydrochloride* separates from alcohol in yellow, rhombic crystals. The *platinochloride*, $(C_{12}H_{16}N_2O_2)_2 \cdot H_2PtCl_6$, is yellow and amorphous.

Metamidobenzylpiperidine, $C_{12}H_{18}N_2$, crystallises from light petroleum in colourless needles, and melts at 112° .

Paranitrobenzyltetrahydroquinoline, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot C_5NH_{10}$, can be obtained by heating paranitrobenzyl chloride (1 mol.) with tetrahydroquinoline (2 mols.) for 1 to 2 hours in alcoholic solution, and decomposing the salt thus produced, with water; it crystallises from hot alcohol or ether in long, bright-red prisms melting at 102° . The *platinochloride*, $(C_{12}H_{16}N_2O_2)_2 \cdot H_2PtCl_6$, is a sparingly soluble, yellowish-red compound. The corresponding ortho-compound crystallises in brownish-red plates, melts at 111° , and forms a yellow, amorphous *platinochloride*. The *meta-base* crystallises from alcohol in short, red prisms, melts at 99° , and is only moderately easily soluble in ether,

cold alcohol, chloroform, and dilute acids. The three nitrobenzyl-tetrahydroquinolines are only feeble bases, and their hydrochlorides are decomposed by water; they give König's reaction for tetrahydroquinoline with oxidising agents, and on reduction they yield the corresponding amido-compounds, of which the meta-derivative, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{NC}_6\text{H}_5$, is crystalline, and melts at 82° .

Paranitrobenzylpyridine chloride, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}_2\cdot\text{C}_5\text{NH}_5\text{Cl}$, is formed when paranitrobenzyl chloride is warmed with excess of pyridine. It crystallises from alcohol in yellow prisms, sinters together at about 90° , melts at about 103° , and is readily soluble in water, alcohol, benzene, and mineral acids, but only very sparingly in ether and light petroleum. The *platinochloride*, $(\text{C}_{12}\text{H}_{11}\text{N}_2\text{O}_2\text{Cl})_2\cdot\text{PtCl}_6$, crystallises from dilute hydrochloric acid in golden plates, and melts at 220 — 223° with decomposition.

Paramidobenzylpyridine chloride hydrochloride, $\text{C}_{12}\text{H}_{13}\text{N}_2\text{Cl}\cdot\text{HCl}$, is obtained in yellow crystals when the nitro-compound is reduced with tin and hydrochloric acid. It melts at 183 — 185° , decomposes at 200 — 202° , and is only sparingly soluble in alcohol. When treated with alkalis, it yields a yellowish, resinous compound which does not melt below 280° , and when heated at 210 — 220° it is decomposed into the hydrochlorides of pyridine and parabenzyleneimide. The *platinochloride*, $(\text{C}_{12}\text{H}_{13}\text{N}_2\text{Cl})_2\cdot\text{H}_2\text{PtCl}_6$, is crystalline.

Ortho-nitrobenzylpyridine chloride, $\text{C}_{12}\text{H}_{11}\text{N}_2\text{O}_2\text{Cl}$, prepared by heating pyridine with ortho-nitrobenzyl chloride, crystallises from alcohol and ether in yellowish prisms, melts at about 76° , and gradually decomposes at a higher temperature; it resembles the corresponding para-compound in its behaviour with solvents. The *platinochloride*, $(\text{C}_{12}\text{H}_{11}\text{N}_2\text{O}_2\text{Cl})_2\cdot\text{PtCl}_6$, crystallises in yellow scales.

Orthamidobenzylpyridine chloride hydrochloride, $\text{C}_{12}\text{H}_{13}\text{N}_2\text{Cl}\cdot\text{HCl}$, is a colourless, semi-crystalline powder, which melts at about 169° and decomposes at a higher temperature, yielding orthobenzyleneimide; the last-named compound is a reddish-brown powder which does not melt below 290° .

Metanitrobenzylpyridine chloride, $\text{C}_{12}\text{H}_{11}\text{N}_2\text{O}_2\text{Cl}$, crystallises from alcoholic ether in yellow needles, sinters together at 60° , and melts completely at 100° . The *platinochloride*, $(\text{C}_{12}\text{H}_{11}\text{N}_2\text{O}_2\text{Cl})_2\cdot\text{PtCl}_6$, crystallises in small, yellow needles. *Metamidobenzylpyridine chloride hydrochloride*, $\text{C}_{12}\text{H}_{13}\text{N}_2\text{Cl}\cdot\text{HCl}$, is a colourless powder which melts at about 220° with decomposition.

Metabenzyleneimide, $\text{C}_6\text{H}_4\langle\begin{smallmatrix} \text{NH} \\ \text{CH}_2 \end{smallmatrix}\rangle$, is obtained, together with pyridine hydrochloride, when the preceding compound is heated at 230° ; it is a yellow, amorphous powder melting at 120 — 145° . The *platinochloride* has the composition $(\text{C}_7\text{H}_7\text{N})_2\cdot\text{H}_2\text{PtCl}_6$. Molecular weight determinations by Raoult's method gave results which showed that parabenzyleneimide is probably a polymeride of a compound of the molecular formula $\text{C}_7\text{H}_7\text{N}$.
F. S. K.

Tropidine. By A. EINHORN (*Ber.*, 23, 2889—2894).—By the action of aqueous hypochlorous acid on tropidine, two compounds are formed, and may be separated by recrystallisation from dilute

alcohol; the one is deposited in long, lustrous prisms which melt at 138° ; the second is more soluble, separates in white, nodular crystals melting at $108-109^{\circ}$, and has the formula $C_8H_{13}N_2HOCl$.

On heating tropidine with a glacial acetic acid solution of hydrobromic acid in a sealed tube at 100° , the salts of two isomeric hydrobromotropidine hydrobromides are formed, and may be separated by crystallisation from alcohol; the more insoluble is termed the α -compound, and the second the β -compound. *α -Hydrobromotropidine hydrobromide*, $C_8H_{14}NBr \cdot HBr$, is obtained as the chief product if the heating is continued for 70 hours; it is very soluble in water, and crystallises in transparent prisms which melt at $219-220^{\circ}$. The free base is liberated by the action of aqueous soda. *β -Hydrobromotropidine hydrobromide*, $C_8H_{14}NBr \cdot HBr + H_2O$, is formed if the reaction is allowed to proceed for only 24 hours; it crystallises from alcohol in lustrous, prismatic needles melting at $113-114^{\circ}$; on heating to 105° , the anhydrous compound is obtained, which differs, however, from the α -derivative. The free base is formed by the action of alkalis; on treating it first with anhydrous sodium acetate and then with aqueous soda, a small quantity of a base is obtained which yields a *platinochloride* melting at 200° ; tropine platinochloride melts at the same temperature. The author suggests that the compound prepared by Ladenburg (compare Abstr., 1890, 1167), by the action of hydrobromic acid on tropidine at low temperatures, is really identical with β -hydrobromotropidine.

Tropidine dibromide, $C_8H_{12}NBr_2$, is prepared by treating a glacial acetic acid solution of tropidine with excess of bromine dissolved in the same medium; the oil which separates is washed with sulphurous acid; on the addition of potassium carbonate, the dibromide separates. On adding water to the alcoholic solution, it crystallises out in small, lustrous plates which melt at $66-67.5^{\circ}$ with previous softening. On boiling the dibromide with dilute sodium hydroxide solution, a penetrating, aromatic odour is produced which greatly resembles that of dihydrobenzaldehyde (compare this vol., p. 67). J. B. T.

Aconitine. By A. LURBE (*Chem. Centr.*, 1890, ii, 148—149; from *Apoth. Zeit.*, 5, 321).—From the tubers of the Japanese plant *Kusa-uzu*, the author has extracted, by means of Duquesnel's method, an alkaloid of the formula $C_{33}H_{47}NO_{12}$, which he considers to be identical with the alkaloid obtained from *Aconitum napellus*. Wright's formula for aconitine is $C_{33}H_{47}NO_{12}$, whilst that of Jürgens is $C_{33}H_{47}NO_{13}$.

Aconitine forms radially fibrous groups of crystals of the rhombic system. The crystals measured by the author had the following faces:—Obtained from the cold saturated solution, $\infty P\infty$, ∞P , OP ; from the hot saturated solution, ∞P , $\infty P\infty$, OP , $P\infty$, P . At 110° , it is partially decomposed; it melts at $183-184^{\circ}$; $[\alpha]_D -34.46$. The taste is not bitter, but prickly and burning. The most delicate reagents for aconitine are hydrogen iodide and potassium mercury iodide. The hydriodide, even when present in very small quantity (0.02 milligram), appears crystalline under the microscope. Pseudo-aconitine could not be detected. The author finds that aconitine has the same physiological properties as are ascribed to it by Lewins,

acting on the extremities of certain nerves. It does not appear itself to undergo any change, nor does it in any way decompose the blood corpuscles.

From the tubers of Langaard's variety, "*Shirakawauzuware*" of *Aconitum sinense*, the author obtained 0.02 per cent. of a crystalline alkaloid and two amorphous bases. He considers the alkaloid to be identical with aconitine from *Aconitum napellus*; it melts at 180.9° . Pseudoaconitine could not be detected. J. W. L.

Hydrastine. By M. FREUND and M. HEIM (*Ber.*, 23, 2897—2910).—It has previously been shown (Abstr., 1890, 532) that alkylhydrastines are formed by the action of alkalis on the additive compounds of hydrastine and alkyl haloids; aqueous ammonia reacts in a similar manner in the cold, but on boiling an alcoholic solution of hydrastine methiodide with concentrated aqueous ammonia, a compound is obtained crystallising from alcohol in white, strongly refractive, rhombic plates which melt at 180° , are almost insoluble in water, and dissolve sparingly in ether, carbon bisulphide, or benzene. The substance is a powerful base, and decomposes ammonium salts; it has the formula $C_{22}H_{26}N_2O_6$, and the author proposes to term it *methylhydrastamide*. It may also be obtained by the action of ammonia on methylhydrastine. The salts of the amide are somewhat difficult to prepare, as they readily part with the elements of water. The *picrate* crystallises from alcohol in small, yellow needles. The *hydrochloride*, $C_{22}H_{26}N_2O_6 \cdot HCl + 2H_2O$, is deposited in white needles which melt at $116-118^{\circ}$.

Methylhydrastimide, $C_{22}H_{24}N_2O_5$, is prepared by the action of dilute acids, or of concentrated potassium hydroxide solution, on the amide; it crystallises from alcohol in slender, light-yellow needles which melt at 192° , and are insoluble in water. The *hydrochloride*, $C_{22}H_{24}N_2O_5 \cdot HCl$, crystallises from absolute alcohol in slightly yellow needles which melt at 227° ; a hydrated salt melting at $110-120^{\circ}$ may also be obtained. The *platinochloride* crystallises from hydrochloric acid in brown rhombohedra melting at 205° with decomposition. The *sulphate* is deposited from alcohol in yellow crystals which melt at 218° . The *nitrate*, $C_{22}H_{24}N_2O_5 \cdot HNO_3 + H_2O$, crystallises in slender needles which decompose at about 230° .

Hemipinimide, $C_8H_2(OMe)_2 <\begin{smallmatrix} CO \\ CO \end{smallmatrix}>NH$, is formed by the oxidation of methylhydrastamide with dilute nitric acid.

Ethylhydrastamide, $C_{24}H_{30}N_2O_6$, is prepared by the action of ammonia on hydrastine ethiodide, and is more readily soluble in alcohol than the methyl derivative; it crystallises in rhombic plates which melt at 140° .

Ethylhydrastimide, $C_{24}H_{28}N_2O_5$, is obtained on treating the amide with dilute acids; it crystallises from alcohol in rhombohedra which melt at $150-151^{\circ}$.

Methylhydrastimide methiodide, $C_{22}H_{24}N_2O_5 \cdot MeI + 1\frac{1}{2}H_2O$, is formed by the action of methyl iodide on methylhydrastamide or methylhydrastimide; it crystallises from water in yellow, flat rhombohedra which melt at $240-245^{\circ}$.

The action of amines on the additive compounds of hydrastine and alkyl haloids is strictly analogous to that of ammonia itself. *Methylhydrastomethylamide*, $C_{23}H_{26}N_2O_6$, is prepared by heating hydrastine methiodide with an alcoholic solution of methylamine in a sealed tube at 100° ; it crystallises from alcohol in white rhombohedra melting at 182° , and is not acted on by concentrated aqueous potash. The *hydrochloride* crystallises from alcohol in white needles which melt at 193° . Hemipinomethylimide is formed by the oxidation of the base with dilute nitric acid. *Methylhydrastethylamide*, $C_{24}H_{30}N_2O_6$, is obtained by digesting hydrastine methiodide with an alcoholic solution of ethylamine for several days; it forms white crystals which melt at 162° , and yields hemipinethylimide on oxidation. *Methylhydrastisoamylamide*, $C_{27}H_{36}N_2O_6$, is deposited from alcohol in long, slender crystals which melt at 171° . On heating this compound with a large excess of dilute hydrochloric acid, *methylhydrastisoamylimide* is formed as an oily liquid; the *platinochloride* is a yellow, crystalline powder. *Methylhydrastallylaniide*, $C_{25}H_{30}N_2O_6$, crystallises from alcohol, and melts at 158° . By the action of dilute hydrochloric acid, the corresponding *imide* is obtained as a viscid liquid which yields a crystalline *platinochloride*. In the authors' opinion, the above results all tend to confirm the second of the formulæ proposed for methylhydrastine (*loc. cit.*); the action of ammonia on methylhydrastine is therefore represented as being strictly analogous to its action on benzyldenephthalide; methylhydrastamide and methylhydrastimide would consequently be represented by the formulæ

Hydrastine. By M. FREUND and A. PHILIPS (*Ber.*, 23, 2910—2917; compare preceding abstract).—*Hydrastine allyl iodide*,

is prepared by treating an alcoholic solution of hydrastine with excess of allyl iodide; it crystallises from water or dilute alcohol in small, white needles which melt at 193° . By the action of potassium hydroxide (1 mol.) on this compound, *allylhydrastine*, $\text{C}_{24}\text{H}_{28}\text{NO}_6$, is formed, crystallising from alcohol and ether in deep-yellow needles which melt at 116° . *Allylhydrastene*, $\text{C}_{24}\text{H}_{28}\text{NO}_7 + \frac{1}{2}\text{H}_2\text{O}$, is prepared by boiling allylhydrastine with concentrated aqueous potash, and is deposited from water in white crystals which melt at 136° . *Allylhydrastamide*, $\text{C}_{24}\text{H}_{28}\text{N}_2\text{O}_6$, is formed by the prolonged action of aqueous ammonia on an alcoholic solution of hydrastine allyl iodide; it may be recrystallised from dilute alcohol, and melts at 156° . *Allylhydrastimide*, $\text{C}_{24}\text{H}_{28}\text{N}_2\text{O}_6$, is prepared by the action of dilute acids, or of concentrated aqueous potash, on the amide; it is deposited from dilute alcohol in pale-yellow crystals which melt at 139° . The

hydrochloride is obtained from alcohol in pale-yellow crystals melting at 211° . The *sulphate* crystallises from dilute alcohol in small, deep-yellow, slender needles which melt at 235° . *Allylhydrastimide allyl iodide*, $C_{27}H_{31}N_2O_4I$, is formed by the action of allyl iodide on allylhydrastamide or allylhydrastimide; it crystallises from dilute alcohol, and melts at 207° . On boiling this compound with concentrated aqueous potash, diallylamine is eliminated, and a substance of the formula $C_{26}H_{17}NO_5$ is formed, to which it is proposed to apply the term *hydrastophthalimidine*; it is deposited in deep-yellow crystals which melt at 226° , and is strictly analogous to the compounds previously described (*loc. cit.*). *Dibromohydrastophthalimidine*, $C_{26}H_{17}NO_5Br_2$, is prepared by treating the preceding compound with bromine (2 mols.); and on the addition of light petroleum to its benzene solution, it crystallises in pale-yellow plates melting at 158° .

The constitution of the above compounds corresponds with that of the derivatives previously described (*loc. cit.*). J. B. T.

Hydrobromanhydroecgonine. By A. EICHENGRÜN and A. EINHORN (*Ber.*, 23, 2888).—Anhydroecgonine hydrochloride is heated at 100° for 6—7 days with five parts of a solution of hydrogen bromide in glacial acetic acid, saturated at 0° . The product is allowed to crystallise, and the crystals treated with hot water; on cooling, *hydrobromanhydroecgonine hydrobromide*, $C_8H_{14}NO_2Br \cdot HBr$, is deposited in strongly refractive prisms which melt at 250° with decomposition, and are very sparingly soluble in water, alcohol, or glacial acetic acid. J. B. T.

Alkaloids of the Areca Nut. By E. JAHNS (*Ber.* 23, 2972—2978).—The author has previously described the preparation of the two alkaloids, *arecoline*, $C_8H_{13}NO_2$, and *arecaine*, $C_7H_{11}NO_2$, from the areca nut (*Abstr.*, 1889, 420), and mentioned also a third substance, obtained in small quantity, the nature of which could not then be ascertained. Further investigation has shown that this compound is choline, which was identified by its *platinochloride*. The latter crystallises from water in orange-red, anhydrous, monosymmetric plates, and not as stated by Hundeshagen (*J. pr. Chem.* [2], 28, 246), in rhombic crystals. The statement of the latter, that the platinochloride crystallises from dilute alcohol in anhydrous, yellow octahedra is also partially incorrect, as the crystals thus obtained contain 1 mol. H_2O . The anhydrous compound melts with evolution of gas at 225° . *Choline aurochloride* melts at 244 — 245° .

When arecoline is heated in a sealed tube with hydrochloric acid, or boiled with hydriodic acid, potash, or baryta-water, a methyl group is eliminated, and a new compound having the composition $C_7H_{11}NO$, obtained. This is isomeric with arecaine, and may therefore be termed *arecaine*. It is most readily prepared by means of baryta-water or hydriodic acid, and crystallises from 60—70 per cent alcohol in colourless, four- or six-sided plates which contain 1 mol. H_2O . It loses the latter at 100° , and then melts with evolution of gas at 222 — 223° , and carbonises on further heating. It is readily soluble in water and dilute alcohol, almost insoluble in absolute alcohol, ether, chloroform, and benzene. Its solution is coloured red by a

trace of ferric chloride, and, like arecaine, which it closely resembles in other respects, it is not poisonous.

Its *platinochloride*, $(C_7H_{11}NO_2)_2 \cdot H_2PtCl_6$, crystallises in yellow octohedra which melt at $208-209^\circ$ with evolution of gas, and the *aurochloride*, $C_7H_{11}NO_2 \cdot HAuCl_4$, forms four-sided prisms which melt at $197-198^\circ$.

If finely divided arecaine be suspended in methyl alcohol, and the latter saturated with hydrogen chloride, arecoline is re-formed. If ethyl alcohol be substituted for methyl alcohol, *arecaine ethyl ether*, or *homarecoline*, $C_9H_{15}NO_2$, is obtained; this is a colourless, strongly alkaline liquid, miscible with water, alcohol, and ether, distils without decomposition, is volatile with steam, and has poisonous properties very similar to those of arecoline. Its *hydrochloride* crystallises in very hygroscopic needles which deliquesce in the air. The other salts are also deliquescent, and cannot be obtained in crystals. The *picrate* is an amorphous resinous mass, and the *aurochloride* an oily liquid, sparingly soluble in cold, readily in hot water. The *platinochloride* forms an orange-red, amorphous mass which has the composition $(C_7H_{11}NO_2)_2 \cdot H_2PtCl_6$, and commences to decompose at 100° .

The above reactions show that arecaine is a monobasic acid, and that both oxygen atoms are present as carboxyl. This is confirmed by the fact that no acetyl derivatives of arecaine can be obtained, which should be readily formed if the oxygen were present as hydroxyl. The formula for arecoline may therefore be partially resolved into $C_6H_{10}N \cdot COOMe$. Experiments to determine the composition of the group $C_6H_{10}N$ are now in progress. H. G. C.

Action of Sulphurous Anhydride on Flour. By — BALLAND (*J. Pharm.* [5], 22, 241—244).—The gluten of flour which has been acted on by sulphurous anhydride loses its cohesion, so that, in place of 28—30 per cent., not more than 6 or 7 per cent. can be obtained by the ordinary process of washing, the remainder passing away with the wash water. The gluten is simply modified, not destroyed, as the flour retains its nutritive properties. Sulphuric and sulphurous acids, and alkaline sulphides, all affect gluten in this way, whilst certain compounds, such as sodium chloride, alum, and copper sulphate, favour the aggregation of gluten. Perfectly sound and good bread can be made from the sulphurised flour by mixing with fresh flour and increasing the proportion of salt and yeast. Biscuit made from the defective flour is quite good. J. T.

Formation of Carbamide from Albumin. By E. DRECHSEL (*Ber.*, 23, 3096—3102).—The author has previously shown that a mixture of several bases is obtained by boiling casein with concentrated hydrochloric acid and stannous chloride; the nitrate of one of these bases forms with silver nitrate an additive compound of the formula $C_6H_{11}N_3O_2 \cdot HNO_3 \cdot AgNO_3$, as the salt probably contains a molecule of water of crystallisation; the base, which the author terms *lysatine* or *lysatinine*, is homologous with creatinine or with

creatine, and, like the latter, it yields carbamide on boiling with baryta-water. The author points out the physiological importance of his observations, which prove, for the first time, that carbamide may be obtained from albumin by simple hydrolytic processes.

Physiological Chemistry.

Influence of Bile on Pancreatic Digestion. By S. MARTIN and D. WILLIAMS (*Proc. Roy. Soc.*, 48, 160—165).—In a previous communication (*Abstr.*, 1888, 618), it has been pointed out that in the pig the presence of bile or bile salts hastens the action of the pancreatic juice on starch. The same holds good for these secretions in oxen and in the human subject. Investigations made with certain constituents of the bile and related substances gave the following results:—Sodium taurocholate hastens the pancreatic digestion of starch; glycocholic acid arrests it; sodium glycocholate acts like the taurocholate; glycocine has no effect; leucine and tyrosine both hinder the digestion to a slight extent; sodium carbonate, when present in the proportion of 0.25 per cent. and over, retards the digestion of starch by pancreatic extract; but this retardation can be, to a certain extent, neutralised by the addition of bile salts.

In another series of experiments, it was found that the power of bile to hasten pancreatic digestion is not limited to amylolytic digestion, but that it is equally, if not more, marked in its influence on proteolytic digestion. This property is due to the bile salts present; the action of the sodium glycocholate was found, however, to be less effective than the bile salts as a whole.

W. D. H.

Action of Nicotine on the Heart and Blood-vessels. By E. COLAS (*Compt. rend. Soc. Biol.* [9], 11, 31—33).—Experiments were made on dogs in which small doses of nicotine, dissolved in water, were injected into the femoral vein. Blood pressure was taken from the carotid artery. At first the pressure falls and the heart beats irregularly; the pressure returns to the normal level, then rises above it; the heart beats are very small and very rapid; it gradually slows, however, till the normal is re-established. This action is considered to be due to the action of the drug on the intracardiac nerve centres; the acceleration is, however, probably due to its action on the cardiac muscle. It was also noted that a rise of venous pressure occurs simultaneously with that in the arterial system. The rise of pressure is probably due to the increased tonicity of the heart, as the drug stimulates the vaso-dilatator nerves, producing increased redness of the organs.

W. D. H.

Pigments of the Aplysiæ. By R. SAINT-LOUP (*Compt. rend. Soc. Biol.* [9], 11, 116—117).—The green pigment of the liver of this

marine mollusc can be extracted from the organ by alcohol. The extract has an intense green colour, and shows spectroscopically the bands of chlorophyll. After saponification with lime, ether or chloroform dissolves out a yellow pigment, the residue being green. The origin of the pigment is believed to be the food (Algæ) of the animal. The pigment is absent in young *Aplysiæ* which had never fed, and gradually diminishes in those allowed to die of starvation.

W. D. H.

Liquids from Hydatid Cysts. By ROESER (*J. Pharm.* [5], 22, 244—249).—The contents of a cyst, examined in 1888, measured about 1100 c.c. The liquid was slightly opaline, faintly alkaline, and had a sp. gr. of 1·0075. The solid residue of 14·7 grams per litre, on calcination, yielded 9·30 grams of ash which contained—sodium chloride, 6·95 grams; sodium phosphate, carbonate, sulphate, 0·71 gram; calcium phosphate, sulphate, and carbonate, 1·26 grams; iron, magnesia, and loss, 0·38 gram. The organic matter, corresponding with 5·40 grams per litre, consisted of—albumin, precipitated by heat and acetic acid, 1·060 gram; glucose, 0·585; fatty matter, soluble in ether, 0·260; urea, 0·500; colouring matter of bile, peptone, extractives, 2·995 grams. The nature of these extractive substances has not been clearly determined, although the liquids of cysts have been frequently investigated. Numerous authors are quoted to show that the composition of the liquids is extremely variable.

J. T.

Lanolin and the Detection of Cholesterin Fats in Man. By O. LIEBERMANN (*Chem. Centr.*, 1890, ii, 149—150; from *Arch. Physiol.*, 1890, 363—365).—In studying the question of the presence of cholesterin and similar fats in the animal epidermis, the author has applied Liebermann's cholestol reaction with acetic anhydride and concentrated sulphuric acid, and also the property which cholesterin fats have of emulsifying with water to the extent of 200 per cent. In this way, cholesterin fats were found on human skin and hair, the feathers and beaks of birds, and the hoofs of horses.

In addition to the Liebermann's test already mentioned, the author has used a modification in which chloroform is used, and which is a much more delicate test.

Further, a separation of the cholesterin fats has been effected by the author, by treating them with hot ethyl acetoacetate or ethyl ethylacetoacetate, which dissolve cholesterin much more freely than lanolin. Lanolin was found in human vernix caseosa.

J. W. L.

Composition of the Milk of Cows during Early and Late Periods of Lactation. By M. KÜHN (*Bied. Centr.*, 19, 622—628; from *Milchzeit.*, 18, 922—926).—Experiments were made with cows in early and late periods of lactation, in order to determine the difference in the amount and quality of the milk with cows of the same kind, and of about the same weight, under the same conditions as to feeding. The results show that considerably more milk is produced in early than in late periods, but that the milk of the latter contains rather more dry matter, fat and protein, than that of the former. The amount of ash and lactic acid is about the same in both

cases. In the late period, the amount of dry substance, milk-sugar, and fat, varies more than in the early period, when the reverse was observed, but in less degree, regarding the other constituents.

N. H. J. M.

Elephant's Milk. By C. A. DOREMUS (*Chem. Centr.*, 1890, ii, 209; from *Meierei. Tübing. Milchstg.*, 1890, 227).—The following analyses have been made:—

	April 5th, morning.	April 9th, midday.	April 10th, morning.
Water	67.567	69.286	66.697
Total solids	32.433	30.713	33.303
Fat	17.546	19.095	22.080
Solids not fat	14.887	11.619	11.233
Casein	14.236*	8.694	2.212
Sugar	14.236	7.267	7.392
Mineral matter	0.651	0.658	0.629

The milk has a pleasant taste and smell, and resembles that of the cow; no unpleasant odour is produced on warming it.

J. W. L.

The Passage of Naphthol into the Urine. By E. DESSESQUELLE (*Compt. rend. Soc. Biol.* [9], 11, 101—104).—Naphthol is sometimes employed as an inunction in cases of psoriasis. After its use it can be detected as such in the urine. The residue of the ethereal extract of urine, dissolved in chloroform, treated with soda and then with sulphuric acid, gives the green coloration described by Gautrelet (*Traité d'analyse urologique*, 1889) as characteristic of naphthol. Its extreme insolubility renders its absorption slow as a rule, and this property also justifies Bouchard's selection of the drug in cases where it is necessary to keep up prolonged antisepsis.

W. D. H.

Uro-phosphates and Hippuro-phosphates. By GAUBE (*Compt. rend. Soc. Biol.* [9], 11, 404—405).—The salts of uric and hippuric acids in the urine are considered to be double salts composed of two acids united to the same base, and thus so-called uro-phosphates and hippuro-phosphates of sodium, potassium, calcium, &c., are described.

W. D. H.

Colouring Matter of Yellow Silk and its Relation to Vegetable Carotene. By R. DUBOIS (*Compt. rend.*, 111, 482—483).—Yellow silk contains several colouring matters, those actually isolated being (1) a golden-yellow compound, soluble in potassium carbonate solution, from which it is precipitated in very brilliant plates; (2) macled crystals, reddish-yellow by transmitted light, and brown-red by reflected light; (3) a lemon-yellow, amorphous substance, which separates in rounded granules when its alcoholic solution evaporates spontaneously; (4) lemon-yellow, octahedral crystals, resembling those

* Evidently the wrong figure has been given here.

of sulphur; and (5) a deep greenish-blue pigment, which is probably crystallisable, but which is present only in very small quantity.

The substances 2, 3, and 4 agree in many respects with vegetable carotene; they are yellowish-red and crystallisable, dissolve in alcohol, ether, chloroform, and benzene, giving golden-yellow solutions, and in carbon bisulphide giving a brownish-red solution; they alter when exposed to air and light, give a continuous absorption spectrum, and dissolve in sulphuric acid with production of a blue coloration which changes to green, and disappears on addition of water.

Yellow silk owes part, at any rate, of its colour to a substance showing very close analogies to the colouring matter recently extracted from *Diaptomus denticornis* by R. Blanchard, who regards it as carotene of animal origin.

C. H. B.

Poisoning by Hydrocyanic Acid applied to the Surface of the Eye. By N. GRÉHANT (*Compt. rend. Soc. Biol.* [9], 11, 64—65).—It was demonstrated that the statement of the older writers that an animal may be poisoned by hydrocyanic acid absorbed through the mucous membrane of the eye is quite correct. Dogs or rabbits are killed in this way in the course of a few minutes. The animals were tracheotomised, and care taken that no poisoning took place from fumes of the drug entering the respiratory cavity.

W. D. H.

Physiological Action of Potassium Ferrocyanide. By COMBEMALE and DUBIQUET (*Compt. rend. Soc. Biol.* [9], 11, 169—172).—Potassium ferrocyanide is not toxic even when given to animals in doses of 2 grams per kilo. of body weight. In those animals which do not vomit (for instance, the cobaye), there is a diuretic action even after small doses, three hours after its administration. In dogs this is not the case. Repeated doses of the salt, however, cause intestinal troubles in the dog, vomiting being produced if the amount given exceeds 80 centigrams per kilo. of body weight.

In its passage through the system, the ferrocyanide is changed into the ferricyanide, which is eliminated in the urine. Its diuretic action appears to be connected with this transformation, and the simultaneous formation of diuretic potassium salts.

W. D. H.

Physiological Action of the Soluble Salts of Strontium. By J. V. LABORDE (*Compt. rend. Soc. Biol.* [9], 11, 453—459).—Strontium appears to be quite innocuous. In the dog, the only noticeable feature after the administration of the chloride is slight diuresis. It thus differs from barium salts, which are very toxic, producing cessation of respiration. Soluble salts of potassium, especially the chloride, lactate, and sulphate, are also poisonous, producing emesis and diarrhoea, and in larger doses slowing of the heart and death from asphyxia. Calcium salts, like those of strontium, are apparently harmless.

W. D. H.

Physiological Action of Guaiacol. By P. MARFOET (*Chem. Centr.*, 1890, ii, 155—156; from *Ann. chim. farm.*, 11, 304—327).—The

A 2

physiological value of guaiacol was pointed out by Seidel in 1880, since then one difficulty met with in using it has been the absence of distinctive tests of its purity. The author finds that one part of guaiacol should dissolve in 60 parts of water, the presence of impurities rendering it more soluble. Its boiling point is 200—202°. One drop of pure guaiacol mixed with a few drops of concentrated sulphuric acid gives a beautiful permanent purple-red coloration, which is interfered with by even a trace of impurity.

The general action of guaiacol consists in first exciting and then paralyzing the nerve centres. The paralytic effects are the feeblest the higher the animal subjected to its influence. In small doses, guaiacol does not affect the pulse, in larger doses it is quickened. The temperature is reduced. After death from the effects of guaiacol, the author has observed, in the case of dogs, that the heart is not affected by electric stimulus, although the other muscles are. Its action is similar to that of phenol or catechol, and it is ejected from the system in a similar condition; it is, however, not so poisonous as these.

J. W. L.

Substances which Favour Infection. By G. H. ROGER (*Compt. rend. Soc. Biol.* [9], 11, 307—310).—There are certain materials, such as lactic acid, which, when introduced simultaneously with microbes into an animal, favour the development of the bacteria. The bacillus of symptomatic anthrax is innocuous to the rabbit, but is fatal when there is a simultaneous injection of the materials formed by the activity of certain other micro-organisms (*B. prodigiosus*, *Staphylococcus aureus*, &c.). The substance in the cultures that acts thus is soluble in glycerol but insoluble in alcohol, and therefore resembles the soluble ferments; it is, however, not the same substance which liquefies the gelatin in the culture tubes, as it is not destroyed by a temperature of even 130°. Similar interactions between other bacteria are described; and the fact is thought worthy of note, as it may furnish bacteriologists with a means of re-establishing the virulence of micro-organisms which have become attenuated by prolonged cultivation through the bodies of a long series of animals; and also that it may help to explain why some vegetable poisons like papain and jequirity, which are free from microbes, yet produce a condition of the body in which it swarms with numerous bacteria which normally are harmless, or only harmful to a slight degree.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

The Soluble Ferment of Urea. By P. MIQUEL (*Compt. rend.*, 111, 397—399).—The soluble urea ferment described by Musculus has not been isolated by subsequent observers. It can, however, readily be obtained in the following way:—Peptone solution mixed with 2 to 3 grams of ammonium carbonate per litre is sterilised by

filtration through porcelain, and is then inoculated with one of the active bacillian ferments of urea, which the author has previously described (*Ann. Micro.*, 1 and 2). After some days, the liquid becomes turbid, and contains the diastase in question. It is necessary that the cultivations of bacilli be quite pure, for other organisms may develop to the exclusion of the microbes, or may destroy the diastase as fast as it is formed. The quantity of soluble ferment obtained in this way per litre of peptone solution is sufficient to convert 60 to 80 grams of urea into ammonium carbonate in less than an hour. The temperature at which this change takes place most rapidly is 50° to 55°, but even at 50° in contact with air, the diastase undergoes profound alteration, and it is completely destroyed after three or four hours. At a temperature near 0°, however, the solutions of the diastase in the peptone solution can be kept for several weeks without alteration. At 75°, the ferment is completely destroyed in a few minutes, and at 80°, in a few seconds. On the other hand, the organisms which secrete the ferment often resist a moist temperature of 95° for two or three hours.

The author has cultivated 14 species of micro-organisms, exclusive of *Mucedinæ*, which are capable of producing ammoniacal fermentation of urea, and which present perfectly distinct morphological characters, and different degrees of activity. All these microbes secrete the soluble ferment when they are grown in proteid cultivation fluids free from urea, and the author concludes that the destruction of urea at the ordinary temperature in the absence of chemical reagents is due to the action of this soluble ferment. Urea itself has very little nutritive power for lower organisms, and it would seem that the ammoniacal fermentation of urea is not due directly to an act of nutrition, but that the microbes secrete the soluble ferment, and the latter acts on the urea.

C. H. B.

Nitrification and Denitrification in Soils. By T. LEONE (*Gazzetta*, 20, 149—151). The author has previously shown (Abstr., 1890, 1453) that the phenomena of nitrification and denitrification in waters are due to the activity of bacteria and occur in alternation, according to the amount of nutriment present; thus, when an abundance of nutritive matter is at hand, the rapid development of the germs is accompanied by the oxidation of the proteids, partly at the expense of the oxygen in the nitrates present, ammonia and nitrites being formed. On the other hand, nitrification commences as soon as the decomposable azotised products are either assimilated or converted into ammonium compounds. If nitrification and denitrification are determined by similar conditions in soils, the effect of manuring would be in the first instance to suspend the ordinary process of nitrification, and to convert part of the nitrates present into nitrites, nitrification only recommencing when the organic matter was decomposed, and the formation of ammonia had attained a maximum. The following experiments show that this is actually the case.

Two samples, A and B, of 10 kilos. each, of garden mould were placed in cylinders through which air could freely circulate; with one of these, B, 300 grams of fresh manure (fowl's dung) was mixed. The mould contained 250 milligrams of N_2O_5 per kilo., and

an appreciable quantity of nitrous acid, but no trace of ammonia. It was, therefore, in the last stage of nitrification when ammonia had disappeared, but small quantities of nitrites still remained. The sample A (not manured) showed a gradual increase in the quantity of nitric acid up to 282 milligrams of nitric anhydride per kilo., when the whole of the nitrous acid had disappeared. In the manured sample, B, the nitric acid decreased in two days to 230 milligrams of nitric anhydride per kilo., in four days to 190 milligrams, and so on. In the initial period, nitrous acid was formed, but subsequently disappeared; after 15 days, no trace of either nitric or nitrous acid remained; the quantity of ammonia, on the other hand, increased regularly and attained a maximum on the 29th day, after which it remained constant for five or six days. On the 35th day, nitrification recommenced, nitrous acid reappearing and the ammonia beginning to decrease; the transformation of the ammonia into nitrous acid and of the latter into nitric acid continued during three months, after which no trace of either ammonia or nitrous acid could be found, only nitric acid remaining in the soil.

The manuring of soils, therefore, gives rise to a cycle of phenomena, nitrification being first arrested and the nitrates and nitrites reduced until a maximum formation of ammonia is attained, when nitrification again commences. The destruction of the nitrates and nitrites in the soil is complete or partial, according as the supply of manure is abundant or otherwise.

S. B. A. A.

Reducing Power of Micro-organisms. By T. LEONE (*Gazzetta*, 20, 152—154).—The author criticises the methods and results of De Blasi and Travali (Abstr., 1890, p. 1453), and maintains that nitrification is a biological phenomenon taking place under the conditions described (see preceding abstract and 1890, 1453). The reduction of nitrates in the presence of rapidly developing germs takes place simultaneously with the oxidation of the organic compounds present, and is due to the abstraction of oxygen from the nitrates for that purpose.

S. B. A. A.

Biogenesis of Hydrogen Sulphide. By DEBRAÏE and LEGRAIN (*Compt. rend. Soc. Biol.* [9], 11, 466—468).—It is well known that certain bacteria produce hydrogen sulphide from albuminous materials. The number of microbes that act thus is by no means limited, and by appropriate means nearly all of them can be made to produce the gas in cultures in which the action is anaërobic. The formation of the gas appears to depend on the amount of the nascent hydrogen present.

W. D. H.

Chlorophyllic Assimilation by Trees with Red Leaves. By H. JUMELLE (*Compt. rend.*, 111, 380—382).—The relative activity of green and other leaves was compared by exposing them to sunlight under comparable conditions in a closed atmosphere containing a known quantity of carbonic anhydride, and determining how much carbonic anhydride was decomposed; the weights of the dried leaves being ascertained at the end of the experiment. The results show that in trees with red or coppery leaves, the chlorophyllian assimilation is always lower than in the same trees with green leaves, a result

which explains the well known fact that trees of the former class increase in size much more slowly than those of the latter. In some cases the differences are very great; the assimilation of the green beech is about six times as great as that of the copper beech, and there is the same difference between the ordinary and the purple sycamore.

C. H. B.

Sugars in Mushrooms. By E. BOURQUELOT (*Compt. rend.*, **111**, 534—536 and 578—580).—*Lactarius piperatus* Scop., when examined immediately after it is gathered, contains a considerable quantity of trehalose, but very little mannitol. If, however, it is dried and then treated with water, no trehalose is obtained; mannitol alone is present. The same phenomenon is observed if the mushrooms are merely kept for a few hours after being gathered, and hence the disappearance of the trehalose is a result of the continuance of the vital processes of the mushroom. This conclusion is confirmed by the fact that if the mushrooms are kept in a vessel filled with chloroform vapour, the trehalose remains, although the mushrooms become dark-brown and exude a large quantity of liquid.

Examination of various species of mushrooms at different stages of growth shows that when young they contain trehalose and no mannitol, in the middle period they contain both, and when mature they contain mannitol only. *Amanita mappa* is an exception, since in all stages it contains mannitol and no trehalose.

The conversion of trehalose into mannitol is a process of reduction, and is probably connected with the formation and maturation of the spores. In many species the phenomena are complicated by an increase in the amount of glucose that they contain, and in others by the appearance of glucose which is not present in the earlier stages of their growth.

C. H. B.

Loss of Sugar in Beetroot. By G. MAREK (*Bied. Centr.*, **19**, 619—622; from *Deut. Landw. Presse*, **17**, 310—311).—The loss of sugar in beetroot is closely connected with the amount originally contained. Roots were examined in December, 1888, and in March 1889, the sugar being determined by the polarisation of the juice and by extraction with alcohol. The loss in all cases was very considerable. The loss is greatest with roots containing most sugar; the kind, soil, and manuring have less to do with it, and everything which raises the amount of sugar in the roots increases the liability to lose sugar. It is also shown that the higher the temperature at which the roots are kept, the greater is the amount of sugar which is lost. When roots which originally contain equal amounts of sugar lose unequally, the greatest loss will be in those which contain the greatest amount of non-saccharine substances. This fact is of importance in the selection of roots for seed. Comparative experiments were made with nitrogenous and phosphatic manures, the results of which show that phosphoric acid has no unfavourable effect on the durability of the roots, as is frequently stated.

In the manufacture of sugar, those roots which contain most sugar should be used first.

N. H. J. M.

Behaviour of Tannin in Plants. By M. BÜSSEN (*Forsch. Gebiete agrik. physik.*, 13, 305; from *Jena. Zeit. Naturwiss.*, 24).—Experiments were made to determine whether a disappearance of tannin in any parts of plants can be shown to take place. Microchemical methods were employed. Kraus makes a distinction between "primary" tannin, which is produced with, and "secondary" tannin, which is formed without, the intervention of light. In certain cases both were found to disappear. Tannin was found to disappear from cells which were on the point of dying as well as from cells possessing more vitality. The author doubts whether the tannin is again used in building up. Direct proof of the production of tannin from sugar was obtained in a manner similar to that of the formation of starch from sugar. Portions of shade-leaves of various plants were placed with the upper side on a 10 per cent. solution of grape-sugar, the chief veins having been cut to facilitate the entry of the solution. Portions of the same leaves were similarly placed on water as a control experiment—a necessary precaution, as in many leaves the amount of tannin increases after they are cut off and kept in the dark. After four to six days, the leaves showed a considerable increase in the amount of tannin. It has still to be shown what intermediate compounds are formed, and also whether other substances besides grape-sugar will produce tannin. N. H. J. M.

Cultivation of Wheat in a Sterile Siliceous Sand. By PAGNOUL (*Compt. rend.*, 111, 507—509).—Calcium sulphate and natural phosphates were mixed with the sand; soluble salts were added by watering the experimental pots with solutions of definite strengths. Phosphates are indispensable; a yield of 46 quintals per hectare with a complete manure fell to 12 quintals in absence of soluble phosphate, and to 2 quintals when no phosphate was added at all. The ratio of grain to straw also depends on the supply of phosphate, and the suppression of phosphoric acid retards the maturing of the wheat by 10 days. Presence or absence of nitrogen is not of such vital importance, probably because the wheat can obtain a certain quantity from the air. Absence of nitrogen reduced the yield from 46 to 11 quintals per hectare. In a complete manure, nitric nitrogen has only a slightly greater efficiency than ammoniacal nitrogen, but in absence of potassium, the yield with the former is double the yield with the latter. It follows that the presence of potassium is essential when ammoniacal manures are used.

The proportion of nitrogenous compounds in the grain increases with the quantity of nitrogen placed at the disposal of the plant. It fell to 8—9 per cent. with a non-nitrogenous manure, but rose to 20 per cent., which is higher than the ordinary maximum, when the quantity of nitrogen supplied was greater than that existing in the most fertile soils.

Nitric nitrogen was never found in appreciable quantity in plants stinted of nitrogen, but rises to 0.2 per cent., especially in February and March, in those plants which had received nitrogen either in the form of ammonia or nitrates. In absence of potassium, the quantity

of nitric nitrogen is very small, and traces of ammoniacal nitrogen are present.

Examination of Potato-Spirit Liquor. By M. KÜHN (*Bied. Centr.*, 19, 628; from *Milchzeit.*, 18, 926).—The following numbers show the percentages in the sample of the liquor which was used as cattle food :—

Fat.	Protein.	Pure ash.	Crude fibre.	Non-nitrogenous extractives.	Sand in pure ash.
0.13	1.61	1.20	0.43	3.50	0.44

N. H. J. M.

The Behaviour of Sandy Soil towards Superphosphate. By A. THOMSON (*Bied. Centr.*, 19, 585—588).—The absorptive power of pure sea-sand for phosphoric acid was determined as well as that of the same sand containing known amounts of orthoclase, of calcium carbonate, of ferric and aluminium hydroxides, of calcium carbonate and orthoclase, and of calcium carbonate and the mixed ferric and aluminium hydroxides. The effect of sodium chloride and potassium nitrate on the process of absorption was also studied.

Pure sand offers no resistance to the extraction of the phosphoric acid of superphosphate by pure water, or solutions of sodium chloride and potassium nitrate. The addition of orthoclase is without effect. Calcium carbonate combines quickly with the soluble phosphoric acid; and the hydroxides of iron and aluminium are very active in retaining phosphoric acid, especially when used in conjunction with calcium carbonate. 1 or 2 per cent. solutions of sodium chloride extract from superphosphate rather less phosphoric acid than distilled water; but in presence of calcium carbonate and ferric and aluminium hydroxides, the dilute salt solution extracts more phosphoric acid than water alone. Dilute potassium nitrate solutions diminish the absorptive power of all the substances employed more than sodium chloride.

The results point to the conclusion that the full benefit of manuring with superphosphate (in a sandy soil) will only be attained when large amounts of lime or smaller amounts of lime and ferric and aluminium hydroxides are well distributed in the soil, and when the soil does not contain too much nitrate. In absence of these conditions, the application of superphosphate should be avoided. The methods of experimenting and the apparatus employed are described in detail in the original paper (*Inaug. Diss. Dorpat*, 1890).

N. H. J. M.

Composition of Bone-meal. By J. STOCKLASE (*Chem. Zeit.*, 14, 1—2, 21, 32—33).—The author has examined bone-meal obtained by different methods. In the first series of experiments, bones were digested for six hours in soft water, at 95°, by which they yielded 2.3 per cent. of fat, and lost 0.53 per cent. of nitrogen; they were then steamed, either under a pressure of 2.5 atmospheres for 75 minutes (Results A), or under 1.5 atmospheres for 60 minutes (Results B), or under 0.5 atmosphere for an hour (Results C), dried at 40°, pulverised, and the meal and grit analysed, with the results given in the table. In the second series of experiments, it was sought to

extract the fat by means of light petroleum:—Results D were obtained from meal prepared from bone containing 9·2 per cent. of fat; the extraction was conducted under 1·2 atmospheres, the residual petroleum expelled with steam, the extracted bones dried at 45°, and pulverised. For Results E, the bones containing 8·8 per cent. of fat were extracted without pressure, and treated like D, but dried at 36°. Results F: Bones containing 8·7 per cent. of fat, extracted under 1·3 atmospheres, then steamed under 2 atmospheres pressure for 20 minutes, &c. Results G: Bones containing 8·9 per cent. of fat, extracted under 1·2 atmospheres pressure, then steamed under 3 atmospheres for 30 minutes, &c.

Results.	A.	B.	C.	D.	E.	F.	G.
Organic non-fatty matter	26·38	27·82	29·54	33·67	31·24	34·25	26·34
Fat	5·51	9·38	11·32	7·84	6·42	9·06	2·85
Inorganic matter	56·24	52·13	50·43	49·35	48·93	47·87	61·69
Water	11·87	10·37	8·71	9·14	8·41	8·82	9·12
Nitrogen	3·77	4·05	4·25	4·83	4·36	4·96	3·94

Steaming, when the pressure is sufficiently great to remove fat, also removes much nitrogen. By the second method of extraction, less nitrogen is lost, the coarse crushed bone makes a superior granular charcoal, and the gelatin from the bone grit is excellent, whilst the fat contains less calcium and ammonium oleates, palmitates, and stearates. For agricultural purposes, the fat impedes decomposition, both of the nitrogenous matter and the phosphate. The fragments of bone containing most fat are more brittle; hence the meal is found to contain more fat than the grit, and so on up the scale of coarseness. The author gives results showing this. He regards finely pulverised bone meal deprived of fat as an excellent manure, superior to basic slag, and not even second to precipitated phosphate in action, its apparent failure, hitherto being attributed to want of attention to the points now set forth in the present paper.

D. A. L.

Amount of Fat in Bone-meal. By J. MERZ (*Chem. Zeit.*, 14, 95).—Referring to Stocklasa's communication (preceding abstract), it is considered that justice is not done to the extraction method in the results quoted; therefore the author of the present note calls attention to three experiments of his own, wherein the fat in bones was reduced to 0·32, 0·28, and 0·26 respectively, in from six to seven and a half hours, by extraction with petroleum without pressure, the latter not being regarded as a factor in the extraction of fat on a large scale any more than it is on a small scale in laboratory fat estimation. In fact the more the former operation is made to resemble the latter, the greater is the yield of fat, and the better the quality of the bone-meal.

Analytical Chemistry.

Estimation of Hydrogen Chloride in Solutions of Hydroxylamine Hydrochloride. By J. A. MULLER (*Bull. Soc. Chim.* [3], 3, 605).—Phenolphthalein is unaffected by solutions of hydroxylamine hydrochloride, and the amount of acid present may be estimated by means of a standard solution of sodium hydroxide, free from carbonate, using phenolphthalein as the indicator. Pyridine, picolines, and lutidines behave similarly. T. G. N.

Estimation of Sulphur in Inorganic Sulphides. By L. BLUM (*Zeit. anal. Chem.*, 29, 411—412).—The method published by Jannasch (*Abstr.*, 1889, 1244, and 1890, 1187) is not new, having been already brought forward by Sauer, in 1873 (*Abstr.*, 1873, 939). M. J. S.

Estimation of Nitrogen by the Schultze-Tiemmann (Schloesing's) Method. By F. COCHUS and T. MOELLER (*Chem. Zeit.*, 14, 33).—Low results are obtained by this method, especially in the examination of explosives. This is attributed by the authors to the addition of too much water, and to the want of proper relationship between the size of the apparatus used and the quantity of material employed. In some test experiments they used a long-necked 350 c.c. flask, a measuring tube of 150 c.c. capacity, ferrous chloride solution containing 70 grams in 100 grams of water, hydrochloric acid of about 37 per cent., and employed 0.3—0.4 gram of potassium nitrate, 5—15 c.c. of the ferrous chloride solution, and twice the quantity of the hydrochloric acid. The ordinary course of operation was followed, avoiding unnecessary boiling to drive out the air. When 25 to 50 c.c. of water was added, the analysis lasted 30 to 40 minutes, and the results varied between 13.76 and 13.86, mean 13.81, whilst with 80 to 150 c.c. of water the variation in the results was from 13.05 to 13.39, mean 13.21, and the analysis lasted 70 to 90 minutes.

D. A. L.

Estimation of Nitrogen in Sodium Nitrate. By O. FORSTER (*Chem. Zeit.*, 14, 509—510; compare *Abstr.*, 1889, 547, 746).—Two or three grams of the nitrate is dried at 150° or by heating to incipient fusion, weighed, and repeatedly evaporated to dryness on a water-bath in a tared crucible, with 25 c.c. of about 19 per cent. hydrochloric acid. After about the third evaporation, the nitrate is completely converted into chloride, which is dried at 150°, ignited slightly, and weighed, and the nitrogen calculated from the difference. The method yields satisfactory results, but only in the absence of other substances, which would be attacked by hydrochloric acid.

D. A. L.

Estimation of Nitric Nitrogen as Nitric Oxide. By F. SCHEIDING (*Chem. Zeit.*, 14, 635—637).—For estimating nitric nitrogen as nitric oxide, the author has devised and employs the apparatus shown in the drawing, which is provided with a measuring tube

having a globular expansion, a glass tap H with a small funnel at the top, and a special arrangement intimately attached by india-rubber tubing or fusion to the bottom. In operation, tube L is connected

in a suitable manner with a movable reservoir containing sodium hydroxide, sp. gr. 1.25, with which the apparatus is charged to the level of 4 by raising the reservoir, and clip 4 is closed. The substance is placed, along with a little water, in a 200–250 c.c. flask, to which the stopper and tubes are fitted, connections made, and to expel the air through tubes 2 and 3, the water in the flask is boiled until the water into which tube 3 dips is caused to boil by the issuing steam, clip 5 is then closed, and the air still in tube 1 driven into the measuring tube by opening clip 4, which is again closed, and the flame removed from below the flask. The measuring tube is filled to the top with sodium hydroxide, and tap H is closed. 20–25 c.c. of cold saturated ferrous chloride, and then 8–10 c.c. of concentrated hydrochloric acid are carefully drawn into the flask through tubes 2 and 3, which are then washed with water in the same way; the flask, suspended a few cm. above the wire gauze, is now heated, and as

soon as a pressure is indicated in the india-rubber tube at 4, that clip is opened, the nitric oxide passes into the measuring tube, and by the time the liquid has volatilised in the flask, all the nitric oxide is concluded to be in the measuring tube. The temperature in the jacket tube surrounding the measuring tube is made to correspond with that in the vicinity of the bulb, and the level in the reservoir being adjusted to that in the measuring tube, the volume is read off, and after the necessary corrections are made, the percentage of nitrogen is calculated therefrom. The saucer under the measuring apparatus is filled with water to keep the tubes immersed in it cool. For substances which might be decomposed by boiling with water, a tap funnel is fitted to the flask, and is used for charging it. D. A. L.

Estimation of Nitrogen in Organic Substances by means of Alkaline Permanganate. By R. L. WAGNER (*Chem. Zeit.*, 14, 269).—The author some years ago recognised the possibility of oxidising nitrogenous organic substances by means of alkaline permanganate, without the formation of ammonia. In his experiments he mixed 0.5 to 1 gram of substance with 25–30 times its weight of potassium permanganate, and 5 c.c. of 25 per cent. potassium hydroxide, placed the mixture in a tube closed at one end, terminating at the other in a capillary for the escape of oxygen, warmed in a water-bath to aid admixture, and then heated at 150–170° in an air-bath for two to two and a half hours. The contents of the tube were turned into a porcelain basin, the excess of manganate reduced with manganese sulphate and sodium carbonate, and the nitric acid determined in the clear liquid by a modification of Eder's method; but irregularity of combustion and breaking of tubes rendered the method practically useless, except, perhaps, for substances soluble in alkalis. Non-volatile nitro-derivatives and ethereal nitrates can be safely oxidised by alkaline permanganate in a porcelain dish, excess of permanganate being subsequently reduced with alcohol, and the diluted filtrate treated with ferrous sulphate, zinc-dust, and hydrochloric acid; the nitrogen is then estimated as ammonia, by any of the usual distillation methods.

Carbon bisulphide and thiophen can be oxidised by similar treatment, and the sulphur estimated in them; they are enclosed in thin glass bulbs, and placed in tubes containing the alkaline permanganate; the tube is sealed up, the bulb broken, and the digestion proceeded with. D. A. L.

Detection of Foreign Raw Phosphates in Powdered Basic Slag. By L. BLUM (*Zeit. anal. Chem.*, 29, 408–411).—The relative superiority of basic slag as a fertiliser over natural phosphatic minerals, owing to its ready absorbability, and the high price which it has in consequence attained, have led to its falsification with other raw phosphates. Only such are likely to be used as, from their low percentage of phosphoric acid, cannot profitably be worked up as superphosphate, and these in most cases contain much calcium carbonate. Fresh basic slag is almost absolutely free from carbonates, and even on long exposure to air, absorbs very little carbonic acid

(2.47 per cent. was found in an extreme case), so that the presence of much carbonate in a specimen would be enough to throw suspicion on it. A low percentage of iron and manganese might furnish an additional indication, since these metals are rarely present in natural phosphates. In estimating the carbonic acid by decomposition with an acid, some chromic acid should be added, to prevent evolution of hydrogen sulphide from the sulphides present, but a simple estimation of the loss on ignition would generally allow an opinion to be formed.

M. J. S.

Estimation of Water in Superphosphates. By J. STOKLASA (*Zeit. anal. Chem.*, 29, 390—397).—Pure monocalcium tetrahydrogen phosphate, $\text{CaH}_4(\text{PO}_4)_2 + \text{H}_2\text{O}$, loses its water of crystallisation at 100° , but only completely after 40 hours. It may be kept at 105° for 20 hours with but little change, but on longer heating at the same temperature begins to show decomposition. At higher temperatures, the amount of change is dependent not alone on the temperature, but also on the time of drying. The statement of Drewsen (*Abstr.*, 1881, 465) that drying even at 300° does not diminish the proportion of soluble phosphate, but merely reduces it to a soluble pyrophosphate, cannot be confirmed for pure or nearly pure monocalcium phosphate. It might be true for a superphosphate in which free phosphoric acid constituted 80 per cent. of the total soluble phosphoric acid.

On drying for one hour at 200° , one-half of the monocalcium phosphate undergoes decomposition, thus: $4\text{CaH}_4(\text{PO}_4)_2 = \text{Ca}_2\text{P}_2\text{O}_7 + \text{Ca}(\text{PO}_3)_2 + \text{CaH}_2\text{P}_2\text{O}_7 + 2\text{H}_3\text{PO}_4 + 4\text{H}_2\text{O}$. At lower temperatures for the same length of time, the proportion decomposed is smaller, but if the time is prolonged, a further decomposition takes place even at 150° , and less free phosphoric acid is found in the soluble part. A temperature of 200° sufficiently prolonged results in the following decomposition: $4\text{CaH}_4(\text{PO}_4)_2 = 3\text{Ca}(\text{PO}_3)_2 + \text{CaH}_2\text{P}_2\text{O}_7 + 7\text{H}_2\text{O}$, whilst at 210° , there remains nothing but insoluble, glassy calcium metaphosphate. In presence of free phosphoric acid, the contrary action may on heating take place, thus: $\text{Ca}_2\text{P}_2\text{O}_7 + 2\text{H}_3\text{PO}_4 = 2\text{CaH}_2\text{P}_2\text{O}_7 + \text{H}_2\text{O}$, and thus the soluble phosphoric acid actually undergo increase.

M. J. S.

Separation of Barium from Strontium. By R. FRESSENIUS (*Zeit. anal. Chem.*, 29, 413—430; see *Abstr.*, 1890, 924).—All attempts to obtain complete separation by means of chromic acid in a single precipitation resulted in failures. The seemingly satisfactory separation obtained by Frerichs and by Russmann (next abstract) resulted from the accidental compensation of opposite errors, since they washed the barium chromate with acetic acid, in which it is distinctly soluble, and weighed it after drying at 110° , at which temperature it still retains some moisture. In a solution containing alkaline acetate and dichromate, barium chromate is, however, quite insoluble. It can also be rendered anhydrous without decomposition by ignition at a dull red heat, even the portion adhering to the filter reoxidising after temporary reduction. By double precipitation of the barium, a complete separation can be effected even when the proportion of

strontium is large. The solution of the chlorides is feebly acidified with acetic acid, and diluted until it contains not more than 0.5 per cent. of the bases, then precipitated hot with an excess of ammonium chromate, which has been carefully neutralised with ammonia. After cooling for an hour, the precipitate is washed by decantation with very dilute ammonium chromate until the washings no longer give a precipitate with ammonium carbonate, and then further with warm water until the washings are scarcely coloured by silver nitrate. The precipitate is then dissolved in the smallest possible quantity of nitric acid, and the solution again diluted and heated. Ammonium acetate is added in sufficient quantity to displace the free nitric acid by acetic acid, and then ammonium chromate until the odour of acetic acid has completely disappeared. After an hour, the liquid is poured through a filter, the precipitate is digested with hot water, cooled, filtered, and washed thoroughly with cold water. It is then free from strontium, whilst the filtrates contain no barium. Double precipitation from neutral or alkaline solutions has not been successful.

M. J. S.

Separation of Barium, Strontium, and Calcium. By A. RUSSMANN (*Zeit. anal. Chem.*, 29, 447—454; from *Inaug. Diss. Berlin*, 1887).—Barium cannot be satisfactorily estimated by Frerichs' method (precipitation from an acetic acid solution by normal potassium chromate), since the filtrate always contains traces of barium, and some potassium chromate is carried down by the precipitate. The precipitate will also contain strontium, if the proportion of the strontium in the solution exceeds 30 parts per 100 of barium. Calcium is not so precipitated. The simplest way to ascertain the weight of the barium chromate, is to dissolve it in dilute hydrochloric acid, add potassium iodide, and immediately titrate with thiosulphate. Diehl's method for separating barium and calcium by digesting the sulphates with sodium thiosulphate solution is complicated by so many sources of error that it cannot be recommended. Fresenius' method of separating barium and calcium by dilute sulphuric acid in a solution acidified with hydrochloric acid is thoroughly satisfactory. The method of Sidersky (*Abstr.*, 1883, 509) for separating strontium and calcium only yields approximate results. For separating barium and calcium, it is, however, serviceable. Bloxam's method (*Abstr.*, 1886, 920) is not suitable for quantitative separations, as the strontium sulphate carries down with it considerable quantities of calcium, and the calcium ammonium arsenate cannot readily be brought into a form for weighing in which it contains a constant proportion of calcium. Fleischer's method for separating barium and calcium by digestion with 3 parts of potassium sulphate and 1 part of carbonate, followed by titration of the calcium carbonate in the weighed precipitate gives good results. Lastly, Leison's method for the estimation of the individual alkaline earths, by precipitation with oxalic acid and alcohol, and titration of the oxalic acid in the precipitate by permanganate, is accurate. The barium oxalate must be dissolved by hydrochloric acid, as it is not completely decomposed by sulphuric acid. Strontium and calcium oxalates can be decomposed by sulphuric acid. The solutions must not be filtered through paper,

and must be highly dilute. Ignition of the oxalates is, however, as a rule, the quicker process. M. J. S.

Estimation of Cadmium in the Products of Zinc Manufacture and in Calamine. By W. MINOR (*Chem. Zeit.*, 14, 4, 34, and 348—349).—The material is dissolved in hydrochloric acid, treated with hydrogen sulphide, and the precipitate washed with hot water, dissolved in hydrochloric acid, heated to boiling, and poured into dilute sodium hydroxide likewise heated to boiling. This precipitate, after washing with hot water, is ignited in a current of oxygen, and weighed as cadmium oxide. Material containing but little iron, such as "pure cadmium," is dissolved in hydrochloric acid, and precipitated directly with the sodium hydroxide. This method of precipitation may also be used to separate zinc and cadmium in the ordinary method of examining calamine; the ammoniacal solution containing the zinc and cadmium is rendered slightly acid and poured hot into the hot hydroxide, &c.

In the method described in the last of the three papers, the material is dissolved in hydrochloric acid, filtered from undissolved lead, precipitated with hydrogen sulphide, the precipitate, containing zinc and an inconsiderable amount of arsenic, is washed, dried, weighed, dissolved in dilute hydrochloric acid, and treated with sodium hydroxide in excess. The cadmium hydroxide is filtered off, and the zinc titrated in the filtrate with sodium sulphide, calculated to zinc sulphide, and deducted from the weight of the cadmium sulphide precipitate. In another method (requiring the absence of other metals precipitated by sodium hydroxide) after removal of iron with ammonia, the solution of zinc and cadmium is nearly neutralised with hydrochloric acid, and then treated with sodium hydroxide. The precipitate of cadmium hydroxide is dissolved in dilute hydrochloric acid, evaporated to dryness, dissolved in water, and titrated with standard sodium hydroxide, using litmus or sodium sulphide papers as indicators. Good results have been obtained by both methods, the first being the more suitable in the presence of much zinc and *vice versa*. D. A. L.

Estimation of Cadmium as Sulphide by Precipitation with Sodium Sulphide Solution. By W. MINOR (*Chem. Zeit.*, 14, 439—440).—The material is dissolved in hydrochloric or nitric acid, and the lead separated by sulphuric acid; the solution is then treated with soda, and the precipitate digested with ammonia. The ammoniacal solution is free from lead, zinc, and iron, but contains all the cadmium, which can then be determined by means of sodium sulphide solution, either volumetrically by titration, using ferric hydroxide as indicator, or gravimetrically by precipitating, and weighing the precipitate after drying for some hours at 140—145°. D. A. L.

Volumetric Estimation of Zinc and Copper. By E. DONATH and G. HATTENSAUR (*Chem. Zeit.*, 14, 323—325).—Various experiments have been made by the authors. They find that for titrating zinc by Schaffner's method, it is better to use sodium hydrosulphide

(prepared by adding a known volume of dilute sodium hydroxide to an equal volume of the same solution previously saturated with hydrogen sulphide) than a solution of the crystalline sulphide of commerce; however, in using this reagent in solutions containing tartaric acid and ammonia, the iron commences to precipitate before all the zinc is converted into sulphide. The estimation of zinc by using excess of ferrocyanide, after the removal of the iron, and titrating back with permanganate does not answer, since in the cold a clear solution cannot be obtained, whilst if warm, decompositions occur which cause irregularities. It is noticed that ferrocyanide precipitates zinc but not iron in the presence of tartaric acid and ammonia, and that the excess of either of these substances does not seriously disturb the relative quantity of 1 mol. ferrocyanide to 2 atoms of zinc; therefore 1 c.c. of a solution containing 33·5 grams of potassium ferrocyanide per litre corresponds with 0·010 gram of zinc. As small an excess of ammonia as possible, and a hot solution, are favourable to the precipitation. The zinc precipitate is not decomposed by acetic acid; therefore, by placing drops of this acid and the solution under examination in contact, in the presence of iron, a coloration indicates complete precipitation of the zinc. The following method is based on these considerations:—3 to 4 grams of material is dissolved in hydrochloric acid with some nitric acid, diluted to a definite volume with water, an aliquot part filtered, treated with 20—25 c.c. of concentrated tartaric acid solution, a slight excess of ammonia added, and the liquid warmed to about 80°. The ferrocyanide is now run in until the precipitation of the zinc is complete, as indicated in the manner described above. The proportion of iron to zinc in the solution under examination should be the same as that present in the solution used for standardising the ferrocyanide.

Under similar circumstances, copper is precipitated in a like manner, but the precipitation is greatly influenced by ammonia; therefore the solution for titration should be neutral or nearly so. The ferrocyanide is standardised from a solution of copper of known strength, and cannot be approximated to by the weight of ferrocyanide employed, inasmuch as the composition of the copper precipitate is uncertain. Copper and zinc may be estimated in the same solution by this method; first both are titrated, then the copper is precipitated out of another portion of solution, and the zinc alone titrated, &c.

D. A. L.

Estimation of Lead by Phosphomolybdic Acid. By H. BEUR (*Bull. Soc. Chim.* [3], 3, 852—855).—To the boiling neutral solution of the metal, an aqueous solution of phosphomolybdic acid is added until the supernatant liquid is coloured yellow by the excess of reagent used. After washing, the precipitate is dried at 90—100° and weighed. It forms a dense, white powder which is insoluble in water (1 in 500,000) and aqueous ammonia, but dissolves in nitric and in acetic acids; it contains 54·8 per cent. of lead, and corresponds with the formula $\text{Mo}_{25}\text{Pb}_{25}\text{P}_2\text{H}_{14}\text{O}_{112}$; at a high temperature it loses 7 mols. H_2O .

By decomposition of the precipitate with dilute sulphuric acid and zinc at a gentle heat, a brown liquid is obtained, which may be

titrated for lead by a solution of permanganate which has been previously standardised against a solution resulting from the similar treatment of a known weight of a lead salt.

The phosphomolybdic acid is made by evaporating to dryness a solution of ammonium phosphomolybdate in nitric acid. Iron is eliminated by a previous treatment with sodium hydroxide, copper, potassium, and ammonium by washing the mixed phosphomolybdates with ammonia-water, but the presence of zinc or arsenic vitiates the estimation.
T. G. N.

Separation of Copper from Arsenic by the Electric Current. By L. W. McCAY (*Chem. Zeit.*, 14, 509).—Under the influence of the current from four to six Meidinger elements, alkaline arsenates remain in solution, whereas copper is completely and quantitatively precipitated, and has been estimated with good results. Moreover, the copper is quite free from arsenic, and the solution may be safely employed for the determination of the original amount of the latter metal.
D. A. L.

Estimation of Aluminium in Commercial Aluminium. By G. KLEMP (*Zeit. anal. Chem.*, 29, 388—390).—The process employed for zinc (*Abstr.*, 1890, 1190) cannot be applied to aluminium since, even with highly dilute alkali and a large excess of iodate, hydrogen is always evolved, but by dissolving the aluminium in potash, and burning the hydrogen in Fresenius' apparatus, a very accurate estimation can be made. About 1 gram of the metal in filings is placed in a 150 c.c. flask with a little vaselin to prevent frothing, and the potash solution (35 grams of KOH in 100 c.c.) is added gradually, with warming towards the close. The operation takes about 45 minutes.

M. J. S.

Estimation of Alumina in Bread, &c.; Solubility of Aluminium Phosphate in Acetic Acid. By W. C. YOUNG (*Analyt.*, 15, 61—63; 83—84).—In Dupré's process, the aluminium is precipitated as phosphate from an acid solution containing ammonium chloride and acetate, and is collected after remaining all night in the cold. Test analyses, with weighed quantities of alum, show that under these conditions the results are much below the truth. The best result (from a mixture of alum, sodium phosphate, and acetic acid) was obtained by boiling the mixture both before and after the addition of ammonium acetate, and filtering immediately. The amount of ammonium acetate must not be too small, nor that of acetic acid too large. For 0.1 gram of potash alum, there was used 1 gram of ammonium acetate and 5 c.c. of ordinary acetic acid. The presence of ammonium chloride has little effect when the liquid is filtered immediately after boiling, but lowers the result if the precipitation is performed in the cold, or the mixture is allowed to cool before filtering.
M. J. S.

Estimation of Iron Oxide and Alumina in Phosphates. By R. JONES (*Chem. Zeit.*, 14, 269—271).—The author criticises the methods employed until recently, and recommends as the best the following combination of Glaser's method, slightly modified, with

part of Stutzer's method. The phosphate is dissolved in hydrochloric and nitric acids, made up to a definite volume, an aliquot part taken and treated with a quarter of its volume of sulphuric acid of sp. gr. 1·84, and its own volume of 95 per cent. alcohol, making up to definite volume with the alcohol; after 12 hours, the gypsum is collected, and when weighed, gives good results for calcium in absence of much magnesium. The alcohol is driven off from the filtrate, which is rendered alkaline with ammonia and boiled to completely drive off the ammonia. The precipitate may be weighed, and half the weight taken as iron oxide and alumina, which gives good results, or it may be treated with molybdic solution, the phosphoric acid separated in the usual way, the iron and alumina precipitated with dilute ammonia, redissolved in hydrochloric acid, reprecipitated, &c., and weighed. D. A. L.

Titration of Chromates, Barium Salts, and Sulphates. By P. SOLTSEIN (*Chem. Centr.*, 1890, ii, 217—218; from *Pharm. Zeit.*, 35, 372).—The titration of solutions of barium salts with potassium dichromate, and inversely the titration of chromates with barium salts, may be readily performed with either hæmatoxylin or logwood extract as indicator. A solution of barium chloride is prepared equal to one of potassium dichromate, and for the determination of barium salts, potassium dichromate is run in from the burette until a drop placed on a warmed porcelain plate with a drop of hæmatoxylin just shows the formation of a blue-black coloration. The solution to be titrated must be neutral, and may not contain more than the merest trace of either acetic acid or ammonia. Chlorides and nitrates do not interfere with the reaction, nor does rosolic acid, which latter may be used as an indicator for the titration of solutions of salts of barium. If the solution of a chromate contains sulphates, the titration with barium chloride gives the total quantity of the two salts, from which must be deducted the amount of the latter as determined gravimetrically.

For the determination of the combined sulphuric acid, an excess of barium chloride solution is added, and the excess determined by titration with potassium dichromate.

Salts of aluminium, copper, and iron must be removed from the solutions. J. W. L.

Estimation of Antimony by Marsh's Method. By A. VAN BYLERF (*Ber.*, 23, 2968—2971; compare Kühn and Saeger, *Abstr.*, 1890, 1187).—For the estimation of antimony in alloys of tin, silver, and antimony, the author recommends the following process:—A three-necked Woulffe's bottle is connected on the one hand with an apparatus for evolving carbonic anhydride, and on the other with the usual calcium chloride tube and hard glass tube. The central neck of the Woulffe's bottle is fitted with a wide tube reaching to the bottom of the flask. About 0·5 gram of the alloy is dissolved in 20 c.c. of mercury at 60°, and poured, after cooling, into the flask. 100 c.c. of 10 per cent. sulphuric acid is then added through one of the side tubes, and the air expelled from the apparatus by carbonic anhydride. A freshly prepared sodium amalgam, obtained by dissolving 5·5 grams of sodium in 25 c.c. of mercury, is then added drop

by drop through the wide tube. The sublimate of antimony quickly appears in the heated tube; the apparatus is then periodically shaken, care being taken that no liquid is allowed to pass into the central tube. After the evolution of gas has ceased, carbonic anhydride is again passed through the apparatus to expel all the hydrogen and hydrogen antimonide. The mercury solution is then poured off, dried with filter-paper, and divided into two equal portions, one of which is returned to the cleaned and dried apparatus, and covered with 75 c.c. of a 10 per cent. sulphuric acid, whilst the other is mixed with 3 grams of sodium, and added drop by drop through the central tube as before.

The results obtained are fairly accurate, but might possibly be improved by employing hydrogen in place of carbonic anhydride for driving out the air. Another source of error is the oxidation which takes place in the manufacture of the alloy, and during its solution in the mercury.

H. G. C.

Estimation of Hardness of Natural Waters. By E. L. NEUGEBAUER (*Zeit. anal. Chem.*, 29, 399—401).—The author proposes the following modifications of Clark's test. The standard water is a mixture of 8 vols. of calcium sulphate solution of 12° of hardness with 2 vols. of a 12° magnesium sulphate solution. Of this mixture, 100 c.c. is used. The soap solution is of such strength that 12 c.c. is required for the 100 c.c. of standard water. The following new table has been drawn up from titrations of the standard water diluted to the required degrees:—

Hardness.....	0°	1°	2°	3°	4°	5°	6°
C.c of soap solution ..	0·6	1·7	2·8	3·9	4·9	5·9	6·9
Hardness.....	7°	8°	9°	10°	11°	12°	
C.c of soap solution ..	7·8	8·7	9·6	10·4	11·2	12·0	

and a special burette (titanometer) constructed, the readings of which give at once the degrees of hardness.

M. J. S.

The Analysis of Sulphurous Waters. By D. VITALI (*Chem. Centr.*, 1890, ii, 166; from *L'Orosi*, 13, 73—78).—Thiosulphates may be detected by the addition of potassium nitrite and a mineral acid or acetic acid. Nitric oxide is liberated, and the solution is thereby coloured yellow; later, sulphur is precipitated, and the liquid becomes milky. This reaction is extremely delicate, 0·0001 per cent. of thiosulphate being detectable. In testing for nitrites in presence of thiosulphates with potassium iodide and starch, this reaction of the thiosulphate may prevent the formation of the blue iodide of starch, a yellow coloration being produced instead. In testing for iodine, in presence of thiosulphates, with potassium nitrite and an acid, it is better to evaporate the water to dryness after neutralising with sodium carbonate, and then to extract the residue with absolute alcohol, which dissolves the iodide, leaving the thiosulphate undissolved. In the case of waters containing large quantities of calcium sulphate, it is recommended to first precipitate the calcium as calcium carbonate before determining the silicic anhydride. In order to prevent the precipitation of sulphur during the evaporation of water

for determination of the total solid residue, the author recommends that a current of hydrogen should be passed through the water.

J. W. L.

Examination of Water for Contamination by Gas Works. By F. DICKMANN (*Zeit. anal. Chem.*, 29, 398—399).—In a specimen of water from a brook which had suffered contamination from a neighbouring gas works, and by which poultry had been poisoned, the author detected traces of a substance giving the reactions of diphenylamine. Owing to the stability of this compound and the sensitiveness of its reaction with nitric acid, its presence might be used as a proof of contamination by tar-water, if it should be found to be a constant constituent of that liquid.

M. J. S.

Detection and Estimation of Organic and Inorganic Poisons in Corpses. By A. SEYDA (*Chem. Zeit.*, 14, 31—32, 51—53, 128—129, 181—184, and 198—200).—The author describes his system of examining corpses. The chemical examination proper is preceded by a preliminary examination of the blood, urine, and contents of the stomach and accessories.

The *blood*, when not too decomposed to show the absorption bands, is examined spectroscopically; if dry, it is dissolved in water, and made very slightly alkaline with sodium hydroxide; the two oxyhæmoglobin bands and the intermediate hæmoglobin band merge into one continuous band in partially decomposed blood; the faint band in the red is attributable to methæmoglobin in alkaline material or to hæmatin in acid blood. In the former case, further examination is only made under exceptional circumstances, such as the presence of hydrogen sulphide not emanating from ordinary putrefactive processes; but, in the latter case, the red band being due to hæmatin, is regarded as indicating the presence of other reducing agents, or of acids, potassium chlorate, ferricyanides, nitroglycerol, or nitrobenzene, which are tested for in the urine and in parts of the body. Other isolated lines in the red are carefully noted, and carbonic oxide is sought for; the presence of hæmatin, already reduced or otherwise, indicates the absence of carbonic oxide poisoning; carbonic oxide hæmoglobin is recognised in presence of oxyhæmoglobin and hæmoglobin by the mere displacement of the absorption band towards the red part of the spectrum when ammonium sulphide is added; chemical tests with sodium hydroxide with or without calcium chloride are considered of little value.

In the *urine*:—Notes are taken of the quantity, colour, odour, of reactions as to the presence of blood, albumin, and sugar, of the action in alkaline copper solutions, of the behaviour towards barium chloride before and after treatment with hydrochloric acid, and of the occurrence of balsams, alkaloids, soluble metallic poisons, and of such salts as potassium chlorate, iodide, or bromide.

The *contents of the stomach* are examined in the dark for phosphorescence, which is only due to phosphorus in acid mixtures, otherwise fungoid growth may cause it. The odour of the contents of the stomach may be acid, alkaline, like decayed cheese, or they may have a specific odour, or be putrid; sometimes they are well preserved, and

have a sweetish, repulsive odour, observed by the author in cases of arsenical poisoning. *Food magmas* and *vomits* are carefully sampled, treated with alcohol and then with ether, and examined macro- and micro-scopically. The alcoholic extract is examined for oxalates and foreign bases and acids; matters found in the folds are also examined. The arsenic test is applied, and an aqueous extract of the magma is examined for soluble poisons.

For the chemical examination proper, parts of organs, finely divided, are heated with water in a boiling water-bath for several hours, acidified with tartaric acid, and distilled with steam. Two fractions are made: the first will contain the more volatile matters, such as alcohol, aldehyde, acetone, chloroform, nitrobenzene, otheral oils, turpentine, camphor, amines, and their volatile combinations; the other, the remains of these more volatile products, and any less volatile substances, such as fatty acids, phenol, hydrocyanic acid, &c. A plain distillation of alkaline material is required at times; if, however, the presence of chloral hydrate or hydrocyanic acid and ferrocyanides is suspected, the finely divided organs are first moistened with potash or with hydrogen sodium carbonate respectively. A steam distillation from alkaline solution, when necessary, is best effected, not directly, but with the liquid obtained by extraction with water and tartaric acid. The residue from the acid distillation is employed in testing for alkaloids.

The odour, colour, opalescence, quantity, &c., of the first fraction of the acid distillate are noted. It is tested with silver nitrate, both in nitric acid and in ammoniacal solution, with sodium nitroprusside, potash, and acetic acid; with alkaline permanganate; with iodine and potash (iodoform reaction); with zinc-dust and hydrochloric acid for nitrobenzene; with hydrochloric acid and alcoholic phloroglucinol for etheral oils (a reaction frequently takes place, but too much dependance is not to be placed on it; it is better to examine the *urine* for some of these substances, also for altered camphor). The reagents for turpentine oil, in tangible quantities, are a mixture of fresh guaiacum alcohol and fresh citronella oil. Resorcinol and potash are better reagents for detecting chloroform than the isonitrile test. A quantitative examination for these substances is seldom possible, with the exception of alcohol, but this cannot be estimated by distillation in the presence of amines; therefore it is oxidised to acetic acid as follows.

A portion of the distillate is redistilled, the first portions collected are dried with potassium carbonate, distilled again, treated with sodium dichromate and sulphuric acid, rendered alkaline with potash, boiled to eliminate amine bases, then acidified, steam distilled, and the distillate, containing the acetic acid, titrated; any sulphuric acid, if accidentally present, being estimated and allowed for. The author attaches great importance to the estimation of alcohol, especially in the case of children. Various parts of corpses of persons addicted to alcohol yield distillates containing alcohol, but not pure ethyl alcohol; therefore such distillates reduce alkaline permanganate, &c., give the iodoform reaction, and yield an inflammable distillate on redistillation from potassium carbonate. Alcohols readily evaporate from corpses, the more volatile disappearing first.

Passing on to the second fraction from the acid distillation, phenol, as a normal product of the decomposition of albuminoids, is frequently detected by Millon's reagent, less readily by bromine-water. Large quantities of phenol are estimated by filtering the fraction containing it from the fatty acids, extracting with ether, drying the ethereal residue over sulphuric acid, and weighing, taking precautions against the phenol creeping over the edge of the evaporating dish. As regards hydrocyanic acid, the distillate is tested with copper sulphate and guaiacum, and if the reaction is noticed, it is confirmed by some other test, and the acid determined as silver cyanide. Phosphorus is generally recognised by the phosphorescence, but if this does not occur phosphorous acid must be tested for and estimated in the residue. In examining the distillate for phosphorus, it is redistilled, using an upright bulbed tube, the distillation being continued for an hour after phosphorescence has ceased to appear; the new distillate is treated with silver nitrate, &c., and also is tested for phosphorus by oxidising with chlorine-water and adding ammonium molybdate.

In examining for alkaloids, special care must be taken not to mistake ptomaines for other alkaloids, and to allow for the impure form of the latter. The material is treated with alcohol containing tartaric acid, the extract filtered, evaporated, dissolved in water, filtered, neutralised with potash, concentrated, treated with alcohol, separated from the potassium tartrate, and the neutral aqueous solution is tested with alkaloid reagents (a preliminary test with tartaric acid and iodic acid being made for morphine) and examined systematically if required. A portion is rendered alkaline, and steam-distilled for nicotine, coniine, aniline, &c. In the absence of these volatile bases, another portion is extracted with ether successively when neutral, acid, and alkaline, then with chloroform while still alkaline, and finally is made ammoniacal and extracted with amyl alcohol. The third portion is reserved for the direct confirmatory examination of any alkaloid indicated in the other portions. The aqueous residue is tested for narcotine and curarine, whilst the various extracts are examined separately. The residue from the alkaline-ether extract is tested with phosphoric acid for aconitine. Vitali's atropine reaction is liable to be hidden by xanthoprotein colour reactions. For strychnine, a double test is made: first, a drop of vanadic acid solution is mixed with the residue, dissolved in sulphuric acid, which is subsequently diluted with concentrated sulphuric acid, and then solid ammonium vanadate is dusted over another portion of the same solution. Attention is called to the fact that colocynthine gives reactions with both vanadic and chromic acids, which resemble those of strychnine with the same reagents. The amyl alcohol extract, after purifying, serves for confirming the presence of morphine.

Another portion of the original extract is examined for metallic poisons soluble in alcohol. The examination for metallic poisons generally is made with the residue from the first distillation or that from the alcoholic extraction; in the latter case the alcohol is expelled by warming. The residue is heated with hot water, potassium chlorate, and hydrochloric acid until the organic tissue is destroyed and all chlorine driven off, the magma is treated with tartaric acid, then

largely diluted with water and, after 24 hours, filtered. The insoluble portion is treated (if required with more chlorate and hydrochloric acid, then) with alcohol, and with ether to extract fat, and is ignited. The ash is treated with very dilute hydrochloric acid, and the residue dried, ignited, weighed, and proved conclusively to be silica by fusion with sodium carbonate; or is examined for silver, lead, barium, and strontium. The soluble portion is made up to a definite volume, and must be free from chlorine and chloric acid.

For mercury, a portion is nearly neutralised by means of potash, and is digested with brass wool for 15 minutes at 70°; if the brass is visibly amalgamated, the presence of mercury is confirmed by heating in a test-tube, &c.; but when the presence of mercury is not so evident, the brass wool is burnt with copper oxide in a current of air in a tube 25 cm. long, drawn out to a doubly bent capillary, in which any mercury is accumulated, and identified with iodine. To estimate mercury, the hot hydrochloric solution is treated with hydrogen sulphide, the precipitate collected on an asbestos filter (or if arsenic is present, it is first digested with yellow ammonium sulphide) washed with hydrochloric acid, dissolved in nitric acid, filtered through some asbestos, and the washings and filtrate diluted and treated with phosphorous acid. After 24 hours, the calomel is filtered off, washed with water, alcohol, and ether, and weighed on a tared filter. Throughout the estimation, high temperatures and contact with organic matter are to be avoided.

To detect antimony, some of the liquid partly neutralised with ammonia is placed in a bright platinum dish with a piece of zinc for six hours; the brownish-black antimony flakes obtained in this manner being more trustworthy than Marsh's test. This test does not answer in the presence of tin; but by fusing the mixed oxides with sodium hydroxide, most of the tin can be separated. To estimate antimony, hydrogen sulphide is passed through the slightly acid, and at first boiling, solution until it has cooled down; after three days, most of the hydrogen sulphide is driven off by carbonic anhydride, the precipitate washed with an acetic acid solution of ammonium acetate, treated and washed with a solution of sodium sulphide, containing hydrogen sulphide, the solution treated carefully with hydrochloric acid, warmed, and then boiled. After 24 hours, the precipitate is collected, treated with an acetic acid solution of ammonium acetate, then carefully with nitric acid, evaporated, the residue moistened with sodium hydroxide, intimately mixed with dry sodium carbonate, dried, introduced by small quantities at a time into fused sodium nitrate in a silver crucible, and the mass, when cold, treated with water. After 24 hours, the precipitate is washed with 45 per cent. alcohol, containing soda, digested with a hot solution of tartaric and hydrochloric acids for half an hour, filtered, and washed with a dilute solution of tartaric and hydrochloric acids. The filtrate and washings combined are concentrated in a water-bath, the excess of acid reduced with ammonia, and the antimony precipitated by hydrogen sulphide as a pure orange-coloured sulphide which is converted into oxide by Bunsen's method. The purity of the antimony is ultimately confirmed by its volatility.

To detect arsenic, mercury and antimony being absent, various obvious precautions are observed in applying the Marsh test to some of the liquid, and when a mirror is obtained, the tube containing it is divided by a diamond into four parts, of which one is used for the odour test, another for solubility in freshly-prepared sodium hypochlorite, a third for dissolving in nitric acid and testing with silver nitrate, whilst the fourth is dissolved in nitric acid, and converted into arsenic sulphide by colourless ammonium sulphide. To estimate arsenic, hydrogen sulphide is passed through the warm hydrochloric solution for 12 hours, and after remaining three to five days in a closed flask, most of the hydrogen sulphide is driven off by a current of carbonic anhydride; the procedure then resembles that described in the antimony estimation, but various points are to be observed:—

1. Ammonia or ammonium carbonate are the only solvents used for arsenic sulphide on the filter.
2. The fusion is conducted in a porcelain crucible with fusion mixture and potassium nitrate.
3. The arsenic is always weighed as magnesium pyroarsenate.
4. The alkaline solution is not precipitated directly with magnesia mixture, but is first submitted to the following treatment:—Neutralisation with nitric acid, expulsion of carbonic anhydride and nitrous acid, precipitation with hydrogen sulphide, and conversion into arsenic acid.
5. The ammonium magnesium arsenate is redissolved in hydrochloric acid and reprecipitated by ammonia.
6. Small quantities of magnesium arsenate are converted into pyroarsenate by dissolving in very dilute nitric acid, evaporating in a porcelain crucible over a water-bath, and carefully and gradually igniting the residue; the method is susceptible of great accuracy; as little as 0.0093 to 0.0077 gram of arsenic in a portion of a dead body has been estimated.
7. Large quantities of pyroarsenate are preserved as such for reference; small quantities are converted into metallic arsenic in a Marsh's apparatus, and are preserved in a sealed tube.

In the absence of mercury, antimony, and arsenic, the hydrochloric acid solution is made alkaline with soda, acidified with acetic acid, hydrogen sulphide passed in at the boiling point of the liquid and until cold, sodium carbonate added to distinct alkalinity, and the whole allowed to remain corked up until clear. The solution serves for detecting and estimating tin. The precipitate is washed with sodium sulphide containing hydrogen sulphide, oxidised with nitric acid, evaporated, moistened with sodium hydroxide, mixed with fusion mixture, dropped into molten nitre in a silver crucible, extracted with water, supersaturated with hydrochloric acid, filtered, and the hydrochloric acid solutions submitted to the ordinary methods of analysis, weighing any metal isolated in a definite form. The separation of iron, alumina, and zinc in the presence of calcium and magnesium phosphates is effected in the following manner:—The hydrochloric acid filtrate from the hydrogen sulphide precipitate is concentrated on the water-bath, treated with chlorine-water, evaporated, the residue dissolved in very dilute hydrochloric acid, filtered, the solution supersaturated with ammonia, excess of the latter nearly expelled on the water-bath, the precipitate removed, the solution acidified with acetic acid, and hydrogen sulphide passed into the boiling hot liquid until it gets cold. The zinc

sulphide is weighed. The ammonia precipitate is dissolved in nitric acid, treated in a platinum dish with tin, which by repeated and careful treatment with nitric acid is converted into stannic oxide, and with it the phosphoric acid into insoluble stannic phosphate, from which the alumina is washed out by very dilute nitric acid, and estimated in the solution by precipitating with ammonia, igniting the precipitate, fusing the ignition residue with sodium carbonate, extracting with water, filtering, &c. The alkaline filtrate from the hydrogen sulphide precipitate is examined for tin:—It is acidified with hydrochloric acid, boiled, hydrogen sulphide passed through until it is cold; after remaining for 24 hours in a warm place the precipitate is collected, washed with an acetic acid solution of ammonium acetate, and ignited with the filter. The residue is moistened with nitric acid, evaporated, ignited, and to get rid of the iron present it is washed into a silver crucible, dried, and treated for half-an-hour with molten sodium hydroxide, extracted with water, filtered, the filtrate acidified with hydrochloric acid, and the tin obtained in the usual manner.

In conclusion, it is pointed out that not only are potassium, sodium, calcium, magnesium, iron, and manganese normally present in the human body, but that aluminium, copper, and zinc are always met with, and less frequently tin and lead. These extraneous metals are derived from food, cooking utensils, medicine, &c.; aluminium comes from various sources, and even after death may be introduced in the dust, when the post-mortem takes place in the country. The author in advocating his employment of a solution prepared directly from the corpse material for the detection of arsenic, points out that considering the sensitiveness of the arsenic reaction a concentration of the solution is not necessary, that the "brown speck" on the porcelain lid referred to by Otto cannot interfere in his method, which, moreover, obviates any chance of vitiation through arsenical hydrogen sulphide. It is also shown that the presence of chlorides and nitrates does not stop the formation of gaseous hydrogen arsenide, provided that the zinc and hydrochloric acid are in excess and the evolution of hydrogen is allowed to proceed sufficiently long; but the presence of free nitric acid stops the evolution temporarily. It is still doubtful whether solid hydrogen arsenide is converted into the gaseous modification by zinc and hydrochloric acid.

Ordinarily only one poison is found in a corpse, but nevertheless it should be borne in mind that there is the possibility of more than one being present.

D. A. L.

Detection of Paraffin in Beeswax. By H. HÄGER (*Zeit. anal. Chem.*, 29, 480—481; from *Pharm. Centralhalle*, 30, 565).—A few grams of the substance in fine, air-dried shavings is gradually heated in a small, porcelain capsule, until fumes begin to rise. A half-litre wide-mouthed bottle is then inverted upon the capsule, and when filled with white vapours is closed and set aside until the fumes have condensed upon its walls. The sublimate is then dissolved in 3 c.c. of chloroform, the chloroform evaporated in a test-tube, and the residue boiled with 4 c.c. of soda solution. If paraffin was present, it will after cooling be found floating on the clear solution. A drop of

the chloroform solution may also be evaporated on a slip of glass and examined microscopically.

The fumes from pure beeswax are not so white as from paraffin, and are only obtained at a higher temperature (300—320°). The sublimate gives a coloured solution with chloroform, and a coloured and turbid solution with soda. The residue from the chloroform solution is a dull film; paraffin on the contrary gives separate grains in a clear field.
M. J. S.

Condition of the Sulphuric Acid in Plastered Wines, and a Method of Distinguishing between Plastered Wines and Wines mixed with Sulphuric Acid. By L. ROOS and E. THOMAS (*Compt. rend.*, 111, 575—577).—Wines which have been mixed with calcium sulphate do not contain potassium hydrogen sulphate. The liberated tartaric acid interacts with the organic potassium compounds in the wine, and forms a new quantity of potassium hydrogen tartrate. Direct experiment shows that when calcium sulphate is added to a solution of potassium hydrogen tartrate, and an acetate, malate, citrate, or succinate, the liquid contains no free sulphuric or tartaric acid, but acetic, citric, malic, or succinic acid is liberated. No potassium hydrogen sulphate could be detected in plastered wines by the following method, which will detect the addition of 0.25 gram of sulphuric acid per litre.

The proportion of chlorine and the total sulphuric acid in the wine are estimated. 50 c.c. of the wine is mixed with a small quantity of ammonium acetate, and exactly precipitated with a standard solution of barium chloride. The filtrate is evaporated to dryness, heated gently, and the chlorine in the residue is estimated. If only normal potassium sulphate is present, the reaction is $K_2SO_4 + BaCl_2 = BaSO_4 + 2KCl$, and the chlorine in the residue should be equal to the chlorine of the barium chloride, plus the chlorine originally present in the wine; if the acid sulphate is present, the reaction is $KHSO_4 + BaCl_2 = BaSO_4 + HCl + KCl$, and the free hydrogen chloride is expelled in the process of evaporation, the loss increasing with the quantity of hydrogen-sulphate present.
C. H. B.

Estimation of Dissolved Solids in Wine. By E. LÁNZLÓ (*Chem. Zeit.*, 14, 438, 455).—Results are quoted, showing the unsatisfactory character of estimations of "extractives" made by drying residues for 2½ hours. The author suggests determining the alcohol both by distillation and by an alcoholometer at 15°; the difference between the two observations being due to the "extractives" present may be utilised as a measure for them, and he finds that multiplying this difference by 0.32 gives numbers for the quantity of dissolved solid matter in 100 c.c. of wine concordant with actual determinations. The alcoholometer should not have a greater range than 10°, or at the outside 12°, and for wines of sp. gr. greater than 1.000, a saccharometer showing volume percentages is employed.
D. A. L.

Detection of Methylated Nitrous Ether. By J. MUTER (*Analyst*, 15, 48).—Much of the sweet spirits of nitro in commerce is prepared from methylated spirit instead of from pure ethyl alcohol

as prescribed in the pharmacopœia. The two may be discriminated by dissolving a fragment of solid potash in a sample. The methylated ether darkens, the colour varying from deep-yellow to orange-red, while the odour of methylated spirit becomes very distinct. The ether from pure spirit loses its odour of ethyl nitrite, and retains only that of ethyl alcohol, and it does not darken beyond the faintest straw colour. On treating with Hubl's reagent the distillate obtained after digestion with potash, the methylated sample will absorb 0.4 to 0.7 per cent. of iodine, but that from pure spirit none.

M. J. S.

Analysis of Carbolic and Sulphurous Disinfecting Powders. By J. MURER (*Analyst*, 15, 63—68).—The author calls attention to the ambiguities in the usual forms of specification for disinfecting powders. Whilst the contracts are nominally for "carbolic acid," it is commonly understood that the powder may contain chiefly cresol and other high-boiling tar phenols. There have, however, been cases where the supply of the more costly absolute phenol has been insisted on. The omission of the word "available" before "sulphurous acid" sometimes renders a literal compliance with a specification impossible.

For the estimation of the phenols, the author still employs his own process (*Abstr.*, 1888, 92), with the single modification that 150 c.c. of a 10 per cent. solution of sodium hydroxide is now used instead of 200 c.c. of a 5 per cent. solution. The cresol, measured in contact with brine, retains about 5 per cent. of water. Since anhydrous cresol increases in volume by about 5 per cent. when shaken with 3 volumes of brine, whilst that containing water does not increase or may even diminish, this furnishes a rough but ready test for the presence of water. For more accurate work the water must be distilled out. Naphthalene, which is usually present in commercial cresol, may be estimated as follows:—50 c.c. is shaken with 200 c.c. of a 10 per cent. solution of sodium hydroxide. The phenols dissolve, leaving the naphthalene floating. The solution is removed, the naphthalene washed with a 5 per cent. soda solution, then rapidly filtered off. It is rinsed from the filter with water and again collected on a pair of filters. After drying as far as possible by pressing between blotting paper, the filters are separated and the inner one with its contents is weighed, using the outer one as a tare.

For estimating the available sulphurous acid, 2 grams of the powder is washed on a filter with dry ether until the phenols and tarry matters are removed. As soon as the ether has evaporated, the contents of the filter are thrown into a bottle containing 50 c.c. of N/10 iodine solution, and after half an hour the residual iodine is titrated by thiosulphate. This method is unsatisfactory when the basis of the powder is lime.

In sulphurous powders which have undergone oxidation, the amount of original sulphurous acid cannot be ascertained if the mixture had consisted of gypsum and calcium sulphite, but where the basis is silica, the sulphates present may be regarded as oxidised sulphites, and where sodium hydrogen sulphite has been mixed with gypsum, the estimation of calcium, sulphuric, and sulphurous acids in an aqueous extract will give the necessary data.

M. J. S.

Detection of Diresorcinol as an Impurity in Synthetically Prepared Phloroglucinol. By J. HERZIG and S. ZEISEL (*Monatsh.*, **11**, 421—423).—The presence of diresorcinol, as an impurity in phloroglucinol, scarcely affects its melting point, or the numbers obtained on estimating carbon and hydrogen. It may be best detected by dissolving a few milligrams of the sample in about 1 c.c. of concentrated sulphuric acid, adding 1—2 c.c. of acetic anhydride, and warming the mixture for a few minutes in a water-bath. If diresorcinol—or its tetrethyl ether or tetracetyl derivative—be present, a bluish-violet colour, which disappears on the addition of much water or of an excess of alkali, will be produced. By this means, the presence of 0·4 per cent. of diresorcinol may be clearly shown, and the delicacy of the test is probably much greater. G. T. M.

Estimation of Sugars by means of Copper Potassium Carbonate Solution. By H. OST (*Ber.*, **23**, 3003—3011; compare *Abstr.*, 1890, 1031).—A solution containing 23·5 grams of crystallised copper sulphate, 250 grams of potassium carbonate, and 100 grams of hydrogen potassium carbonate per litre has the following advantages over Fehling's solution for the gravimetric determination of sugars:—(1) It is unchanged by keeping. (2) Its action on cane-sugar is relatively slight. (3) After 10 minutes boiling, the precipitation of cuprous oxide is practically complete, and thus more concordant results are obtained. (4) The monosaccharoses precipitate almost twice as much cuprous oxide from this solution as from Fehling's solution. (5) The quantity of precipitate obtained from different kinds of sugars varies considerably, thus rendering it possible to determine the composition of mixtures. The solution may also be employed for volumetric estimations, as the end reaction is sharp; the time required for boiling, is, however, longer than with Fehling's solution. For gravimetric determinations, 50 c.c. of the copper solution is mixed with 25 c.c. of the sugar solution, water is added and the liquid boiled for 10 minutes, filtered through an asbestos filter, and the cuprous oxide reduced in a stream of hydrogen. The following table shows the quantity of copper precipitated by different sugars:—

Copper.	Invert-sugar.	Dextrose.	Levulose.	Galactose.	Arabinose.
Milligrams.	Milligrams.	Milligrams.	Milligrams.	Milligrams.	Milligrams.

In the case of lactose, the factor copper/lactose = 1.51 to 1.57 for solutions containing from 125 to 198 milligrams of sugar. For volumetric work, an indicator must be employed; after 20 minutes boiling, 198 milligrams of lactose precipitate 190 milligrams of copper.

Raffinose, $C_{12}H_{22}O_{11} + 5H_2O$, does not affect the copper solution,

but after hydrolysis, it has the highest reducing power, 50 milligrams precipitating 150 milligrams of copper. J. B. T.

Estimation of Sugar in Milk. By M. KÜHN (*Bied. Centr.*, 19, 628; from *Milchzeit.*, 18, 926).—Results obtained by Tollens' method agree better with those obtained by Soxhlet's method, when only so much serum solution is employed that the colour is bluish after boiling. If so much sugar solution is used that the liquid is greenish after reduction, results will be obtained which are 0.1 to 0.15 per cent. too low. The phosphotungstic acid method is not recommended. If Soxhlet's method is not used, the lead acetate method should be employed. N. H. J. M.

Estimation of Ash in Raw Sugar. By W. MINOR (*Chem. Zeit.*, 14, 510).—Stammer objects to the use of oxygen, and recommends air for the incineration of raw sugar in estimations of ash. The author has investigated the point, and sees no reason for disqualifying oxygen nor any special virtue in the atmospheric nitrogen, and as burning the charred sugar in oxygen takes 25 minutes, whilst combustion in air, with the aid of mechanical agitation, requires from 6 to 15 hours, he considers the oxygen method is distinctly to be recommended. D. A. L.

Estimation of Starch. By O. REINKE (*Zeit. anal. Chem.*, 29, 472—475; from *Zeit. Spiritindust.*).—The author divides the processes hitherto proposed into those with and without high pressure, and recommends the following as the best of the respective methods:—*With high pressure:* 3 grams of the finely ground substance is stirred with 25 c.c. of a 1 per cent. solution of lactic acid and 30 c.c. of water in a metallic beaker, then covered and heated for $2\frac{1}{2}$ hours in a digester (Soxhlet's or Lintner's) at $3\frac{1}{2}$ atmospheres pressure, then mixed with 50 c.c. of hot water and, after cooling, made up to 250 c.c. and filtered. 200 c.c. is then inverted by cohobating with 15 c.c. of hydrochloric acid (1.125 sp. gr.) for $2\frac{1}{2}$ hours, then neutralised with soda, made up to 500 c.c., and 25 c.c. of it titrated with Fehling's solution. *Without high pressure:* 3 grams of the substance is boiled with 50 c.c. of water, and then digested for an hour at 62.5° with 0.05 gram of Lintner's diastase. It is then cooled, made up to 250 c.c., and 200 c.c. inverted with acid as above. For the preparation of Lintner's crude diastase, 1 part of green malt is extracted for 24 hours with 2 to 4 parts of 20 per cent. alcohol. The extract, filtered by suction, is precipitated with twice, or at most $2\frac{1}{2}$ times, its volume of absolute alcohol. The upper liquor is poured off and the precipitate thrown upon a pressure filter, then rubbed down with absolute alcohol in a mortar, again filtered and washed with absolute alcohol and then with ether, and finally dried in a vacuum over sulphuric acid. For the purification of this raw product, the precipitation and digestion with alcohol, washing with ether, and drying are repeated. By this means, albuminoid impurities are rendered insoluble and dextrinoid extractive matters removed. The dried product is a loose, yellowish-white powder, which has no action on

Fehline's solution either before or after boiling with hydrochloric acid, and which does not turn brown when its solution is evaporated on the water-bath. It exhibits great hydrolytic activity.

M. J. S.

A New Application of Molisch's Reactions. By G. COLASANTI (*Gazzetta*, 20, 299—305).—Molisch (Abstr., 1886, 923) found that the merest traces of sugar or glucosides (0.00001 per cent.) could be detected by the addition of one or two drops of an alkaline solution of α -naphthol or thymol (15 to 20 per cent.), together with an excess of concentrated sulphuric acid. Molisch further derived from this reaction a confirmation of the alleged presence of sugar in normal urine.

The author finds that extremely dilute solutions of potassium or sodium thiocyanate, treated in the same manner, show first a green band and, on agitation, an intense violet coloration resembling in all respects that obtained from solutions of sugar. On cooling the liquid, a compound containing the naphthalene nucleus and the sulphonic group separates in a mass of long, slender needles. The solution of thiocyanate or thiocyanic acid must be very dilute, or on addition of sulphuric acid a brown coloration is produced, and hydrogen sulphide is evolved. Urine must similarly be diluted before treatment with α -naphthol, and altogether fails to give the thymol reaction.

As urine has been found to contain thiocyanic acid, Molisch's reaction affords no confirmation of the presence of sugar in that fluid.

S. B. A. A.

Reaction of Thiocyanic Acid. By G. COLASANTI (*Gazzetta*, 20, 306—308).—If a few drops of a solution of auric chloride ($\frac{1}{100}$ th per cent.) made alkaline with a saturated solution of sodium carbonate or a 5 per cent. solution of potash are added to a few c.c. of a dilute solution of a thiocyanate (0.01 per cent.), a deep violet coloration is obtained, and a precipitate of metallic gold gradually separates. The thiocyanic acid in urine does not give the reaction, the liquid merely acquiring a reddish coloration.

S. B. A. A.

Schneider's Method for the Estimation of Malic Acid in Wine. By E. NIEDERHÄUSER (*Chem. Centr.*, 1890, ii, 172; from *Pharm. Centralhalle*, 31, 378—379).—100 c.c. of the wine is neutralised with decinormal alkali, evaporated, incinerated, and the carbonic anhydride in the ash determined. From this amount, the quantity of carbonic anhydride equivalent to the total tartaric acid present is deducted, the difference being then calculated into malic acid. Since, however, wines usually contain other substances (tannic, succinic, acetic acids), all of which neutralise alkalis, and would when incinerated produce carbonates, the author considers the method valueless.

J. W. L.

Comparison between Methods for Estimating Tartaric Acid. By J. TÜRK (*Chem. Zeit*, 14, 63—64).—To compare the three rival methods for the estimation of tartaric acid, the "original Goldenberg" method, the "Lorenz-Guldenberg" method, and the "modified Goldenberg" method, the author made simultaneous and duplicate

estimations in crystalline calcium tartrate, in wine lees, in argol, and in tartaric acid, following rigidly the directions laid down in each method; the numbers obtained are tabulated, and from the results it is concluded that the Lorenz modification of the Goldenberg method is the best method, and is applicable in all cases, a specially valuable factor about it being the introduction of one-third normal soda for the titration. With regard to Boessneck's suggested method, the author shows that the amount of antimonious oxide taken up by the calcium tartrate is not $\frac{1}{2}$ a mol. for 1 mol., but is a variable quantity, which seems to depend on the amount of free tartrate in solution.

D. A. L.

Estimation of Tartaric Acid. By J. WOLFMANN (*Chem. Zeit.*, 14, 220; compare Tóth, preceding abstract).—The author considers the use of litmus tincture unsatisfactory in deeply coloured tartaric solutions; he has noticed neutralisation of alkali by humus in such solutions, and does not regard the question of the estimation of tartaric acid as solved by the Lorenz method, in fact, looks with greater favour on the Goldenberg-Geromont results. He himself endeavoured unsuccessfully to determine tartaric acid by titration with permanganate.

D. A. L.

Estimation of Tartaric Acid in the Crude Products of Tartaric Acid Factories. By J. TELBISZ (*Chem. Zeit.*, 14, 347).—In consideration of results recently published by Tóth (see above), the author has made several estimations of tartaric acid in various samples of calcium tartrate and dried wine lees, applying, with much precision, both the "original" and "modified" Goldenberg-Geromont, and also the Lorenz method: the results are tabulated, and in his hands the latter method yielded undoubtedly higher results than the first two methods, and he agrees with Wolfmann (preceding abstract) in considering the modified Goldenberg-Geromont method the most trustworthy, up to the present time. Variations as great as 7–10 per cent., noted by Tóth, in different estimations of the same sample by this method, have not been observed in the present experiments.

D. A. L.

Estimation of Citric Acid in Parts of Plants. By E. CLAASSEN (*Zeit. anal. Chem.*, 29, 468–469).—The plant is extracted with very dilute ammonia and ammonium carbonate, the liquid somewhat concentrated, precipitated with lead acetate, and filtered. The dried precipitate is boiled out with strong alcohol, then suspended in water, and decomposed by hydrogen sulphide. The filtrate is evaporated to a thin syrup, mixed with ammonium chloride, excess of ammonia, and calcium chloride, and 3 volumes of alcohol added. The precipitate is filtered, washed with 75 per cent. alcohol, dried, and dissolved in hot dilute hydrochloric acid. After cooling, it is filtered, treated with excess of ammonia, and again filtered, and evaporated on the water-bath to dryness. The residue is taken up with boiling ammoniacal water, and the insoluble calcium citrate collected on a weighed filter. Traces of citrate in the filtrate may be recovered by repeating the evaporation.

M. J. S.

Amount of Volatile Fatty Acids in Rancid Butter. By P. CORBETTA (*Chem. Zest.*, 14, 406).—Samples of fresh butter were taken and examined on the 16th of February for volatile fatty acids; they were then exposed in vessels covered with paper, and again examined on April 3rd, when, in all cases, a reduction in the quantity of volatile fatty acids was observed; in a subsequent examination on April 30th, no further change was noted, but a final test, on August 9th, indicated a still further falling off in these acids. The disappearance of volatile fatty acids in the rancid butter, although progressive in these experiments, was in no instance very considerable, and in no case could volatile fatty acids be washed from the rancid butter either by water or sodium hydrogen carbonate. D. A. L.

Butter and Margarine. By C. VIOLETTE (*Compt. rend.*, 111, 345—347).—The acids resulting from the saponification of 50 grams of pure, dry butter by aqueous potash are distilled in a current of steam, and the successive portions of the aqueous distillate (the total volume of which should not be less than 10 litres) are titrated with normal sodium hydroxide, using phenolphthalein as an indicator. The volatile acids, which solidify, and the non-volatile acids also, are weighed, after being dried in a vacuum and melted. A table is given showing the results obtained with various butters and with margarine. It is assumed, on the evidence of Duclaux's results, that the ratio between butyric and caproic acids in genuine butter remains constant, and equal to 1.645.

In ordinary butters the mean proportion of volatile acids is 7.6 per cent., with a minimum of 7.0, and the proportion of non-volatile acids is 84.0 per cent., with a maximum of 84.6. In the case of a butter of high quality, the addition of about 20 per cent. of margarine would lower the proportion of volatile acids from 8.5 to the minimum of 7 per cent., and would raise the non-volatile acids from 82.63 to 84.76. In the case of ordinary butter, the addition of 9 per cent. of margarine would reduce the volatile acids to 7 per cent.

C. H. B.
Optical Analyses of Butters. By C. VIOLETTE (*Compt. rend.*, 111, 348).—From his observations, the author concludes that butter and margarine have different indices of refraction, the deviations in the oleorefractometer being -33° to -27° for butters, and -15° to -8° for margarines. The indications of the oleorefractometer are sufficiently exact when the instrument is applied to mixtures of constituents giving known deviations. It is necessary to ascertain, by means of a large number of observations, the minimum deviation below which a butter may be regarded as adulterated with margarine. The oleorefractometer may be used for the analysis of commercial butters, but its indications will not be very exact, because these butters will give deviations below the minimum for good butters, and the proportion of margarine deduced from the results will be too low.

C. H. B.
Analysis of Lard, Cotton Oil, and Tallow. By J. MUTER and L. DE KONINGH (*Analyst*, 15, 48—50).—Employing the method described by themselves (*Analyst*, April, 1889) for estimating the

liquid fatty acids in fats, and for treating them with iodine without exposure to air, the authors have obtained the following results. They regard tallow as the best material for the preparation of oleic acid, and for this acid they find the iodine absorption to be 90 per cent., and to vary at most 0·2 per cent. from theory. The oleic acid from lard never gives so low a number, the average being about 93 per cent., whilst that from cotton oil is found to be 135, with very little variation. In consequence of this wide difference, the percentage of cotton oil in a sample of adulterated lard can be indirectly estimated with considerable accuracy. M. J. S.

Beeswax. By A. BUISINÉ and P. BUISINÉ (*Bull. Soc. Chim.* [3], 3, 867—873).—The authors confirm the results previously obtained by Hübl and Hebner with respect to the free, total, and combined acids of beeswax; further, they have determined the iodine numbers for this substance, and describe a process for estimating the alcohols present. This consists in the fusion of the wax with potassium hydroxide and potash lime at 250°, which causes the evolution of hydrogen proportionally to the amount of alcohols acted on, and from the residue of this experiment the hydrocarbons existing in the wax are determined by extraction with a suitable solvent. Their results for pure, dry, washed beeswax are summarised:—

M. p. 63—64°. Entirely soluble in hot chloroform.

Wax Acids.

Free acids corresponding with	19—21 milligrams KHO per gram.
"	13·5—15·5 per cent. cerotic acid.
Total acids	91—97 milligrams KHO per gram.
Combined acids	72—76
"	32·85—34·67 per cent. palmitic acid
Ratio of free to combined acid	3·5 to 3·8.

Iodine Numbers.

100 parts of wax absorb 8·3—11 parts iodine; which corresponds to 9—12 per cent. oleic acid.

Wax Alcohols.

Hydrogen liberated by fusion with KHO, 53·5—57·5 c.c. per gram.

Wax Hydrocarbons.

M. p. 49·5. Percentage 12·5—14. Iodine fixed by 100 parts of hydrocarbon 22·05. T. G. N.

Estimation of Resin in Soap. By R. WILLIAMS (*Analyst*, 15, 81—82).—Gladding's method (Abstr., 1885, 603) yields very good results. The author prefers to work on the soap itself rather than on the acids separated from it. M. J. S.

Estimation of Camphor. By F. FOERSTER (*Ber.*, 23, 2981—2989).—A number of substances now occur in commerce, consisting

of nitrocellulose and camphor, and up to the present no method is known for estimating the amount of camphor which they contain. The author proposes to carry out the estimation by distilling the substances with soda solution, when the camphor readily passes over. This may be then extracted with benzene, and the specific rotatory power of the benzene solution ascertained. Detailed instructions for carrying out the reaction, and tables of the rotation of camphor in benzene solution at different concentrations and temperatures are given in the original. The results obtained are about 0.7—1.0 per cent. too low, probably owing to the difficulty of driving out the last portions of camphor.

The author finds that sublimed camphor contains a small quantity of impurity, and that for the determination of its rotatory power, high temperatures must be avoided in its preparation, and the camphor finally twice recrystallised from 50 per cent. alcohol. It then melted at 174.8—175.3°, and after six crystallisations at 176.3—176.5°, and after 10 crystallisations the solidifying point was found by Landolt's method (*Abstr.*, 1890, 1) to be 178.7° (corr.). The boiling point of the purified camphor was 209.1° under 759 mm. H. G. C.

Estimation of Tannin in Tea. By P. MALTSCHERFSKY (*J. Pharm.* [5], 22, 270—271; from *Pharm. Zeit. f. Russ.*, 29, 127).—The tannin is precipitated by means of normal copper acetate, and the excess of copper is titrated by the aid of potassium ferrocyanide solution. The copper solution contains 7.657 grams of copper oxide per litre (1 c.c. = 0.01 tannin), and its strength is controlled by evaporating a measured volume to dryness, moistening with nitric acid, heating to redness, and weighing the oxide. The ferrocyanide solution is prepared by making up to 1 litre, 100 c.c. of a saturated solution. To standardise this solution, it is added, 1 c.c. at a time, to 5 c.c. of the copper solution diluted to 100 c.c., until a drop of the mixed liquids gives a blue colour with a solution (1 : 100) of ferric chloride. A second assay, in which the additions of ferrocyanide solution are made by tenths of a c.c. towards the end, gives the exact strength of the solution. 2 grams of tea dried at 100—107° is extracted four times with 100 c.c. of boiling water each time; the filtrates are united, made up to 400 c.c.; 100 c.c. of this solution is boiled and treated with 10 c.c. of copper solution. The precipitate is filtered off, washed with hot water, and the filtrate and washings are made up to 200 c.c.; half of this is taken, and the excess of copper is determined approximately by means of the ferrocyanide solution; the second half of the solution then serves for the exact determination of the copper. In 14 samples, the amount of tannin varied from 6.10 to 11.08 per cent. The water varied from 5.59 to 12.48 per cent.; ash, 3.14 to 9.25; aqueous extract, 17.3 to 39.4; caffeine, 1.09 to 2.88 per cent. J. T.

Estimation of Urea. By P. MIQUEL (*Compt. rend.*, 111, 501—502).—Many of the urophagic microbes, and especially micrococci and sarcinae, can develop in a neutral and even in a slightly acid cultivation fluid. Several grow solely at the bottom of the vessels and produce more or less granular deposits without rendering the

liquid turbid, whilst at the same time they produce a large quantity of the soluble ferment (this vol., p. 100). These clear liquids should be used for the estimation of urea.

An aqueous solution of urea is simply mixed with the cultivation fluid containing the ferment; the alkalinity is at once estimated by titration, and the liquid is heated at 50° for two hours in a well-closed vessel, which it nearly fills. The alkalinity is again determined, and from the quantity of ammonium carbonate formed the amount of urea present is calculated.

Urine and other organic liquids are previously heated with a slight excess of ammonium carbonate, filtered if necessary, and then mixed with the ferment, the object of this treatment being to prevent loss of ammonia from formation of double salts, neutralisation of any acid present, &c.

A quantity of urea exceeding 10 per cent. interferes with the activity of the ferment, and in solutions of 30 per cent. the ferment is inactive. Concentrated solutions must, therefore, be diluted. Ammonium carbonate, sodium chloride in small proportion, uric acid, ammoniacal and alkaline salts, extractive matters, albumin, and sugar in large quantity do not interfere with the results. C. H. B.

Simple Mode of Estimating Urea. By C. W. HEATON and S. A. VASEY (*Analyst*, 15, 106—107).—The method, which does not aim at great accuracy, is suggested for the use of medical men in cases where none of the special forms of apparatus is available. An 8-ounce bottle is fitted with a thistle funnel and gas delivery tube which dips under water in a basin. In the bottle is placed 1 fluid drachm of bromine and 10 fluid drachms of a 40 per cent. solution of caustic soda. A bottle full of water is inverted over the delivery tube to receive the gas; 2 fluid drachms of urine is then poured into the generator and rinsed in by 1 fluid drachm of water, and the bottle is shaken until gas ceases to be evolved. The receiver is then closed by the thumb, removed from the basin, placed in an upright position, and filled up with water, the volume required being noted. Deducting 200 minims for the volume of air displaced by the urine and water introduced into the generator, the remainder is equal in volume to the nitrogen evolved, and each 100 minims corresponds with 0.25 per cent of urea. M. J. S.

Rapid Method of Estimating Urea in Urine. By C. J. H. WARDEN (*Analyst*, 15, 201—203).—The apparatus is a modified Crum's nitrometer, 630 mm. long and of about 75 c.c. capacity. Into its lower end is ground a stopper, on which 10 narrow grooves have been filed. The cup above the stopcock is of 5 c.c. capacity, and is accurately marked at 2.5 c.c. The tube is graduated to show percentages of urea at once, assuming that 1 per cent. of urea in 2.5 c.c. of urine will yield 9.27 c.c. of gas. The hypobromite solution is stated to be made by dissolving 100 "grains" (? grams) of caustic soda in 750 c.c. of water and adding 25 c.c. of bromine. The inverted tube is filled with this solution and the stopper inserted. Its exterior and the cup are then rinsed and

dried. It is stood in a vessel of brine and the stopper is removed. 2.5 c.c. of urine is then placed in the cup and there mixed with its own volume of saturated brine to increase its density, and this mixture is allowed to enter the tube in small portions. The last traces are rinsed in by brine. The tube is then grasped by the right hand, the thumb being tightly pressed against the open end, and the contents thoroughly agitated. It is then transferred to a vessel of water, where the heavy solutions flow away, and the volume of the nitrogen is read in the usual manner. M. J. S.

Estimation of Theïne in Tea. By G. L. SPENCER (*Chem. Centr.*, 1890, ii, 172; from *J. Amer. Chem. Soc.*, 4, 158).—2 to 3 grams of the finely ground tea is extracted in a small beaker seven times with boiling water, the extract being each time decanted off, and the residue finally transferred to a filter, and washed with a few c.c. of boiling water. Basic lead acetate is added to the extract, about 8 c.c. usually being sufficient; the precipitate is filtered, washed with hot water, and the lead separated as sulphide, after which the filtrate is concentrated to about 50 c.c., with addition of about 5 grams of calcium hydroxide or magnesium oxide. The liquid is again filtered, the insoluble portion extracted with hot water, and the filtrate is extracted with chloroform seven times. The chloroform extract is distilled from a tared flask, and the weight of the residual theïne recorded after drying at 75°. The method has been in use in the Department of Agriculture. J. W. L.

Estimation of Quinine. By SEATON and H. D. RICHMOND (*Analyst*, 15, 42–43).—In solutions containing quinine bisulphate dissolved in an acid, and free from salts whose base is precipitable by baryta, the quinine may be estimated by titration. Quinine bisulphate is neutral to methyl-orange, whilst the base itself has no action on phenolphthaleïn. To 25 c.c. of the solution there are added 2 drops of methyl-orange solution (0.25 gram in a litre of water), and 2 drops of phenolphthaleïn solution (0.5 gram in a litre of 50 per cent. alcohol). Baryta solution (N/10) is then run in until the red colour changes to a brown, at which point all the free acid is neutralised. The addition of baryta is then continued until the pink colour of the phenolphthaleïn appears. As the pink colour develops slowly, care must be taken not to overstep this point. The number of cubic centimetres required for this second stage, multiplied by 0.0218, gives the weight of the hepta-hydrated quinine sulphate present. M. J. S.

Reaction for Cocaine. By F. DA SILVA (*Compt. rend.*, 111, 348–349).—A small quantity of cocaine, or one of its salts, or of the residue obtained by evaporating a solution, is mixed with a few drops of fuming nitric acid of sp. gr. 1.4, evaporated to dryness on the water-bath, and the residue mixed with 2 or 3 drops of concentrated alcoholic potash. A distinct and peculiar odour, recalling that of peppermint, is developed. In Dragendorff's systematic scheme of

analysis, cocaine is found among the alkaloids extracted by benzene from an aqueous ammoniacal solution. Of the other alkaloids of the same group, atropine, hyoscyamine, strychnine, codeine, and eserine give colorations when treated in the same way, and eserine also develops a disagreeable odour resembling that of phenylcarbylamine. Delphinine, brucine, and veratrine give only indistinct odours, which cannot be confounded with that from cocaine. Sabadilline and narcotine can be recognised in the same way, but the other alkaloids give no sensitive reactions of this order.

The reaction will detect 0.5 milligram of cocaine hydrochloride.

C. H. B.

Detection of Colchicine in Corpses. By N. OBOLONSKI (*Zeit. anal. Chem.*, 29, 493).—The finely divided viscera are rubbed up with glass powder, treated with oxalic acid, and digested for 12 hours with alcohol. The liquid is squeezed out, and the dry residue twice washed with alcohol. The extract is concentrated at a temperature not exceeding 80°, and the cooled residue made up to the original volume with alcohol. The filtered liquid is evaporated as before, and this operation repeated until no clots separate on the addition of alcohol. The residue is then dissolved in water, the solution purified by shaking with light petroleum, and the colchicine finally extracted with chloroform as usual.

The alkaloid is best identified by means of the violet colour produced by nitric acid; by Erdmann's reagent (nitrosulphuric acid), which gives in succession green, dark-blue, violet, and yellow colours, turning to raspberry-red on adding alkali; also by Mandelin's reagent (1 gram of ammonium vanadate in 200 grams of sulphuric acid) which gives a green colour. Colchicine is with difficulty destroyed by putrefaction of animal matter. The kidneys, bladder, and urine are best suited for forensic examination.

M. J. S.

Detection of Bile Constituents in Urine. By A. JOLLES (*Zeit. anal. Chem.*, 29, 402–406).—Of the various tests proposed for detecting bile pigments in urine (Gmelin's, Huppert's, Vitali's, Rosenbach's, Ultzmann's, Hoppe-Seyler's, Dragendorff's), those of Rosenbach and Huppert, with the following modifications, give the best results:—

Rosenbach's Test.—A large quantity of the urine is filtered through clean, white filter-paper, the interior of the filter is touched with a drop of strong nitric acid containing nitrous acid, and the funnel is gently warmed over a flame. After a few minutes a green ring is formed round the spot moistened by the nitric acid.

Huppert's Test.—About 10 c.c. of the urine is shaken with an equal volume of milk of lime containing 10 grams of calcium oxide in the litre. The success of the test depends on the proper concentration of the milk of lime. The precipitate is filtered off and washed into a test tube with alcohol and dilute hydrochloric acid, then filtered, and the filtrate boiled. With only traces of bile pigments, the liquid becomes green to blue. An estimate of the amount of bile constituents can be obtained from the iodine number of the urine. If a

is the number of grams of iodine absorbed by 10 c.c. of the urine, and s the specific gravity, the iodine number is $\frac{1168g}{s-1}$. The number for normal urine, filtered after cooling, is 6.5 to 8.1, though even in specimens rich in uric acid it rarely exceeds 7.8. The presence of even traces of bile pigments raises the number to 9.6, and values as high as 17.4 have been observed. M. J. S.

New Test for Albumin. By A. JOLLES (*Zeit. anal. Chem.*, 29, 406—407).—About 8 or 10 c.c. of albuminous urine is mixed with an equal volume of concentrated hydrochloric acid, and then 2 or 3 drops of a saturated solution of bleaching powder deposited quickly on the surface. If as little as 0.01 gram of albumin per 100 c.c. is present, a white turbidity appears at the surface of contact. This test, being less sensitive than that with nitric acid, which latter will detect 0.0015 gram per 100 c.c., may be used to find approximately the proportion of albumin present, since by diluting the urine until the one test gives an indication but the other none, the percentage may be known to lie between the above minimum limits. M. J. S.

Detection of Albumin in Bacterial Urines. By A. JOLLES (*Zeit. anal. Chem.*, 29, 407—408).—The most sensitive test for albumin in urine is that with acetic acid and potassium ferrocyanide, the lower limit of which is 0.0008 gram in 100 c.c. It is, however, necessary to filter the urine to obtain a standard with which to compare the turbidity produced by the test. When bacteria are present, a clear filtrate is best obtained by shaking with infusorial earth before filtering. In the case of purulent, slimy urines, rich in leucocytes, traces of albumin may adhere to the precipitate; but by washing this with warm potash, and testing the filtrate, the smallest traces of albumin may be detected. M. J. S.

General and Physical Chemistry.

Spectra of the Alkali Metals. By H. KAYSER and C. RUNGE (*Ann. Phys. Chem.* [2], 42, 302—320).—The alkali metals or their salts were volatilised in the electric arc, and their spectra, obtained by means of a Rowland grating, were examined. It was found that lines belonging to any one series could be expressed in terms of λ^{-1} , the reciprocal of their wave-lengths, by the formula $\lambda^{-1} = A + Bn^{-2} + Cn^{-4}$, which is a modification of Balmer's formula, and in which n is a whole number, which may vary from 3 to 16.

All the alkali metals have a number of reversible lines, which occur in pairs (except in the case of lithium), and are divided over the whole length of the spectrum; these form the chief series. The formulæ for the first lines in each series of pairs are as follows:—

Lithium....	At. wt.	7.01	$\lambda^{-1} = 43584.73 - 133669n^{-2} - 1100084n^{-4}$.
Sodium....	"	22.995	$\lambda^{-1} = 41536.81 - 129935n^{-2} - 803301n^{-4}$.
Potassium..	"	39.09	$\lambda^{-1} = 35086.55 - 126983n^{-2} - 625318n^{-4}$.
Rubidium..	"	85.2	$\lambda^{-1} = 33762.11 - 125521n^{-2} - 562255n^{-4}$.
Cæsium....	"	132.7	$\lambda^{-1} = 33501.56 - 125077n^{-2} - 489885n^{-4}$.

The wave-lengths are given in Ångström units. It will be seen that all three constants in the formula decrease as the atomic weight rises. The wave-lengths, therefore, increase with rising atomic weight, as Boisbaudran has already pointed out. The difference between the values of λ^{-1} for lines in each pair is inversely proportional to the fourth power of n , the lowest value of n being always 3.

In addition to the above, there are also two series of lines for lithium, rubidium, and cæsium, which (again with the exception of lithium) form one series of pairs; and there are four series of lines for sodium and potassium, forming two series of pairs. The first lines in each pair are given by the above formula, the value of the constants being

	First Series.			Second Series.		
	A.	B.	C.	A.	B.	C.
Li.....	28586	109625	1847	28606	122391	231700
Na.....	24476	110122	3257	24549	120726	197913
K.....	21991	114450	111241	22031	119393	63243
Rb.....	20939	121193	133207	—	—	—
Cs.....	19743	122869	311224	—	—	—

The difference between the values of λ^{-1} for lines in the same pair is always the same for each element. It is equal to that of the first

series when $n = 3$, and appears, therefore, to be characteristic for each element. The mean values of this difference are Na, 172, K, 568, Rb, 2341, Cs, 5450, in wave-numbers. These numbers are very nearly in the proportion of the squares of the atomic weights, for if their square roots be multiplied by 1.706 we get

	Na, 23.0	K, 40.6	Rb, 82.6	Cs, 126.0,
instead of	22.995	39.09	85.2	132.7.

For lithium, assuming the above law to be general, the calculated difference between the pairs is one which would quite fall within the limits of observation, but as the lithium lines do not form pairs, this metal seems to be an exception to the rule.

A comparison has been made between the lines here measured and the Fraunhofer lines in Rowland's solar atlas. Only two pairs in the chief series of sodium lines could be detected, the lines of all the other elements being apparently absent.

Dispersive Power of Organic Compounds. By R. NASINI (*Gazzetta*, 20, 356—361).—A claim for priority as against Barbier and Roux (*Abstr.*, 1890, 1353).

Relation between the Refractive and Rotatory Powers of Chemical Compounds. By I. I. KANONNIKOFF (*J. Russ. Chem. Soc.*, 22, 85—96).—In two previous papers (*Abstr.*, 1888, 326, 453), the author has shown that on expressing the relation of the refractive and rotatory powers of a substance by the equation $\alpha = A\phi - B$, the relation $A/B = C$, a constant peculiar for the solvent, and independent of the optically active substance. The author has investigated solutions of camphor and turpentine in over 70 different organic solvents, and gives his results in tabular form. It is found that in homologous compounds, such as aliphatic alcohols, ethereal salts of fatty acids and their halogen derivatives, the free acids, the aldehydes, chlorides, bromides, &c., the constant C (as a mean = about 26) increases with every increase of CH_2 , the differences diminishing from the lower to the higher members, and varying between 1.35 and 0.46, or, as a mean = 0.85. The difference for an increase of $\text{H}_2 = 1.4$ in genetically connected compounds, and -2.5 for compounds of dissimilar constitution. Similar values are found for other changes in composition and constitution (double linkage, isomerism, polymerism, substitution), but it would occupy too much space to give the results in detail. For aromatic compounds, the equation $\alpha = A\phi - B$ of the fatty series is converted into $\alpha = A\phi + B$. But where in aliphatic compounds increasing complexity in composition is regularly accompanied by an increase of the value of C , in the case of aromatic compounds a decrease is observed. The author proposes to investigate the influence of inorganic solvents on the value C .

B. B.

New Photographic Method. By A. G. GREEN, C. F. CROSS, and E. J. BEVAN (*Ber.*, 23, 3131—3133).—The diazo-compounds of dehydrothiitoluidine and its condensed derivatives, which form the

dyes of the primuline group, can be employed for photographic purposes; as the sensitiveness of these compounds is increased by combination with the complex colloids which constitute animal or vegetable textile fabrics. The sensitive surface is prepared by colouring a cotton or silk fabric with primuline (1 to 2 per cent.), and then diazotising. Such a surface will give a complete positive picture after 40 to 180 seconds exposure, that is to say, in the bright lights the diazo-compound is completely, in the half lights only partially, decomposed, so that a perfect reproduction of the original is obtained in the form of diazo-primuline. The picture can be developed with any of the various amines or phenols which form a dye with the diazo-compound.

The authors' experiments have already brought to light the following facts:—(1.) The action of light consists in the decomposition of the diazo-group, with evolution of nitrogen, probably with formation of the corresponding primuline phenol. (2.) The rapidity of the action of light varies, *cæteris paribus*, with the nature of the substance with which the diazo-compound is combined. (3.) Photographic reproductions of the spectrum show that, as regards intensity of action, the various rays of light are not in the same order as that in which they stand with reference to halogen salts of silver.

F. S. K.

Action of Borax in Developers for Photographic Plates. By P. MERCIER (*Compt. rend.*, 111, 644—645).—Borax, although an alkaline salt, acts as a retarder of development when mixed with pyrogallol or catechol. The author points out that this is doubtless due to the formation of the conjugated acids described by Lambert (*Abstr.*, 1889, 864). Quinol, resorcinol, sodium amidonaphthol- β -sulphonate (eikonogen), and hydroxylamine hydrochloride do not form similar conjugated acids, and with these compounds borax acts as a very good accelerator of development.

C. H. B.

Optical Notes. By E. WIEDERMANN (*Ann. Phys. Chem.* [2], 41, 299—301). The violet colour of iodine dissolved in carbon bisulphide changes to brown when the solution is cooled by means of ether and solid carbonic anhydride (*Abstr.*, 1888, 543). The author now finds, in accordance with a statement by Liebreich, that when the brown solutions of iodine in ethereal salts of the fatty acids are heated to about 80° they become violet, provided the solutions be not too concentrated.

Solutions of eosin or Magdala-red in alcohol, heated in capillary tubes, are found to exhibit a very marked fluorescence at temperatures above the critical. Experiments with saffranine failed owing to its decomposition.

H. C.

Contact Difference of Potential of Metals. By F. PASCHEN (*Ann. Phys. Chem.* [2], 41, 186—209).—The author shows that an amalgam prepared by the electrolytic deposition of zinc on mercury changes in the electromotive properties which it at first exhibits, on merely being allowed to stand for some time. In order to restore its original properties, it must be submitted to a new and longer electro-

lysis. Thus 705.8 grams of mercury were placed in a solution of zinc sulphate of sp. gr. 1.288, and zinc deposited by a current from two Daniell cells for 30 seconds. The amalgam thus produced would contain 0.0000656 gram of zinc to 100 grams of mercury. The E.M.F. of freshly-prepared amalgam $[\text{ZnSO}_4]$, amalgamated zinc, was then measured and found to be 0.14 volt. After remaining for three hours, the E.M.F. had risen to 1.1291 volts, and a further electrolysis for 26 seconds was necessary to restore it to its original value. The above change is, however, only exhibited by an amalgam which contains very small quantities of zinc, and by increasing the quantity of zinc to a sufficient degree the property of the amalgam becomes practically constant.

The suggestion is made that dropping electrodes, similar to those described by the author (*Ann. Phys. Chem.* [2], 41, 62), might be used in determining the contact difference of potential of metals, if filled with the molten metals, and these be then allowed to flow into some suitable liquid electrolyte. If, as in the case of mercury, there is no potential difference at the place where the metal enters the electrolyte, the potential difference between two such electrodes will be that of the metals which they contain. Great practical difficulties lie in the way of such experiments as those here suggested, but it may in some cases be possible to use in place of the metals themselves the amalgams which they form with mercury. The author describes a number of experiments made in this manner with zinc amalgam, and shows that the E.M.F. amalgam | mercury, varies with the amount of zinc contained in the amalgam, the variation in these experiments being from 0.021 to 0.156 volt.

H. C.

Electrical Conductivity of Precipitated Membranes. By G. TAMMANN (*Zeit. physikal. Chem.*, 6, 237—240).—A solution of cupric sulphate superposed on a solution of potassium ferrocyanide precipitates at the dividing surface an exceedingly fine membrane of cupric ferrocyanide, which permits the transfusion of water, but not of any of the salts present in the solutions. Notwithstanding this, the author finds that the presence of such a membrane in an electric circuit does not increase the resistance. His mode of experiment was as follows. He prepared solutions of the above-mentioned salts, having equal electrical conductivity, and superposed them in an electrolytic cell, so that one horizontal electrode was in one solution, the other electrode in the other. The current had thus to traverse the precipitated semipermeable membrane, and it was found that the resistance remained exactly as before. A membrane of zinc ferrocyanide behaves similarly at first, but after some time it increases in thickness, becomes opaque and permeable for the salts, its resistance meanwhile growing greater, and attaining a maximum in about 15 minutes. Precipitated membranes of zinc and cupric hydroxides thicken rapidly and diminish the conductivity by from 5 to 8 per cent. Membranes of insulating material, such as pyroxylin, increase the resistance enormously, the only conduction being probably that through the pores. (Compare Ostwald, *Abstr.*, 1890, 1354.)

J. W.

Influence of Water of Crystallisation on the Electrical Conductivity of Salt Solutions. By J. TRÜTSCH (*Ann. Phys. Chem.* [2], 41, 259—287).—The conductivities of solutions of a large number of different salts have been determined for temperatures ranging from 10° to 80°. The Kohlrausch telephone method was employed, and in order to obviate the difficulty arising from evaporation of the solutions at the higher temperatures the top of each solution was covered with a layer of molten paraffin. The conductivities were measured at every 10°, and the difference d between consecutive readings is taken as a mean temperature coefficient for the 10° rise of temperature.

Solutions of salts which are ordinarily anhydrous in the solid state, such as KCl, NaCl, KNO₃, have temperature coefficients which rise continually with the temperature, or which attain a maximum and then remain constant. On the other hand, the temperature coefficient of solutions of hydrated salts at first increases, reaches a maximum, and then decreases, the author attributing this last behaviour to the loss by the salt of its water of crystallisation. Calcium chloride forms an exception to this rule, the three solutions examined, which contained 4·5, 19·2, and 32 per cent. CaCl₂, behaving throughout as solutions of anhydrous salts. The temperature coefficient in the case of the second solution, however, only undergoes a slight increase with rising temperature, and is far smaller than that of the first or third solutions. Five solutions of cupric chloride were examined, having the percentages 1·35, 9, 18·2, 28·7, 35·2. The two concentrated solutions are green, the two dilute solutions blue, and the colour of the third solution is intermediate between the two. All these solutions behave as solutions of hydrated salts, the temperature coefficient in each case reaching a maximum at between 40° and 50°. At the same temperatures, a change in colour is also observed, the green solutions becoming yellow and the blue solutions becoming green. In each case these changes seem, therefore, to be conditioned by a dehydration of the salt taking place as the temperature rises. Cobalt chloride shows a somewhat similar behaviour, the colour of the solutions changing from red to blue on heating, and at the same time the temperature coefficient reaching a maximum. The temperature of the change is, however, higher in this case, and therefore it is not so readily observed.

The author concludes that salts are contained in solution partly as hydrates and partly in the anhydrous state. At high temperatures, the hydrates part with their water, this taking place the more readily in the more concentrated solutions. The water of hydration exercises a specific influence on the electrical conductivity of solutions.

H. C.

Electrical Conductivity of Saline Solutions. By P. CHROUSHTCHOFF and W. PANEKOFF (*J. Russ. Chem. Soc.*, 22, 110—115), and by CHROUSHTCHOFF (*ibid.*, 115—116).—The two papers contain a large number of experimental data as regards the conductivity of aqueous solutions of salts and mixtures of salts and acids, but the conclusions arrived at are the same as those contained in Chroushtchoff's previous papers (*Abstr.*, 1889, 808—809).

B. B.

Solubility of Mixtures of Electrolytically Dissociated Substances. By A. A. NOYES (*Zeit. physikal. Chem.*, 6, 241—267).—It has been shown by Nernst (this vol., p. 3) that the principles regulating the influence of two salts on each other's solubility are those deduced from the general law of mass action as interpreted in the light of the electrolytic dissociation theory. The author, in the present paper, contributes an account of his experimental work on the subject. He investigated 11 pairs of salts, and finds the results of his experiments in very good agreement with the theoretical values. Most of the work was done with binary electrolytes, for example, $\text{AgBrO}_3 : \text{AgNO}_3$, $\text{TlSCN} : \text{TlNO}_3$, but a few ternary electrolytes were shown to give results equally in harmony with the theory. Experiments were made not only with pairs of salts containing one ion in common, but also with pairs whose ions were all different.

Reckoning back from the solubilities, it is possible to calculate the dissociation constants of strong electrolytes. This is a fact of considerable importance, for the ordinary method of calculation from the electrical conductivity fails in such cases to give a constant number at all. J. W.

Method of Determining Thermal Expansion for Equal Quantities of Heat. By E. J. DRAGOMIS (*Zeit. physikal. Chem.*, 6, 281—284).—Let V be the volume of a substance; g its weight; α its coefficient of cubical expansion; c its specific heat; g its specific gravity; Δt the rise of temperature, and A the expansion caused by the communication of 1 cal.; then $A = V\alpha\Delta t$. But $\Delta t = 1/cg$ and $V/g = 1/s$; therefore $A = \alpha/cs$. In the case of gases, A is evidently inversely proportional to the molecular heat, for α is constant for all gases, and s varies inversely as the molecular weight.

The author determines A in the following manner: A dilatometer packed in cotton wool contains the substance whose expansion is to be measured, and also a platinum spiral, the ends of which are fused through the walls. By means of this spiral the substance is heated, a current of about 0.2 ampère being passed. From the current, the heat communicated is easily calculated, and the expansion for this amount is observed. Comparative experiments with various liquids were executed, and the results found to be satisfactory. J. W.

Estimation of the Specific Gravity of Frothy Syrups. By A. GENIESER (*Zeit. ang. Chem.*, 1890, 44—45).—A tared pycnometer is about two-thirds filled with the syrup, in which air-bubbles are entangled, and the weight is noted. It is then carefully heated in a salt bath, and maintained in ebullition for a few moments. The whole of the air rises to the surface, where it forms an extremely thin layer of froth. After cooling, water is added, so as to float on the surface without mixing. The froth readily dissolves, and the air escapes. The pycnometer is then filled to the mark with water, and weighed. On deducting the excess of weight, above that of the syrup taken, from the total amount of water which the pycnometer will

contain, the remainder gives the weight of water equal in volume to the syrup taken, and thence the specific gravity. M. J. S.

Dissociation Phenomena. By A. W. v. HOFMANN (*Ber.*, 23, 3303—3319).—*Dissociation of Carbonic Anhydride.*—In 1860, the author published a paper in conjunction with H. Buff, in which it was stated that carbonic anhydride is gradually decomposed by the passage of a series of electric sparks through the gas, and that after a time the carbonic oxide and oxygen recombine with explosive violence. A repetition of these experiments has shown that the explosion only occurs under certain special conditions. 6—10 c.c. of dry carbonic anhydride under a pressure of 650—700 mm. are brought into a stout glass tube standing over mercury; a short piece of platinum wire is fused into the shorter limb of a thin U-shaped tube, the tube is filled with mercury, and a second piece of wire wound spirally round the outside of the shorter limb, which is then passed up into the vessel containing the gas; in this way the length of the spark may be readily regulated; in general it should be 2.5—3 mm. Connection is made by two wires dipping into the mercury contained in the U-tube and trough respectively. The electric current is obtained from two Bunsen's elements of medium size, which are connected with a Ruhmkorff's coil and a small Leyden jar, the coil being 30 cm. long and 10 cm. in diameter.

The first explosion usually occurs after 15—20 minutes, and the subsequent ones at shorter intervals, since the regeneration of the carbonic anhydride is not complete. The dissociation of carbonic anhydride may be shown by passing the gas through a glass tube, in the middle of which two platinum terminals are fused; a series of sparks is allowed to pass, and the issuing gas collected over potash; part of the gas remains undissolved, and is found to be explosive. Carbonic anhydride does not appear to be at all affected by a glowing spiral of wire; it was not found possible to prepare the gas free from air.

Dissociation of Steam.—The accompanying illustration (next page) shows a form of apparatus which may be employed for the purpose of showing the dissociation of steam at varying pressures. The wide glass tube is 2.5 cm. in diameter and 20 cm. in length, the lower tube is 1 cm. in diameter and 40 cm. in length; the apparatus is filled with moist mercury and heated with steam; instead of fixed terminals, the U-tube and wires described above may be employed; in one experiment 2.9 c.c. of gas were obtained after ten minutes; no regeneration of water occurred, as in the case of carbonic anhydride. The experiment may be varied by allowing the apparatus to cool whilst the electric current is continued; the dissociated gases gradually combine, and the whole tube becomes refilled with mercury. The current employed is obtained from three Bunsen cells, with the coil and Leyden jar as before. Steam may also be dissociated by means of a glowing white hot spiral of platinum wire; the two ends are connected with accumulators, steam is passed over the coil, and the mixed gases are collected over cold water, which serves to condense the excess of steam.

Dissociation of Gases and Vapours by the Silent Discharge.—Experi-

ments in this direction show that ozone is produced by the decomposition of carbonic anhydride, the results of Andrews and Tait, Brodie,

and others being thus confirmed. Steam may also be decomposed by passing it through a Siemens ozone tube, or by the use of the modified apparatus devised by Berthelot; various experiments were made to prove that the explosive gas obtained was really derived from the steam, and was not due to electrolysis. Berthelot's results on the decomposition of ammonia by means of the silent discharge are confirmed. The vapours of methyl alcohol, ethyl alcohol, and ethyl ether may also be dissociated by means of the silent discharge.

J. B. T.

Influence of Mineral Acids on the Velocity of the Reaction between Bromic and Hydriodic Acids. By G. MAGNANINI (*Gazzetta*, 20, 377—393).—The reaction between bromic and hydriodic acids was shown by Ostwald (Abstr., 1888, 1024) to form an exception to the ordinary rule of mass action, and neither Meyerhoffer's (Abstr., 1889, 9) nor Burchard's (Abstr., 1889, 208) expressions are found to satisfy the experimental data respecting the variation of the speed of the reaction. These discrepancies are evidently occasioned by secondary reactions, which alter the velocity of the changes at every instant. Ostwald found that mineral acids increase the speed of the reaction, and that the increments are sensibly proportional to the affinity coefficients of the respective acids, or to the quantity of hydrogen electrolytically dissociated from them. The author has continued Ostwald's investigations on the accelerating or retarding

effects of mineral acids on this reaction, experimenting with hydrochloric, nitric, sulphuric, and bromic acids, with mixtures of some of these acids, and with potassium bromate; from the tabulated results, he draws the following conclusions. During the course of the different changes, the reaction is influenced in the same way by the secondary actions. The reciprocal values of the times required for the separation of a determinate quantity of iodine vary as the velocity of the respective reactions. The velocity of the reaction is accelerated by hydrochloric acid, but the acceleration is not proportional to the quantity of acid present. The quantity of iodine deposited after equal times in presence of equivalent quantities of hydrochloric and nitric acids is the same. Mixtures of hydrochloric and nitric acids, in any proportions, are equivalent to either of the acids, so that, independently of the nature of the electro-negative radicle, it may be said that the velocity of the reaction depends entirely on the quantity of hydrogen electrolytically dissociated, without, however, being proportional to it. The action of sulphuric acid is more complicated, on account of the incomplete dissociation of that acid. The accelerating effect of bromic acid is almost six times that of hydrochloric or nitric acid.

S. B. A. A.

Velocity of the Halogenisation of Fatty Hydrocarbons. By M. WILDMANN (*Ber.*, 23, 3174—3175).—The following two laws are deduced from a study of the action of bromine or chlorine in sunlight on amyl bromide, amylene bromide, liquid and solid tri-bromopentane, tetrabromopentane, and amylene chloride:—(1) Substitution proceeds more slowly as the quantity of positive hydrocarbon becomes smaller. (2) The larger the quantity of hydrocarbon present, the quicker the substitution.

J. B. T.

Cryoscopic Investigation of Colloidal Substances. By A. SARANSKIY (*J. Russ. Chem. Soc.*, 22, 102—107).—The author has shown that Raoult's method may be conveniently employed for the determination of the molecular weight of colloidal substances (*Abstr.*, 1890, 1215). Similar results were obtained by Morris and Brown, by Ekstrand and Manzelius. On the other hand, Paternò, in his research on gallic and tannic acids, has arrived at the conclusion that their molecular weights cannot be determined by Raoult's method. The values obtained by Paternò give 10 mols. of the first, and 100 mols. of the second, as the molecular weights in solution. The author shows that Paternò's paper includes an error in calculation, and that the values greatly depend on the purity of the material. First the molecular weight of gallic acid was determined. It was dried at 120°, losing 9.65 per cent. water, corresponding with the formula $C_7H_6O_6 + H_2O$. In aqueous solution, containing 0.5238 per cent., the depression was 0.06°, and the molecular weight 166; in acetic acid, containing 0.4107 part, the depression was 0.095°, molecular weight = 168, whereas the value for $C_7H_6O_6$ is 170; gallic acid exists, therefore, as a single molecule in solutions.

Commercial tannin was found to contain some gallic acid, the quantity of which, as calculated from the depression of the impure

preparation, compared with that of the pure preparation, was found to be 2.39 per cent. It was dried for 20 hours at 120° , and the loss was 10.66 per cent. Aqueous solutions with a concentration of 0.822–3.773 show a depression of 0.015–0.060, giving a molecular weight of 1044–1195 (mean, 1104). More concentrated solutions, containing 5.5 to 9.5 per cent., gave higher molecular weights, 1497 to 2136, but the values are useless, as solutions of more than $\frac{1}{4}$ per cent. of tannin in water become turbid at 0° , tannin separating out. In Paternò's solutions, containing 11.5–23 per cent. of tannin, $\frac{1}{3}$ – $\frac{2}{3}$ of the tannin must have separated at 0° in the insoluble state, and his (corrected) molecular weights, = 2643–3700, are of no value. The author finds in acetic solution, molecular weights = 1105–1114 (mean 1113). Pure tannin was prepared by Löwe's method, but it was impossible to work with aqueous solutions, as not more than 0.5 per cent. is dissolved in water at 0° , and even such weak solutions became turbid. In acetic acid solution, as a mean, $M = 1322$ was found, whereas, M calculated for $(C_{14}H_{10}O_6)_4 = 1288$, so that tannin exists in solutions as a quadruple molecule. The author thinks that Paternò's tannin was not quite dry, and shows by experiment that such a preparation causes a much larger depression, owing to the contamination of the glacial acetic acid by the water of crystallisation of the compound. The author says that the empirical formula of tannin requires confirmation by further research. B. B.

Apparatus for Distillation under Reduced Pressure. By H. WISLIGENUS (*Ber.*, 23, 3292–3295).—The author describes two forms of apparatus for use with the Bunsen pump, to prevent backward diffusion. The first consists of a tube, with one round and one pear-shaped bulb; in the depression between these a rubber ring is placed, one end of the tube is sealed, a small opening is made in the side and is covered with a piece of rubber tube, or an ordinary Bunsen valve may be attached; the other end of the tube is connected with the vessel to be exhausted, the pear-shaped bulb fits into a wide tube, the rubber ring serving to make the connection air-tight; the second tube is joined to the pump in the usual manner. The second form of valve consists of two tubes, one closely resembling a thistle funnel, the narrow end of which is attached to the pump; a bulb with a small aperture is blown at the end of the second tube, and it is covered with a rubber cap, through which an opening is pierced at a little distance from the one in the glass; the rubber cap serves to make an air-tight connection between the bulb and the wide end of the first tube.

An apparatus for fractional distillation under reduced pressure is also described; it consists of a combination of several of the first of these joints, and provision is made for changing the receiver without interrupting the distillation. J. B. T.

Isomorphism. Part III. By J. W. RETGERS (*Zeit. physikal. Chem.*, 6, 193–236).—In this communication (for previous papers see *Abstr.*, 1890, 328, 1208), the author first discusses the relations of morphotropy. He would limit the term morphotropic to such substances as show a

total analogy of form, and not, for instance, merely analogy of angles in one zone. Isomorphous substances have not only this total form-analogy, but also analogy of chemical constitution. Morphotropic substances are not necessarily chemically analogous, but must be chemically connected with each other. Substances which show a total form-analogy, but have no chemical resemblance, are termed isogonic. In the regular system, for instance, potassium chloride and rubidium chloride are isomorphous; potassium chloride and sodium chloride are morphotropic; and sodium chloride and sodium chlorate, isogonic.

Isomorphous mixtures are proved by the continuous linear change of physical properties with the composition of the mixture. No intimate crystalline mixture can be obtained with merely morphotropic substances, and in this case identity of system, and of degree of hemihedry, are not essential. The author rejects Marignac and Klein's conception of mass isomorphism, according to which an element or group, largely preponderating in a compound, determines the crystalline form, no matter what the other components may be. It is the *volume* and not the *weight* of the group that is decisive.

An investigation follows of the supposed isomorphism between potassium and sodium sulphates. The author proves that a definite double salt, $3K_2SO_4 \cdot Na_2SO_4$, crystallises from a solution of the mixed sulphates. It usually crystallises in hexagonal prisms or pyramids, but when the mother liquor contains sodium chloride, it separates in tables—the “plate-sulphate” obtained in the manufacture of iodine from kelp. Potassium chloride does not effect this change of form. The three simple forms are then—

K_2SO_4 . Rhombic, pseudo-hexagonal. Forms pyramids and prisms of hexagonal section. Optically biaxial. Weak birefringence. Sp. gr. = 2.666. Not easily fusible.

$3K_2SO_4 \cdot Na_2SO_4$. Hexagonal. Forms pyramids and prisms. Optically uniaxial. Marked birefringence. Sp. gr. = 2.695. Easily fusible.

Na_2SO_4 . Rhombic, but not pseudo-hexagonal. Forms only pyramids with rhombic section. Optically biaxial. Strong birefringence. Sp. gr. 2.673. Fusible with great difficulty.

The double salt is not an isomorphous mixture, as is shown by a consideration of its properties in relation to those of the simple salts. Each simple salt can take up a minute quantity of the other, which points to a very limited isodimorphism. The general results are—

- (1) K_2SO_4 and Na_2SO_4 are not isomorphous.
- (2) They only form one double salt, $3K_2SO_4 \cdot Na_2SO_4$.
- (3) From mixed solution the pure double salt separates out alongside one or other of the simple salts.
- (4) K_2SO_4 and the double salt are morphotropic.
- (5) Na_2SO_4 is not morphotropic either with K_2SO_4 or with the double salt, but is crystallographically completely independent.

The dolomite series is next discussed. In this series we have calcspars containing a little magnesium carbonate, magnesites containing a little calcium carbonate, and dolomites which have the two salts in nearly equal molecular proportions. Calculated from the

specific gravities of the component salts, that of dolomite should be 2·843; it is actually 2·872. The author considers the series not isomorphous, but merely morphotropic.

J. W.

Inorganic Chemistry.

Affinities of Iodine in Solution. By H. GAUTHIER and G. CHARPY (*Compt. rend.*, 111, 645—647).—If mercury is agitated with any solution of iodine, a green precipitate of mercurous iodide is formed, but if the mercury contains another metal, the iodine combines with the latter in proportions depending on the nature of the solvent. In the case of an amalgam of lead, the difference in colour between lead and mercurous iodides enables the change to be followed.

Brown solutions of iodine (in alcohol, ether, acetone) yield with lead amalgam a yellow precipitate of lead iodide, even when the proportion of lead is very small, and no mercurous iodide is formed until all the lead has been converted into iodide.

On the other hand, violet solutions of iodine (in chloroform, carbon bisulphide) give green mercurous iodide, even in presence of considerable quantities of lead and when the iodine is in excess.

Solutions of intermediate tint give precipitates intermediate in colour between lead iodide and mercurous iodide, and it is found that if the solutions of iodine in various solvents are arranged in order according to their colour, and also according to the colour of the precipitate which they yield when agitated with lead amalgam, the two orders are the same. The colour of the precipitate is independent of the composition of the amalgam and the concentration of the iodine solution.

Careful examination of the reaction shows that brown solutions of iodine and pure mercury at first yield mercuric iodide, which passes into solution, whilst violet solutions of iodine at once form mercurous iodide, even whilst some free iodine remains. In presence of lead amalgam, brown solutions of iodine first form mercuric iodide, which attacks the lead, forming lead iodide and mercurous iodide, and the latter is again converted into mercuric iodide by the free iodine. No permanent precipitate of mercurous iodide is formed with brown solutions until all the lead has been converted into iodide.

It follows from these results that violet solutions of iodine contain the element in a more simple molecular condition, with a tendency to at once form mercurous iodide, this tendency being more marked, the simpler the condition of the iodine. The phenomena seem to belong to the same order as those to which Berthelot has given the name "tendency to conservation of type."

C. H. B.

Fluorspar from Quincié. By H. BECQUERREL and IL. MOISSAN (*Compt. rend.*, 111, 669—672).—It is well known that certain

specimens of fluor spar, when powdered, emit a peculiar odour, which has been attributed by different observers to free fluorine, hypochlorous acid, ozone, hydrocarbons, &c. The fluor spar examined by the authors was deep violet in colour, and came from Quincié, near Villefranche. It had the composition Ca , 36.14 ($= \text{CaF}_2$, 70.47); FeO , + Al_2O_3 , 3.95; SiO_2 , 25.00; loss at a red heat 2.10 per cent; sp. gr. 3.117.

When powdered, it emitted an odour recalling that of ozone and likewise that of fluorine. Moissan has shown that fluorine decomposes water with liberation of ozone. The odour from the fluor spar is very similar to that emitted from the electrolytic cell in the isolation of fluorine, and even if the odour is due to ozone, the latter may be a product of the action of free fluorine on the moisture of the air.

Fluor spar from Quincié, when powdered in contact with moist air, evolves a gas which at once acts on ozone paper. If moistened with starch paste and potassium iodide solution, and powdered under a microscope, bubbles of gas are seen to escape, and an intense blue coloration is produced. When the fluor spar is powdered with sodium chloride or potassium bromide or iodide, free chlorine, bromine, or iodine is liberated. When heated above a red heat, the fluor spar decrepitates, loses its colour, and becomes ochreous, and afterwards gives no trace of ozone when powdered. If heated at 250° for an hour, which is quite sufficient to destroy all ozone, it still gives, when powdered, a strong reaction with ozone paper.

Small fragments of the mineral, when heated in a small glass tube, corrode its surface; when powdered with silicon, a pungent odour is emitted, and if the mixture is heated, silicon fluoride is evolved. If small fragments of the mineral are left in contact with water, the water becomes acid, and if the liquid is then evaporated in watch glasses, the latter are corroded.

No similar results were obtained with a white fluor spar from the Pyrenees, and although it is possible that the fluorine results from the dissociation of a perfluoride, the authors regard it as more probable that the free fluorine is occluded in the mineral.

C. II. B.

The Molecular Weight and Refractive Energy of Sulphur Dichloride. By T. COSTA (*Gazzetta*, 20, 367—372).—The existence of a definite compound of the composition SCl_2 has been repeatedly called in question (see this Journal, 1870, 455; 1871, 1163; Abstr., 1878, 553; 1886, 977); and the substance held by some to be sulphur dichloride has been variously regarded as a solution of chlorine in the monochloride, or as a compound in a state of partial dissociation. The author has determined cryoscopically the molecular weight of the reddish-brown liquid obtained by saturating the monochloride with chlorine below 0° , and then removing any excess of chlorine by passing in a current of carbonic anhydride, and the results of the determinations, both in benzene and acetic acid solution, agree with the molecular formula SCl_2 . This substance can, therefore, no longer be said to exist in a state of partial dissociation. Its density at 15.4° is 1.64819 and its molecular refractive energy $\mu_{\text{SCl}_2} = 1.57169$, $\mu_{\text{SCl}_2} = 1.57806$.

S. B. A. A.

Specific Gravity of Sulphuric Acid of Different Degrees of Concentration. By G. LUNGE and M. ISLER (*Zeit. ang. Chem.*, 1890, 129—136).—In consequence of the discovery of errors in Kolb's table, the authors have made fresh determinations with great care. The curve plotted from the results, whilst agreeing in many places closely with that of Kolb, is much smoother, and at the extremes, differs somewhat considerably. The table, of which the following is an abstract, was obtained by graphic interpolation; in the original, it is given for intervals of 0.005 (1° Twaddell) in the specific gravity:

Sp. gr. at 15° in <i>vacuo</i> .	Percentage of H_2SO_4 .	Sp. gr. at 15° in <i>vacuo</i>	Percentage of H_2SO_4 .	Sp. gr. at 15° in <i>vacuo</i> .	Percentage of H_2SO_4 .
1.000	0.09	1.400	50.11	1.800	86.90

M. J. S.

Reduction of Oxygen Compounds with Sodium. By M. ROSENFIELD (*Ber.*, 23, 3147—3149).—Sodium may be obtained in a finely-powdered condition by trituration with some other solid substance. Such a mixture of sodium and zinc oxide ignites spontaneously, and leaves a residue of metallic zinc. Ferric oxide and lead oxide react in a similar manner, whilst gypsum is reduced to calcium sulphide. Certain organic compounds, such as pyrogallol, wheat starch, or salicylic acid, inflame immediately on admixture with sodium, carbon being separated; other substances, such as milk sugar and cane sugar, after admixture with sodium, require to be exposed to moist air before reaction takes place. In the case of compounds which only contain carboxylic oxygen, the sodium salt of the acid is formed. Sodium benzoate and sodium oxalate are obtained from benzoic and oxalic acids respectively. The carbonaceous residue from rosaniline, toluidine, albumin, and other amido-compounds contains sodium cyanide; brucine, morphine, and strychnine yield a

porous mass of charcoal free from cyanogen. Both sodium cyanide and sodium cyanate were obtained from uric acid. "Saccharin" yields a residue containing sodium thiosulphate and sodium cyanide.

J. B. T.

Ammonium Pyrosulphite. By A. FOCK and K. KLÜSS (*Ber.*, 23, 3149—3151).—Ammonium pyrosulphite, $(\text{NH}_4)_2\text{S}_2\text{O}_5$, is prepared by passing sulphurous anhydride into cold, concentrated, aqueous ammonia until the liquid becomes yellow; it is then allowed to evaporate spontaneously in a vacuum. The salt crystallises in large, thick, deliquescent plates, which belong to the rhombic system. Marignac has shown that the corresponding potassium salt crystallises in the monoclinic system.

J. B. T.

Properties of some Beryllium Salts and of the corresponding Aluminium Compounds. By F. SESTINI (*Gazzetta*, 20, 313—319).—(1.) *Phosphates.* The phosphates were prepared in the gelatinous state by precipitating beryllium sulphate and potassium alum respectively with disodium phosphate, and washing the precipitate for 4 to 6 days; they are both sparingly soluble in distilled water, the beryllium salt being considerably the more soluble of the two. On igniting the moist beryllium phosphate, it left 6 per cent. of its weight of white anhydrous phosphate. A litre of a saturated solution of beryllium phosphate in 2 per cent. acetic acid contains 0.550 gram of the anhydrous salt (containing, however, 74.9 per cent. P_2O_5 instead of 74.2 per cent.). A similar solution of the aluminium salt, however, contains 0.375 gram of phosphate dissolved, containing 87.1 per cent. P_2O_5 (instead of 54.8 per cent.); this excess of acid is probably due to the formation of a little beryllium pyrophosphate and to the conversion of a portion of the aluminium phosphate by the acetic acid into a more soluble acid phosphate.

A litre of a saturated solution of the beryllium salt in 10 per cent. acetic acid contains 1.725 grams, and the corresponding aluminium solution 0.30 gram of the respective anhydrous phosphates. On gently heating the acetic acid solution of beryllium phosphate, it becomes turbid, and near the boiling point a white precipitate of a basic phosphate, of the formula $3\text{BeO}, \text{P}_2\text{O}_5, 3\text{H}_2\text{O} + \text{Aq.}$ is deposited; a solution of the aluminium salt at most becomes opalescent.

(2.) *Carbonates.*—100 c.c. of water saturated with carbonic anhydride at the ordinary pressure dissolves 0.185 gram of anhydrous beryllium oxide, and the solution becomes turbid on agitation or on boiling. Under the same conditions, only 0.001 gram of aluminium oxide passes into solution. The solubility of the beryllium oxide is due, according to the author, to the formation of an acid carbonate.

S. B. A. A.

Magnesium Lead Chloride. By R. OTTO and D. DREWES (*Arch. Pharm.*, 228, 495—498).—A hot concentrated magnesium chloride solution dissolves a considerable amount of lead chloride and deposits, on cooling, a double chloride, $\text{PbCl}_2, 2\text{MgCl}_2 + 13\text{H}_2\text{O}$, in small, white, lustrous, indistinct crystals. The salt is exceedingly hygroscopic; moisture quickly converts it into a solution of magnesium

chloride, holding lead chloride in suspension. Calcium and lead chlorides appear to give a similar compound. J. T.

Electrolysis of Fused Aluminium Fluoride. By A. MINIER (*Compt. rend.*, **111**, 603—606). The composition of the bath which gives the best results corresponds with the formula $12\text{NaCl} + \text{Al}_2\text{F}_6 \cdot 6\text{NaF}$; melting point 675° ; temperature at which vapours are evolved, 1035° ; sp. gr. at $820^\circ = 1.76$; coefficient of expansion 5×10^{-4} ; electrical conductivity at $870^\circ = 3.1$. The relation of the conductivity to the temperature is expressed by the equation $C_t = 3.1[1 + 0.0022(t - 870^\circ)]$. For a current of 1200 ampères, the mass of the bath is 20 kilos., the intensity of the current at the positive pole is 1 ampère, and the difference of potential between the electrodes is 5.5 volts. The composition of the bath is kept constant by the gradual addition of a mixture of aluminium hydroxide, $\text{Al}_2\text{O}_3(\text{OH})_3$, 416.4 parts, cryolite, 210.4 parts, and aluminium oxy-fluoride, $\text{Al}_2\text{F}_6 \cdot 3\text{Al}_2\text{O}_3$, 238.4 parts.

The difference of potential, ϵ , between the electrodes when the electromotive force is considerably below that required to produce decomposition is expressed by the equation $\epsilon = KI$, I being the intensity of the current, and the temperature being constant. As the point is approached at which the electromotive force of polarisation is equal to the electromotive force of decomposition of the electrolyte, the difference of potential cannot be calculated by means of any simple expression. At 870° , the maximum density of the current at the electrodes, corresponding with the first period of electrolysis of the bath specified, varies between 0.02 and 0.03 ampère.

During the second period of electrolysis, when the electromotive force is sufficient to produce decomposition, up to a density of 1 ampère at the positive electrode, the difference of potential is expressed by the equation $c = e + \rho I$, where e is the electromotive force of decomposition, and ρ is the resistance of the electrolyte. At 852° , $e = 2.15$ and $\rho = 0.01$; at 890° , $e = 2.40$ and $\rho = 0.0044$; at 980° , $e = 0.34$ and $\rho = 0.0033$. For densities of current higher than 1 ampère, the difference of potential cannot be calculated as a function of the intensity of the current by any simple expression; it rapidly attains a value similar to that existing in the electric arc.

In presence of salts of iron or silicon, within certain limits of density of current at the positive electrode, the salts decompose according to Sprague's law. At 810° , with salts of iron, $e = 0.75$ and $\rho = 0.0093$; at 840° , with silicon compounds, $e = 1.37$ and $\rho = 0.0089$; at 870° , with aluminium salts, $e = 2.15$ and $\rho = 0.0085$.

(C. II. B)

Preparation of Chromium from Potassium Chromium Chloride and Magnesium. By E. GLATZEL (*Ber.*, **23**, 3127 3130).—Chromium can be quickly prepared in an almost chemically pure condition in the following manner:—Potassium dichromate (100 grams) is dissolved in the least possible quantity of water, the solution mixed with hydrochloric acid of sp. gr. 1.124 (400 c.c.), and then 80 per cent. alcohol (100 c.c.) gradually added. The solution of potassium chromium chloride obtained in this way is treated

with potassium chloride (160 grams), the filtered solution evaporated to dryness, the residue heated until anhydrous, freed from the green portions, which are produced by the decomposition of the double salt, then powdered, and mixed with magnesium filings (50 grams). This mixture is heated, for about half an hour, to a bright-red heat, in a closed Hessian crucible in a wind-furnace, care being taken that the potassium chloride does not volatilise completely, otherwise the chromium is partially oxidised. The melt is separated from the superficial layer of chromium oxide, treated with water, and the finely divided metal freed from salts and unchanged magnesium by washing it with water, then boiling it with dilute nitric acid, and again washing with water, all the washing being done by decantation. The yield of the metal, dried at 100° , is about 27 grams.

Chromium, prepared in this way, is a light-gray, crystalline, non-magnetic powder of sp. gr. 6.7284 at 16° ; it can be melted in a Deville's furnace, but only with great difficulty, and after being melted it shows a silvery fracture. Two analyses of the powder showed that it contained 99.53 to 99.57 per cent. of chromium, and that it was free from silver and magnesium. F. S. K.

Mineralogical Chemistry.

Selenium and Tellurium Minerals from Honduras. By E. S. DANA and H. L. WELLS (*Amer. J. Sci.*, 40, 78—82).—The authors received a number of specimens of minerals containing selenium and tellurium from El Plomo mine, Ojojama District, Honduras. Two of these have proved to be of unusual interest. The first occurs in massive forms, with hexagonal cleavage, of a blackish-gray colour, disseminated through a gangue consisting chiefly of quartz and barytes. After deducting 65.68 per cent. of gangue, the analytical results obtained were as follows:—

Se.	Te.	Total.
29.31	70.69	100.00

The mineral is obviously an isomorphous mixture of selenium and tellurium, and is of great interest in that it is the nearest approach to native selenium which has yet been found. The authors propose to call this mineral *Selen-tellurium*. In connection with the hexagonal cleavage of this mineral, it is interesting to note the recent observations of Muthmann (*Zeit. f. Kryst.*, 17, 356), showing the existence of an allotropic form of metallic selenium in hexagonal-rhombohedral crystals, closely isomorphous with tellurium. In the analysis, the separation of selenium and tellurium was effected by the method of Divers and Shimosé (*Trans.*, 1885, 439).

The second mineral is obviously an oxidation product of a greenish-yellow colour. Analysis shows it to be a normal ferric tellurite of

the composition $\text{Fe}_2\text{O}_3 \cdot 3\text{TeO}_3 + 4\text{H}_2\text{O}$. That the mineral is a ferric tellurite is evident since it gives off no chlorine when boiled in hydrochloric acid, nor does it give any reaction for ferrous iron when dissolved in cold hydrochloric acid. Two other tellurium-iron minerals have been described, namely, Genth's *ferrotellurite* and Hillebrand's *emmonsite* (Abstr., 1887, 344). The former is a ferrous tellurite widely different in appearance from the Honduras mineral, for which the authors, therefore, propose the name of *Durdenite*, after the gentleman to whom they are indebted for the material used.

In a note appended to the paper, W. F. Hillebrand gives the results of a repetition of the analysis of emmonsite, which upholds the accuracy of his former analysis, and seems to prove that the two minerals are distinct.

Fluorspar from Quincié. By H. BECQUEREL and H. MOUSSAN (*Compt. rend.*, 111, 669—672).—See this vol. p. 148.

New Variety of Zinc Sulphide. By J. D. ROBERTSON (*Amer. J. Sci.*, 40, 160—161).—A peculiar variety of zinc sulphide has been found in south-eastern Kansas, remarkable from the fact that it is nearly pure white and completely amorphous. It is found in the centre of the town of Galena, Cherokee Co., Kansas. When taken from the mine, it is soft, full of water, and resembles white lead ground in oil. Evidence points to the existence of a large body of this peculiar ore in the mine. An analysis of a dried sample yielded:

Insol. matter.	Zn.	S.	Fe_2O_3 .	Total.
2.52	63.70	30.77	2.40	99.39

The water contained in the original sample showed a slight amount of sulphuric acid. This sulphide was evidently formed by the precipitation of zinc sulphate, resulting from the oxidation of blende, by hydrogen sulphide or an alkaline sulphide.

B. II. B.

Contributions to Mineralogy. By F. A. GENTH (*Amer. J. Sci.*, 40, 114—120).—1. *Tetradynite*.—This mineral occurs, in crystals suggesting an orthorhombic form, near Bradshaw City, Arizona. After subtracting 15.6 per cent. of quartz and 1.8 per cent. of ferric oxide, the analysis gave:

S.	Te.	Bi.	Total.
4.50	33.25	62.23	99.98

These results give a formula analogous to that of bismuthinite.

2. *Iron Pyrites*.—The occurrence of cobalt arsenate with the octahedral crystals of iron pyrites at the French Creek iron mines, Pennsylvania, suggested an analysis of the latter, which gave the following results:—

S.	As.	Cu.	Ni.	Co.	Fe.	Total.
54.08	0.20	0.05	0.18	1.75	44.24	100.50

3. *Quartz, Pseudomorphous after Stibnite*.—Specimens from Durango, Mexico, were found to contain stibnite completely altered into a yellowish-white quartz.

4. *Gold in Turquoise*.—In many collections, specimens of gold enclosed in a bluish-green mineral are represented as turquoise with gold from Los Cerillos, New Mexico. Specimens analysed by the author are proved to contain no turquoise; in one case, the gold-bearing mineral was a chromiferous clay, and in the other, quartz admixed with chrysocolla.

5. *Zircon*.—With the masses of monazite, at Mars Hill, Madison Co., North Carolina, large crystals of zircon, with a sp. gr. of 4.507, occasionally occur. On analysis, the following results were obtained:—

SiO ₂	ZrO ₂	Fe ₂ O ₃	Loss on ignition.	Total.
31.83	63.42	3.23	1.20	99.68

6. *Scapolite*.—At the Elizabeth mine, French Creek, Pennsylvania, small crystals of scapolite occasionally occur, filling cavities of grey garnet, associated with magnetite, pyrites, and remnants of the ossonite from the alteration of which it appears to have been derived. The scapolite is colourless to white; it has a sp. gr. of 2.675, and on analysis gave the following results (I):—

	CO ₂	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	MgO.	CaO.	Na ₂ O.
I.	2.63	52.30	23.68	0.58	0.05	12.36	6.29
II.	1.71	41.42	18.09	10.81	0.59	26.19	—

	K ₂ O.	Loss by ignition.	MnO.	Total.
I.	0.77	1.50	—	100.16*
II.	—	0.51	0.88	100.20

The second analysis is of the grey garnet which also results from the alteration of ossonite.

7. *Titaniferous Garnet*.—A variety of garnet from the Jones mine, Green River, North Carolina, gave, on analysis, the following results:—

SiO ₂	TiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO.	MgO.	CaO.	Loss on ignition.	Total.
35.56	4.58	4.43	20.51	1.88	0.17	31.90	0.55	99.58

8. *Allanite*.—The author analysed two specimens of allanite with the following results:—

	SiO ₂	ThO ₂	TiO ₂	CeO ₂ (LaDi) ₂ O ₃		Y ₂ O ₃	Al ₂ O ₃	Fe ₂ O ₃
a.	31.67	0.33	—	23.98		0.36	12.20	4.42
b.	32.04	—	0.12	12.91	10.24	0.33	14.02	7.17

	FeO.	MnO.	MgO.	CaO.	Loss on ignition.	Total.	Sp. gr.
a.	10.89	2.52	2.08	9.37	2.25	100.07	3.546
b.	7.52	0.37	1.47	11.34	2.63	100.16	3.491

* 100.06 in original.

a. Colour, velvet-black; b. Deep brownish-black.

9. *Lettsomite*.—The author has analysed specimens of this rare material from two new localities: the Copper Mountain mine, near Morenci, Arizona, and Copperopolis, Tintic District, Utah. In both cases, the analysis gives results closely agreeing with those demanded by the formula $\text{Cu}_4\text{Al}_6(\text{OH})_{12}\text{SO}_4 + 2\text{H}_2\text{O}$. B. H. B.

Synthesis of Rubies. By E. FREMY and A. VERNÉUIL (*Compt. rend.*, 111, 668—669).—The authors have made several important modifications in their process for the manufacture of artificial rubies, and are now able to obtain much larger crystals. The alumina in addition to the small quantity of chromium is made alkaline with potassium carbonate, which facilitates the formation of the crystals but does not enter into their composition. It is advantageous not to mix all the materials but to keep the alumina separate from the fluorides of the alkaline earths, and in this way the mineralisation is effected by the interaction of the gases and vapours. The time of heating is extended to not less than a week; gas furnaces are used in place of coke, and the crucibles have a capacity of several litres, and are capable of producing as much as three kilos. of rubies at each operation.

Natural rubies are found which in parts have the colour of the sapphire. Similar crystals are obtained amongst the artificial products, and there can therefore be little doubt that the colours of the ruby and the sapphire are both due to chromium, probably in different states of oxidation.

The artificial rubies have been used as pivots in watches, and are not inferior to the natural stones in hardness. C. H. B.

Curious Occurrence of Vivianite. By W. L. DUDLEY (*Amer. J. Sci.*, 40, 120—121).—Two miles above Eddyville, Kentucky, "blue roots" were discovered embedded in a stratum of clay in such position as to indicate that they were in the place of their growth. The blue mineral, which has almost wholly replaced the woody fibre of the roots, is of a deep-blue colour. It is earthy and very friable, and gave, on analysis, the following results:—

Al_2O_3 .	Fe_2O_3 .	FeO .	CaO .	MgO .	P_2O_5 .	H_2O at 100°.	H_2O at 230°.	Total.
17.74	9.35	24.58	0.59	0.43	27.71	10.59	7.24	100.07

These results seem to indicate that the ferrous iron in the mineral is combined with the phosphoric anhydride to form vivianite, and if the double mol. of vivianite, $2(\text{Fe}_3\text{P}_2\text{O}_8 + 8\text{H}_2\text{O})$, be subtracted, there remains an almost dehydrated double mol. of turquoise, $\text{Al}_2\text{P}_4\text{O}_{11} + 10\text{H}_2\text{O}$, in which 1 mol. of ferric oxide has replaced one of alumina. B. H. B.

Dihydrothenardite. By V. MARKOVNIKOFF (*J. Russ. Chem. Soc.*, 22, 26—27).—Owing to an inexplicable mistake, a new mineral, dihydrothenardite, $\text{Na}_2\text{SO}_4 + 2\text{H}_2\text{O}$, was described by the author (*Abstr.*, 1888, 794), whereas a renewed investigation shows that it is

astrachanite (hydrated sulphate of sodium and magnesium) containing a considerable quantity of thenardite. B. B.

Connellite from Cornwall. By S. L. PENFIELD (*Amer. J. Sci.*, 40, 82—86).—Connellite is of special interest to the author, owing to its apparently close relation to the new mineral *spangolite*, recently described by him (Abstr., 1890, 1073). On examining a specimen from Camborne, the author found that the habit of the crystals agrees well with the general description given by Maskelyne in 1863. The analysis, in which the author places great confidence, gave the following results:—

SO ₃ .	Cl.	CuO.	H ₂ O.	Loss at 100°.	Total.	Less O.
4.9	7.4	72.3	16.8	0.4	101.8	1.7

The ratio is not very satisfactory, unless it is assumed that some OH is isomorphous with the Cl, in which case the formula may be written Cu₁₆(Cl,OH)₈SO₁₆.15H₂O. The mineral is very similar to spangolite in composition, both minerals being very basic sulphato-chlorides. B. H. B.

Nickel Ores from New Caledonia. By T. MOORE (*Chem. News*, 62, 180—181).—The ore known as garnierite is found in or near serpentine masses or mountains, either as cementing material in agglomerations of rounded serpentine pebbles or as an interstitial deposit between thin layers of quartz, steatite, and various hydrated magnesium silicates. The associated minerals vary, but comprise quartz, magnesium silicates, and iron oxides; sometimes one predominates, sometimes another, the others being even absent; it is also accompanied at times by chrome-iron ore and surrounded by a ferruginous earth.

The colour of garnierite varies from pale-green in poor ores to warm dark-green in the richer ones, and passes through almost imperceptible shades to light- and chocolate-browns. It crumbles gradually to powder, on exposure to weather, the brown more readily

	Green ores.		Brown ores.			Ferruginous brown ore.
	1.	2.	3.	4.	5.	6.
SiO ₂ ...	35.55	36.24	36.25	34.78	35.80	20.57
NiO	48.38	44.94	46.30	43.79	43.54	15.56
MgO ...	5.02	8.75	—	2.75	2.65	0.81
Fe ₂ O ₃ ...	1.11	0.21	9.00	6.30	10.73	40.03
Al ₂ O ₃ ..	1.09	1.03	—	—	—	—
Cr ₂ O ₃ ..	0.15	—	0.11	—	—	3.82
MnO ...	—	—	—	—	0.10	trace

than the green varieties; in all forms it dissolves readily in hot hydrochloric acid, leaving a non-gelatinous silica. In the table (p. 157), are given numbers, corrected for quartz, obtained in the analysis of samples of pure ore; samples previously analysed by other workers appear to have been contaminated with gangue:—

Samples 1 and 2 were a fine, brilliant grass-green; hardness, 2—3; sp. gr. 3; streak, light-green; lustre, waxy and slightly translucent at their edges. Before the blowpipe, the colour becomes dark olive-green, or red in presence of much iron.

3, 4, and 5 were various shades of brown, streak yellow to brownish-yellow, fracture conchoidal with resinous lustre, sp. gr. and hardness the same as green ore, but were rather more brittle. From these numbers, both kinds of ore seem to approach very nearly to a hydrated silicate of the composition $7\text{NiO}, 6\text{SiO}_2, 11\text{H}_2\text{O}$, part of the nickel being replaced by magnesia, iron oxide, or alumina.

The ores represented by sample 6 are light-brown in colour, resembling limonite, are easily marked by the nail, and do not seem to belong to the same class as the others just described.

D. A. L.

Minerals occurring near Port Henry, New York. By J. F. KEMP (*Amer. J. Sci.*, 40, 62—64).—At the abandoned Pease quarry, a short distance north-west of Port Henry, a face of white, crystalline limestone has been laid bare, and in this occur streaks of hornblende, plagioclase, muscovite, and quartz, but containing as well a great abundance of yellowish-brown titanite crystals; fine brown tourmalines also occur. West of this quarry is another, where flux is being obtained for local furnaces. The rock, a crystalline limestone, contains small, hexagonal tables of graphite disseminated through it. Occasionally lemon-yellow calcite is found, with fine crystals of clear calcite of great crystallographical interest as being good illustrations of oscillatory forms. Further west is the Treadway quarry in ophiolite, containing streaks of pyrrhotite, phlogopite, brown tourmaline, and well-crystallised light-brown tremolite. The abandoned quarry six miles north-west of Port Henry, the source of the well-known tourmaline crystals, is probably a feldspathic mass either in gneiss or in granite, and cut by three narrow dykes of altered diabase. Great masses of biotite and fine specimens of rose-quartz are also met with. The so-called Lover's Pit at Mineville is affording crystals and cleavage masses of magnetite of unusual size and excellence.

B. H. B.

Fayalite in the Obsidian of Lipari. By J. P. IDDINGS and S. L. PENFIELD (*Amer. J. Sci.*, 40, 75—78).—The Lipari Islands have long been celebrated for their acid lavas and pumices. The chief interest in connection with these rocks attaches itself to the fayalite crystals in the cavities, which have not been noticed hitherto. They are not abundant, but occur in several localities, having been found by J. P. Iddings at Forgia Vecchia, and in the obsidian stream on Volcano, and having been noted in specimens from Monto della Guardia. The crystals at Forgia Vecchia are very thin plates, the crystallographical measurements of which are given in detail by the

authors. The optical properties not only agree with orthorhombic symmetry, but also with the determinations made on the fayalite from Obsidian Cliff, in the Yellowstone Park (this vol., p. 26). The chemical composition, too, is the same in both cases, namely, orthosilicate of iron. The occurrence of fayalite in the hollow spherulites and lithophysæ in the obsidian of the Lipari Islands, whilst not so abundant as in that of the Yellowstone Park, is identical. It is associated in the same manner with tridymite and alkali feldspars, and its development is due to the same causes in the two regions.

B. H. B.

Two New Meteoric Irons. By F. P. VENABLE (*Amer. J. Sci.*, 40, 161—163).—1. A mass is reported to have fallen in 1816 at Deep Springs Farm, in Rockingham Co., North Carolina. It is now in the possession of the State Museum. The weight of the mass was 11·5 kilos. It had the shape of a rhomboid, and was coated with oxidation products, giving it a dull-reddish colour. The surface is irregularly pitted. On being polished and etched, it faintly exhibited Widmanstätten figures. It belongs to the class of sweating meteorites, beads of deliquesced ferric chloride appearing on the surface. The analysis gave—

Fe.	P.	SiO ₂ .	Cl.	Ni.	Co.	Total.
87·01	0·04	0·53	0·39	11·69	0·79	100·45

2. A meteoric iron was found in 1889 in Henry Co., Virginia. It weighed 1·7 kilos., and the detached pieces, mainly crust, 0·22 kilo. The iron contains a considerable amount of ferric chloride, and rapidly crumbles. On polishing one of the sides, the Widmanstätten figures came out plainly, no etching being necessary. The analysis gave the following results:—

Fe.	Cl.	SiO ₂ .	P.	Co.	Ni.	Total.
90·54	0·35	0·04	0·13	0·94	7·70	99·70

B. H. B.

Organic Chemistry.

Action of Chlorine on Trimethylene. By U. GUNTAHON (*J. pr. Chem.* [2], 42, 495—500).—Chlorine has hardly any action on trimethylene in the dark, but explodes with it in direct sunlight. Chlorine was passed into a globe (7½ litres) containing the trimethylene (7 litres) and water; the globe was kept cool, and the oil allowed to collect in a separating funnel ground into the neck. The oil consisted almost entirely of dichlorotrimethylene.

Dichlorotrimethylene, C₃H₄Cl₂, is a colourless liquid of peculiar odour; it boils at 75° (746 mm.), and is nearly insoluble in water. Its chemical stability is great; nitric acid decomposes it with difficulty; water at 180—190° has scarcely any action on it, and it

can be distilled over sodium, which only acts on it at 160—165°, producing substances still under investigation. When dichlorotrimethylene and bromine (equal mols.) are sealed in a tube and exposed to sunlight for 4—5 summer days, or heated at 140—150° for 3—4 hours, the dibromide, $C_3H_4Cl_2Br_2$, is produced; it is a heavy, colourless liquid which boils almost without any decomposition at 203—207° (770 mm.).

Allylene dichloride is the only compound of the formula $C_3H_4Cl_2$, which boils at 75°; that dichlorotrimethylene is not identical with this is shown by the fact that the dibromo-compound obtained from allylene dichloride boils at 190° (Friedel and Silva; 188°, Pinner).

Of the three possible formulæ for this dichlorotrimethylene, the author favours $CCl_2 < \begin{smallmatrix} CH_2 \\ | \\ CH_2 \end{smallmatrix}$; for the dibromide approximates in boiling point to α -epidichlorhydrin dibromide, $CH_2Cl \cdot CClBr \cdot CH_2Br$, and therefore, probably, has a similar structure. A. G. B.

Hexylene Dibromide obtained from Diallyl. By N. DERYANOFF (*J. Russ. Chem. Soc.*, 22, 117—118).—In order to prepare hexylene dibromide, well cooled diallyl (b. p. 59—60°) was saturated with hydrogen bromide, when a mixture of a solid with a liquid was obtained. After washing with water, the two compounds were separated by filtration and suction. The liquid product was a hexylene dibromide boiling at 212—220° with decomposition. The solid product, after recrystallisation from ether, was obtained in large, rhombic scales melting at 38—39°, and boiling almost without decomposition at 210°. The author considers the liquid compound to be $CH_2Br \cdot [CH_2]_4 \cdot CH_2Br$, and the solid as $CHMeBr \cdot CH_2 \cdot CH_2 \cdot CHMeBr$, and that diallyl is a mixture of two (geometrical) isomerides.

B. B.

Oxidation of Potassium Cyanide with Potassium Permanganate. By J. VOLHARD (*Annalen*, 259, 377—380).—Carbamide can be very conveniently prepared in moderately large quantities in the following manner:—A solution of potassium permanganate (63 grams) in water (1 litre) is gradually added to a solution of potassium cyanide (39 grams) and potassium hydroxide (10 grams) in water (100 c.c.), the temperature being kept below 17°; but it is unnecessary to wait until the pink colour has disappeared before continuing the addition of the permanganate. The solution is then placed in cold water for seven to eight hours until it becomes colourless, mixed with a concentrated solution of ammonium sulphate (70 grams), heated to boiling, and filtered; the precipitate is washed with boiling water, the filtrate and washings evaporated to dryness, and the carbamide extracted with 95 per cent. alcohol. The yield is 68 per cent. of the theoretical, but the product still contains a little ammonium chloride and traces of the sulphate, from which it can most easily be freed by treating its aqueous solution with a little precipitated barium carbonate, evaporating to dryness, and then extracting with absolute alcohol. F. S. K.

Combination of Mercuric Cyanide with Cadmium Salts. By R. VARET (*Compt. rend.*, 111, 679—681).—Powdered mercuric cyanide, 25 parts, is gradually added to a boiling concentrated solution of cadmium iodide, 30 parts, and the liquid is filtered and allowed to evaporate over sulphuric acid. The compound $\text{HgCy}_2, \text{CdCy}_2, \text{HgI}_2 + 7\text{H}_2\text{O}$ separates in transparent lamellæ, which alter rapidly when exposed to air, and dissolve in water and ammonia. It becomes anhydrous at 110° , and at the same time decomposes with liberation of mercuric iodide. Dilute acids decompose it with liberation of mercuric iodide and hydrocyanic acid, while mercuric cyanide and the cadmium salt of the particular acid used remain in solution. When heated with a solution of cupric sulphate, cyanogen is evolved, and a precipitate of the composition $\text{Cu}_2\text{Cy}_2, \text{HgI}_2$ is formed. These facts show that all the cyanogen is not combined with the mercury, and that the salt is not simply a compound of cadmium iodide with mercuric cyanide.

Cadmium bromide (18 parts), added gradually to a boiling solution of mercuric cyanide (25 parts), yields slender needles of the compound $2\text{HgCy}_2, \text{CdBr}_2 + 4\frac{1}{2}\text{H}_2\text{O}$, which alters but little when exposed to air, dissolves in water and in ammonia, and becomes anhydrous at 100° . Dilute acids liberate hydrocyanic acid, but no mercuric bromide sublimes when the salt is gently heated; but when more strongly heated, cyanogen and mercury are evolved and some mercuric cyanide sublimes. It follows that the salt is a compound of mercuric cyanide and cadmium bromide.

If a solution containing 25 parts of mercuric cyanide and 30 parts of cadmium bromide is gently evaporated on a water-bath, the salt $\text{HgCy}_2, \text{CdBr}_2, 3\text{H}_2\text{O}$ separates in small, very hard, granular crystals, which alter but little when exposed to air, become anhydrous at 100° , and are less soluble in water and in ammonia than the preceding compound.

If a concentrated solution of 20 parts of cadmium chloride is added drop by drop to a saturated solution of 25 parts of mercuric cyanide, heated at 80° , and the liquid is slowly concentrated after addition of sufficient warm water to dissolve the white precipitate which forms, the compound $\text{HgCy}_2, \text{CdCl}_2 + 2\text{H}_2\text{O}$ separates in small, granular crystals. It is soluble in water and in ammonia, is decomposed by dilute acids, and becomes anhydrous at 110° . C. H. B.

Action of Alcoholic Potassium Cyanide on Halogen Derivatives of Amylene. By C. HILL and M. WILDERMANN (*Ber.*, 23, 3210—3215).—It is well known that whereas the primary dibromides of normal olefines are readily converted into the corresponding dinitriles, the derivatives of the iso-compounds only give very small yields on treatment with alcoholic potassium cyanide. Thus iso-amylene bromide forms, besides the dinitriles, large quantities of bromamylene and of humous substances. The authors find that the reaction takes place more readily if isoamylene chloride is employed in place of the bromide, and the mixture is heated in a sealed tube at 180° . The nitrile formed gave on hydrolysis a crystalline acid seemingly identical with the trimethylsuccinic acid obtained by

Schad (*Inaug. Diss., Berne, 1886*), and an oily acid which could not be obtained crystalline. The yield of both these acids was better than that given by the bromide.

It was also found that addition of hydrochloric acid to the mixture of isoamylene chloride and alcoholic potassium cyanide causes a great increase in the quantity of humous substance formed, whence it would appear that the formation of the latter is due to the action of hydrochloric acid on the hydrocyanic acid; this was confirmed by adding hydrochloric acid to an alcoholic solution of potassium cyanide which had previously been boiled for some time without undergoing alteration, when, after a few minutes, a copious separation of humus took place. Hence all those substances which readily lose hydrogen chloride or bromide by the action of potassium cyanide will give large quantities of humus, owing to the action of the acid thus set free on the hydrocyanic acid, azulmic and hydrazulmic acids being formed.

When isoamylene bromide is heated with bromine, it is converted into a *tribromopentane*, the most probable formula of which is $\text{CMe}_2\text{Br}\cdot\text{CMeBr}_2$. This is readily acted on by alcoholic potassium cyanide without formation of humus or of bromamylene in any quantity. The nitrile formed is almost insoluble in water and ether, but dissolves readily in alcohol. The hydrolysis is best performed by heating it in a sealed tube at $130\text{--}150^\circ$ with concentrated hydrochloric acid, and extracting the product with ether. After removing the latter by evaporation, a yellowish, syrupy acid remains which gradually deposits a small quantity of needles; these after repeated crystallisation from water, melted at $96\text{--}97^\circ$, and evolved carbonic anhydride at $130\text{--}140^\circ$; the quantity of the substance was too small, however, to allow of its being obtained in a pure condition. The syrupy acid, after purification by successive conversion into the calcium, barium, and silver salts, was obtained as a pale-yellow syrup which did not crystallise, even when kept for some time; it has the composition of a trimethylsuccinic or dimethylglutaric acid, but its exact constitution has not yet been determined. It only evolves minimal quantities of carbonic anhydride on heating, due to the presence of traces of the above crystalline acid.

H. G. C.

Derivatives of Melidoacetic Acid. By R. KRÜGER (*J. pr. Chem.* [2], 42, 473—494; compare this Journal, 1875, 1184).—Melidoacetic acid is best obtained as follows:—10 grams of sodium is dissolved in alcohol, the solution cooled and mixed with a solution of cyanamide (20 grams) in alcohol (40 c.c.); an equal volume of ether is then added, and the resulting precipitate is heated with a mixture of cyanamide (10 grams) dissolved in alcohol (20 c.c.) and ethyl chloracetate (30 grams) for 6 to 8 hours in a reflux apparatus. The whole is then dissolved in dilute soda, filtered, and the melidoacetic acid precipitated by acetic acid; it is purified by dissolving it in dilute hydrochloric acid and passing hydrogen chloride into the cooled solution, when its hydrochloride separates in large needles which are recrystallised and decomposed by adding ammonia to the aqueous solution. The potassium, sodium, calcium, and barium salts were obtained.

Amelidoacetic acid, $C_5N_3(OH)_2 \cdot NH \cdot CH_2 \cdot COOH$, is obtained by heating melidoacetic acid with excess of barium oxide and water in a reflux apparatus until no more ammonia is evolved, and crystallising the portion which remains undissolved from hot hydrochloric acid. It crystallises in rhombic or monoclinic tables, and dissolves freely in hot water, but not in alcohol. The *copper salt*, $(C_5H_4N_3O)_2Cu + 6H_2O$, crystallises in dark-blue, rhombic tables; the *silver salt* is a white precipitate of uncertain composition: the *basic lead salt*, $C_5H_4N_3O_4Pb$, crystallises in transparent crystals which are insoluble in water: the *barium salt*, $C_{20}H_{34}N_{16}O_{34}Ba_3 + 8H_2O$, crystallises in long, rhombic tables, soluble in much hot water; the *strontium salt*, $C_{10}H_{10}N_8O_8Sr + 4H_2O$, forms rhombic or monoclinic tables; the *calcium salt*, which was obtained like the last two salts, namely, by adding calcium hydroxide to a solution of the acid, precipitating the excess of calcium with carbonic anhydride, filtering, and crystallising, forms crystals which are similar to the strontium salt, but have an uncertain composition; the *calcium salt*, $C_{10}H_{10}N_8O_8Ca + 4H_2O$, obtained by mixing the calculated quantities of calcium oxide and amelidoacetic acid and crystallising, forms glistening, quadratic prisms; the *sodium*, *potassium*, and *ammonium* salts (each with 2 mols. H_2O) are of normal composition, and easily soluble in water.

Cyanuracetic acid, $C_3N_3(OH)_2 \cdot O \cdot CH_2 \cdot COOH$, is obtained when melidoacetic acid is heated in a sealed tube with strong hydrochloric acid at 180° for several hours until it has all dissolved; when the tube is opened the liquid froths up from the escape of gas, and after a time the new acid crystallises out, together with ammonium chloride, from which it is separated by its solubility in absolute alcohol. It crystallises (with 1 mol. H_2O) in prisms and needles, and dissolves very freely in water. There are three series of salts: the *copper salt*, $C_{10}H_8N_6O_{10}Cu + 2H_2O$; the *silver salt*, $C_6H_4N_4O_6Ag_3 + H_2O$; the *barium salt*, $C_5H_4N_3O_5Ba + 2H_2O$, and the *potassium salt*, $C_5H_4N_3O_5K + H_2O$, are here described; the *ethyl salt*, $C_5H_4N_3O_5Et$, crystallises in silky needles which melt at 208° and solidify at 195° .

Cyanuracetic acid is synthetically obtained by heating disodium cyanurate with sodium chloroacetate in aqueous solution.

A. G. B.

Two New Butyl Nitrates. By G. BERTONI (*Gazzetta*, 20, 372—376).—Of the four theoretically possible butyl nitrates, only one, the isopropyl salt, has hitherto been prepared (Wurtz, *Compt. rend.*, 1854).

The *normal primary nitrate*, $C_4H_9P_1 \cdot NO_3$, is prepared by adding quantities of 10 c.c. of pure normal butyl alcohol, drop by drop, to a strongly cooled mixture of 2 vols. of sulphuric acid (sp. gr. = 1.85) and 1 vol. of nitric acid (sp. gr. = 1.4), and proceeding as in the manufacture of nitroglycerol. It is a colourless liquid, with a pleasant ethereal odour and a sweet taste, which becomes pungent after a time. It boils at 136° , and its sp. gr. at 0° is 1.048. It dissolves in alcohol, ether, acetic acid, carbon bisulphide, &c., but not in water. With acids, it behaves like other ethereal nitrates. It burns with an olive-green flame, and explodes with violence when heated in a sealed tube to a higher temperature than its boiling point.

Secondary butyl nitrate, $\text{CH}_3\text{EtMe}\cdot\text{NO}$, is prepared like the preceding compound, the temperature being carefully kept below 0° during the whole of the reaction. It is a colourless, mobile liquid, with a pleasant, penetrating odour, boils at 124° , and has a sp. gr. of 1.0382. It dissolves in most organic solvents, but not in water. It is more readily decomposed than its isomerides by sulphuric or hydrosulphuric acid. Its vapour explodes when superheated. S. B. A. A.

Action of Hydrogen Chloride and Bromide on Ethyl Allyl Ether. By S. N. KIJNEE (*J. Russ. Chem. Soc.*, 22, 27—32).—The author has made attempts to convert ethyl allyl ether into ethyl propyl ether by acting on it with hydrogen bromide, but the result was quite different when ethyl allyl ether, saturated with hydrogen bromide at -15° , was heated in a sealed tube at 30 — 40° for 10 hours; it was found to be decomposed with formation of allyl bromide and ethyl bromide, this reaction taking place to some extent even at -15° . Hydrogen chloride and allyl ethyl ether in like manner yield allyl and ethyl chlorides, but the reaction requires more time and a higher temperature. This result accords with the fact that the reaction takes place with development of heat. This is evident from the thermochemical data, and the reaction will be more energetic with the gaseous acids than with the aqueous solution, as more heat is developed by the action in the first case than in the second.

B. B.

Tetramethylene Glycol. By P. J. DEKKERS (*Rec. Trav. Chim.*, 9, 92—102; see also Abstr., 1889, 950).—Tetramethylene glycol is the only dihydroxy-derivative of normal butane which has not been prepared up to the present time. The author endeavoured to obtain its dibenzoate by the action of sodium on ethyl benzoate, $\text{C}_2\text{H}_5\cdot\text{O}\cdot\text{C}_6\text{H}_5$, but only obtained a mixture of sodium chloride, sodium benzoate, and ethylene benzoate. The action of sodium and silver nitrite on a solution of tetramethylenediamine sulphate or oxalate also gave negative results, although with the former salt a liquid was obtained which was possibly tetramethylene oxide.

The following method was then adopted with more satisfactory results. Tetramethylenediamine, when mixed with methyl carbonate in the cold, gradually deposits white crystals of *methyl tetramethylenediamidoformate*, $\text{C}_4\text{H}_8(\text{NH}\cdot\text{COOMe})_2$, which, after recrystallisation from water, melt at 128° . When the latter is treated with five times its weight of cold absolute nitric acid, it yields *methyl tetramethylenedinitramidoformate*, $\text{C}_4\text{H}_8[\text{N}(\text{NO}_2)\cdot\text{COOMe}]_2$, which separates from alcohol in crystals melting at 61 — 62° . To convert this into the nitramine, it is warmed with ammonia, the solution precipitated with acetic acid, the precipitate washed with cold water, and recrystallised from the hot liquid. The *tetramethylenedinitramine*, $\text{C}_4\text{H}_8(\text{NH}\cdot\text{NO}_2)_2$, thus obtained forms hard crystals melting at 163° , which are fairly soluble in hot water. When it is warmed on the water-bath with very dilute sulphuric acid, a volatile liquid distils over, and a gas is formed which is partially absorbed by hydrobromic acid with formation of tetramethylene bromide, and by bromine with formation of butine tetrabromide. The unabsorbed gas consists of nitrous oxide. When

the residual liquid in the flask is distilled under reduced pressure it yields *tetramethylene glycol*, $C_4H_8(OH)_2$, as a thick, colourless liquid which boils at $203-205^\circ$ under 752 mm., and at $152-153^\circ$ under 120 mm. pressure, and yields succinic acid on oxidation. When shaken with benzoic chloride and soda solution, it yields the *dibenzooxide*, $C_4H_8(OBz)_2$, melting at $81-82^\circ$.

As mentioned above, a volatile liquid distils over when tetramethylenenitramine is warmed with dilute sulphuric acid. This separates into two layers, the upper one consisting of a liquid boiling at 67° , and the lower of an aqueous solution of a liquid boiling at $83-88^\circ$. These have not been closely examined, but the former probably is tetramethylene oxide. H. G. C.

Starch. By K. ZULKOWSKI (*Ber.*, 23, 3295-3297).—Starch dissolves in hot glycerol, and is converted into the soluble modification; by further heating and treatment with alcohol, erythroextrin and achroodextrin are obtained free from sugar; from the alcoholic filtrate, two soluble carbohydrates may be separated by treatment with barium hydroxide, absolute alcohol, and anhydrous ether; the second of these remains dissolved in the ether-alcohol, and may be precipitated by means of barium hydroxide.

From the extreme difficulty experienced in removing the glycerol, the author suggests that it may take part in the reaction.

J. B. T.

α - and β -Amyrin. By A. VESTERBERG (*Ber.*, 23, 3186-3190; see also *Abstr.*, 1887, 733). The clemi resin employed in these researches, after trituration with alcohol, showed, under the microscope, numerous crystals of amyriu, together with a few isodiametric crystals of elemic acid. The total amount of α - and β -amyriu is 20-25 per cent, a large portion of the residue being of an alcoholic nature, as it is acted on by acetic anhydride. The empirical formula of both α - and β -amyrin was found, from analysis and determination of the hydrolysis equivalent of their acetates, to be $C_{30}H_{48}O$. The compounds are extremely similar, and form slender, elastic, silky needles which are readily soluble in benzene, ether, acetic acid, and hot alcohol, sparingly in cold alcohol and light petroleum. The ratio of their solubility in alcohol at $19-19.5^\circ$ is 3:5.12. α -Amyrin melts at $181-181.5$, and rotates the plane of polarisation to the right, $[\alpha]_D = +91.59^\circ$, whilst β -amyrin melts at $193-194^\circ$, and rotates the plane of polarised light more strongly to the right, $[\alpha]_D = 99.81^\circ$.

Both compounds, unlike cholesterin and lactaceryl, crystallise from aqueous alcohol without water of crystallisation. They are probably secondary alcohols, as they give acetyl and benzoyl derivatives, and on oxidation yield α - and β -amyron, which are probably ketones. Phosphorus pentachloride converts them into dextrorotatory hydrocarbons, $C_{30}H_{48}$, which may be termed amyrienes. Phosphorus pentoxide, on the other hand, yields with α -amyrin a levorotatory amyriylene.

α - and β -Amyrin acetates, $C_{30}H_{46}OAc$, are formed in the separation of the amyrius (*loc. cit.*), but are only obtained pure by repeated

crystallisation from light petroleum or benzene. Both are sparingly soluble in alcohol and ether, readily in light petroleum, and more easily in benzene and chloroform. The α -compound crystallises in large plates, melts at 221° , and has a sp. rot. power $[\alpha]_D = +77^{\circ}$. The β -compound forms long, prismatic crystals melting at 236° , and having a sp. rot. power $[\alpha]_D = 78.6^{\circ}$. Both are oxidised by chromic acid to oxyamyrin acetates, $C_{30}H_{48}O_5Ac$.

The α - and β -amyrin benzoates are obtained by heating α - and β -amyrin with benzoic chloride at 130° . The α -compound is crystallised from alcoholic ether, and is sparingly soluble in alcohol, more readily in ether, and very easily in light petroleum and benzene. The β -compound, after recrystallisation from light petroleum, is almost insoluble in cold alcohol, sparingly soluble in ether and cold light petroleum, readily in the hot liquid and in benzene.

When α - and β -amyrin acetates are dissolved in chloroform or carbon bisulphide, and bromine added, either alone or diluted with acetic acid, the solutions are coloured brownish-yellow, and hydrogen bromide is evolved. The crystalline masses which remain after spontaneous evaporation are recrystallised from benzene (α) or light petroleum (β), and the finely-powdered bromacetates treated with alcoholic potash.

Brom- α -amyrin, $C_{30}H_{48}Br\cdot OH$, melts at 177 — 178° , is sparingly soluble in cold acetic acid and alcohol, readily in benzene, and almost insoluble in light petroleum; it is dextrorotatory, and has a sp. rot. power $[\alpha]_D = +72.8^{\circ}$. Its *acetate*, $C_{30}H_{48}Br\cdot OAc$, crystallises from benzene in six-sided plates or flat prisms, containing benzene of crystallisation, which is evolved when the crystals are allowed to remain in the air. It has not, however, been obtained quite pure, but appears to melt at about 268° ; the bromine is not removed by alcoholic potash, ammonia, or aniline.

Brom- β -amyrin could not be obtained crystalline, the warm solutions in alcohol, benzene, and light petroleum solidifying to jellies. It is very soluble in hot acetic acid and benzene, less readily in alcohol and light petroleum. After drying at 98° , it melts at 182 — 186° . The *acetate* forms prismatic crystals, readily soluble in chloroform and benzene, sparingly in light petroleum, which, after recrystallisation from the latter, melt at 238° . As it is fairly soluble in hot light petroleum, it may be thus easily separated from the brom- α -acetate, and can, therefore, be prepared directly from the mixture of amyryns.

H. G. C.

Isopropylamines. By H. MALBOT and A. MALBOT (*Compt. rend.*, 111, 650—652).—The action of isopropyl iodide on an equivalent quantity of highly concentrated aqueous ammonia, at the ordinary temperature, is very slow, but is complete, the product consisting entirely of isopropylamine hydriodide. At 100° , the action is still slow, and requires about four days before it is complete. The chief product is isopropylamine hydriodide, but a small quantity of the diamine is also formed. Ammonium iodide is formed in quantity larger than that corresponding with the quantity of diamine, a result due to the liberation of some propylene. At 120 — 130° , and at

140—155°, the chief product is still the monamine, mixed with a small quantity of diamine, the proportion of the latter being practically the same in both cases. The quantity of propylene liberated is, however, considerably greater at the higher temperature. The quantity of diisopropylamine hydriodide does not exceed a certain value, because it reacts with the monamine, with elimination of propylene.

Isopropyl chloride reacts with aqueous ammonia at 140°, and the monamine is mixed with some diamine, but the change is far from complete, because the amines are present partly in the free state. In this respect isopropyl chloride differs from isopropyl iodide, and more nearly resembles orthopropyl, isobutyl, and isoamyl chlorides, which yield the free amines. There is, however, this difference, that whilst it is easy to obtain tripropyl-, triisobutyl-, and triiso-amylamines, diisopropylamine is the final term in the action of ammonia on the haloïd salts of isopropyl.

C. H. B.

Propylnitramine and Isopropylnitramine and their Derivatives. By J. C. A. SIMON THOMAS (*Rec. Trav. Chim.*, 9, 69—91).—Propylnitramine and isopropylnitramine are readily obtained in a similar manner to methylnitramine (Franchimont and Klobbie, *Abstr.*, 1888, 492). The propylamine and isopropylamine required for their preparation were obtained by Hoogewerf and van Dorp's method (*Abstr.*, 1887, 245; 1888, 1194), and converted into the corresponding amidoformates by the action of methyl chloroformate in 25 per cent. aqueous solution, extraction with ether, and fractionation. *Methyl propylamidoformate*, $\text{NHPr}^a\text{-COOMe}$, is a colourless liquid, which has a faint penetrating odour, and boils at 180° under 755 mm. pressure. Its sp. gr. is 0.992 at 15°. *Methyl isopropylamidoformate*,

is likewise a colourless liquid, having a faint penetrating odour, which boils at 165.5° under 760 mm. pressure, and has a sp. gr. of 0.981 at 15°. Both compounds are readily converted into the nitroderivatives by gradually adding them to cooled absolute nitric acid, with continuous shaking. In the case of the isopropyl compound, cooling with ice and very gradual addition of the amidoformate, is necessary, as otherwise oxidation readily takes place. The acid solution is then, in both cases, poured on to soda crystals covered with a little water, the yellowish liquid which separates taken up with ether, the ether distilled off, and the residual liquid dried over sulphuric acid. *Methyl propylnitramidoformate*, $\text{NO}_2\text{-NHPr}^a\text{-COOMe}$, is thus obtained as an almost colourless liquid, which has a sweetish odour, and does not solidify at -20°. It has a sp. gr. of 1.187 at 15°, and evolves gas when heated at 139°. *Methyl isopropylnitramidoformate*, $\text{NO}_2\text{-NHPr}^b\text{-COOMe}$, has a sp. gr. of 1.1585 at 15°, and commences to decompose at 120°.

To convert these compounds into the nitramines, dry ammonia gas is passed into their ethereal solutions. The ammonium salt of propylnitramine is precipitated as a crystalline mass, which is collected, washed with ether, decomposed by sulphuric acid, and the propyl-

nitramine extracted with ether. After evaporating off the ether and drying the residue over sulphuric acid, *propylnitramine*, $\text{NHPr}^{\alpha}\text{NO}_2$, is obtained as a colourless, inodorous liquid, which cannot be distilled without decomposition at the ordinary pressure, but boils at $128-129^{\circ}$ under 40 mm. pressure. It has a sp. gr. of 1.102 at 15° , decomposes at 142° , and solidifies between -21° and -23° , and is not coloured on exposure to light. Its aqueous solution has an alkaline reaction, and gives a precipitate with many salts of the heavy metals. The *potassium* salt, $\text{NPr}^{\alpha}\text{K}\cdot\text{NO}_2$, obtained by acting on the nitramine with the theoretical quantity of alcoholic potash, forms small, nacreous, hygroscopic plates, and the *silver* salt, $\text{NPr}^{\alpha}\text{Ag}\cdot\text{NO}_2$, crystallises in small, slender needles, which blacken in the light.

Isopropylnitramine, $\text{NHPr}^{\beta}\text{NO}_2$, is obtained in the same manner as the normal compound, but must be further purified by dissolving it in potassium carbonate solution, extracting the latter with ether, and acidifying the residual solution with sulphuric acid. It is a colourless compound which melts at -4° , distils at $90-91^{\circ}$ under 10 mm. pressure, commences to decompose at 150° , and has a sp. gr. of 1.098 at 15° . It is scarcely soluble in water, but mixes with alcohol and ether in every proportion. The *potassium* salt, $\text{NPr}^{\beta}\text{K}\cdot\text{NO}_2$, forms long, slender, very hygroscopic needles, and the *silver* salt, $\text{NPr}^{\beta}\text{Ag}\cdot\text{NO}_2$, crystallises in thin plates.

When the potassium salts of these nitramines are treated with an alkyl bromide, or the silver salts with an alkyl iodide in alcoholic solution, dialkylnitramines are obtained. The following have been prepared in this manner:—*Dipropylnitramine*, $\text{NPr}^{\alpha}_2\text{NO}_2$, a colourless liquid boiling at $76-79^{\circ}$ under 10 mm. pressure; *di-isopropylnitramine*, $\text{NPr}^{\beta}_2\text{NO}_2$, boiling at $55-57^{\circ}$ under 10 mm. pressure; *propylisopropylnitramine*, $\text{NPr}^{\alpha}\text{Pr}^{\beta}\text{NO}_2$, boiling at $65-68^{\circ}$ under the same pressure; and *benzylpropylnitramine*, $\text{NO}_2\text{NPr}^{\alpha}\text{CH}_2\text{Ph}$, melting at $8-10^{\circ}$, and boiling at $200-205^{\circ}$ under 40 mm. pressure. The first three compounds do not solidify in a mixture of solid carbonic anhydride and ether. The silver and potassium salts of propylnitramine, unlike the corresponding methyl derivatives, do not yield a picryl compound on treatment with picric chloride, the latter being simply converted into silver or potassium picrate. Ethyl and isopropylnitramine behave in a similar manner.

When the silver salts of the nitramines are warmed with acetic or benzoic chloride, a simple reaction does not take place. Some silver chloride is precipitated, and nitrous oxide is evolved. It appears probable that the acetyl or benzoyl compound is first formed, and then splits up into propyl acetate or benzoate and nitrous oxide:—

The author has succeeded in isolating propyl benzoate from the product of the reaction with benzoic chloride.

The molecular weights of picrylmethylnitramine (Abstr., 1886, 455) and of isopropylnitramine have been determined by Raoult's method, the results agreeing with the formulæ above ascribed to them.

H. G. C.

Amylamines. By A. BERG (*Compt. rend.*, **111**, 606—608).—Amyl chloride and saturated aqueous ammonia are mixed in equivalent proportions, and sufficient alcohol of 92° is added to completely dissolve the mixture. The liquid is heated at 110—120° for eight or nine hours, poured off from the crystals of ammonium chloride (mixed with a small quantity of diamylamine hydrochloride), acidified with hydrochloric acid, and distilled, to remove alcohol and unaltered amyl chloride. The residual liquid, when allowed to cool, deposits nacreous plates of diamylamine hydrochloride, which can be almost completely separated by successive concentrations. If recrystallised from boiling water after treatment with animal charcoal, it is obtained in perfectly pure, large plates, with a micaceous lustre.

The mother liquor from the diamylamine hydrochloride is evaporated to dryness and made alkaline with potash or soda; the liberated base consists of almost pure amylamine mixed with a very small quantity of the di- and tri-amine, the proportions in which the three bases are obtained from the original product being monamine 6 parts, diamine 9 parts, triamine $\frac{1}{2}$ to 1 part. The same result is obtained with only half the quantity of alcohol. Alcoholic ammonia yields similar results, but the diamine is formed in still larger proportions.

Pure amylamine is obtained by the method of Duvillier and Buisine. A dilute aqueous solution is mixed with a suitable quantity of ethyl oxalate, a rise of temperature being avoided; diamyloxamide is precipitated, and is almost completely insoluble in water. The mother liquor, when concentrated, yields amylamine amyloxamate, $C_5H_{11}NH \cdot CO \cdot COOH, NH_2 \cdot C_5H_{11}$, very soluble in hot water, but much less soluble in cold water, and easily decomposed by aqueous potash, which has very little action on diamyloxamide. With calcium chloride, amylamine amyloxamate yields a precipitate of calcium amyloxamate, which crystallises readily from hot water in small, brilliant, hydrated lamellæ. C. H. B.

Diethylenediamine. By A. W. v. HOFMANN (*Ber.*, **23**, 3297—3303).—Diethylenediamine purified by treatment with sodium melts at 104°, boils at 145—146°, and solidifies on cooling, forming a hard, white, crystalline mass, which is extremely soluble in water, and is deposited from absolute alcohol in large, transparent crystals. The *benzoyl* derivative is deposited from alcohol in rhombic crystals which melt at 191°. A technical product termed "spermin," "piperazidin," or "piperazin" is found to be identical with diethylenediamine (compare Sieber, *Abstr.*, 1890, 476). J. B. T.

Action of Zinc and Ethyl Chloracetate on Ketones and Aldehydes. By S. REFORMATSKY (*J. Russ. Chem. Soc.*, **22**, 44—64).—Acetone, when treated with ethyl chloracetate and zinc, gives a product which, on decomposition with water yields the β -dimethylethylene-lactic acid (hydroxyvaleric acid), $OH \cdot CMe_2 \cdot CH_2 \cdot COOH$, of M. and A. Saytzeff. Methyl propyl ketone, under similar conditions, yields β -methylpropylethylene-lactic acid, $OH \cdot CMePr \cdot CH_2 \cdot COOH$. This, on distillation with dilute sulphuric acid, yields *methylpropylacrylic acid*, $CMePr \cdot CH \cdot COOH$. Diethyl ketone, when similarly treated, yields

Shinokoff's β -diethylethylenelactic acid, $\text{OH}\cdot\text{C}(\text{Et})_2\cdot\text{CH}_2\cdot\text{COOH}$. By distillation with dilute sulphuric acid, this acid loses the elements of water, and β -diethyldiacrylic acid, $\text{C}(\text{Et})_2\cdot\text{CH}\cdot\text{COOH}$, is obtained. The above reaction when applied to butyryne gives rise to Shinokoff's β -dipropylethylenelactic acid, $\text{OH}\cdot\text{C}(\text{Pr})_2\cdot\text{CH}_2\cdot\text{COOH}$, which, on losing the elements of water, is converted into Albitzky's dipropylacrylic acid. This acid yields a dibromide melting at $102-104^\circ$, whereas the dibromide prepared by the author from Albitzky's original acid melts at $80-82^\circ$. This difference is probably due to geometrical isomerism, as the compounds contain an asymmetrical carbon atom. The above reaction may be represented by the general scheme, $\text{RR}_1\text{CO} + \text{CH}_2\text{Cl}\cdot\text{COOEt} + \text{Zn} = \text{CRR}_1(\text{OZnCl})\cdot\text{CH}_2\cdot\text{COOEt}$, and this with $3\text{H}_2\text{O}$ gives $\text{RR}_1\text{C}(\text{OH})\cdot\text{CH}_2\cdot\text{COOH}$. Analogous results obtained with aldehydes will be communicated in a future paper. B. B.

Action of Phosphorus Trichloride on Organic Acids and Water. By C. H. BOTHAMLEY and G. R. THOMPSON (*Chem. News*, 62, 191).—Thorpe showed (Trans., 1880, 186) that the equation $3\text{CH}_3\cdot\text{COOH} + 2\text{PCl}_3 = 3\text{CH}_3\cdot\text{COCl} + \text{P}_2\text{O}_3 + 3\text{HCl}$ represented the action of phosphorus trichloride on acetic acid. The authors agree that this does represent the fundamental change (which is similar for other monobasic organic acids), and therefore true within certain narrow limits, but with excess of either reagent various secondary reactions take place, which increase with other acids of the series, as the molecular weights become greater and the volatility of the products less. With benzoic acid and phosphorus trichloride, secondary changes take place to a very considerable extent. In fact, this reaction cannot be regarded, as it hitherto has been, as a good method for preparing acid chlorides. Even the action of phosphorus as trichloride on water, which is as follows, $\text{PCl}_3 + 3\text{H}_2\text{O} = \text{H}_3\text{P}(\text{O}) + 3\text{HCl}$, as long as the water is in considerable excess, is disturbed by various secondary reactions as soon as the phosphorus chloride is in excess, giving rise to the formation of yellow phosphorus oxide and other oxides, including the soluble form of the oxide P_4O_6 , which becomes insoluble at 70° ; the yellow oxide was also produced in the other cases given above. Various conditions affect these changes, especially temperature. D. A. L.

Paracrylic and Hydracrylic Acids. By E. KLIMENKO (*J. Russ. Chem. Soc.*, 22, 100—102).—The author's method of preparing paracrylic acid by the action of silver oxide on β -iodopropionic acid yields larger quantities of the pure acid with difficulty only. The author's improved method consists in evaporating hydracrylic acid with hydrochloric acid on the water-bath. On treating paracrylic acid with an excess of bromine, it yields bromopropionic acid. When paracrylic acid is heated with water at 100° for six hours, it is converted into an acid $\text{C}_3\text{H}_4\text{O}_3$, having the composition of hydracrylic acid. By the action of phosphorus pentachloride on hydracrylic acid, a chloride is produced, which with alcohol yields ethyl β -chloropropionate. B. B.

β -Chlorocrotonic Acids. By W. AUTENRIETH (*Annalen*, 259, 358—362).—The sodium salt of β -chlorocrotonic acid, unlike the free

acid, does not undergo intramolecular change when it is heated at 170—180° for 12 hours, but is almost completely decomposed into allylene, sodium chloride, and carbonic anhydride; the sodium salt of β -chlorisocrotonic acid is completely decomposed under the same conditions yielding the same products as the isomeride. F. S. K.

Preparation and Properties of Ethyl Sodacetoacetate and Ethyl Sodethylacetoacetate. By H. ELION (*Ber.*, 23, 3123—3124).—It has been previously shown (*Rec. Trav. Chim.*, 3, 231) that anhydrous ethyl sodacetoacetate and anhydrous ethyl sodethylacetoacetate are readily soluble in ether, but that both compounds form a hydrate which is insoluble in ether. In preparing the anhydrous compounds by the author's method (*loc. cit.*), they are obtained in ethereal solution; this solution can be most suitably employed for carrying out reactions in which the presence of water or alcohol is to be avoided, and the anhydrous compounds can be readily obtained in a solid state by evaporating the ether at a low temperature. Otto and Rössing's statement (*Abstr.*, 1890, 1137) that anhydrous ethyl sodacetoacetate can be obtained by keeping the hydrate over sulphuric acid is contrary to the author's experience, and Michael's assumption (*Abstr.*, 1888, 1034) that pure anhydrous ethyl sodacetoacetate exists in two forms, one of which is soluble, the other insoluble in ether, is quite unwarranted. F. S. K.

γ -Cyanacetoacetates and their Chlorimido-derivatives. By A. HALLER and A. HELD (*Compt. rend.*, 111, 647—650).—Ethyl γ -cyanacetoacetate, boiling at 135—138° under a pressure of 40—45 mm., is mixed with its own volume of absolute alcohol, and the mixture is added to about double the quantity of absolute alcohol saturated with hydrogen chloride and cooled to 0°. Heat is developed, ammonium chloride separates, and the liquid contains a chlorine derivative and ethyl acetodicarboxylate. If ammonium chloride does not separate, the liquid is evaporated in a vacuum, mixed with fine sand, and extracted with ether. The ethereal solution yields slender, white needles of the hydrochloride of the imido-ether of ethyl acetodicarboxylate $(COOEt \cdot CH_2 \cdot CO \cdot CH_2 \cdot C(OEt) : NH, HCl)$, which is decomposed by water with formation of ethyl acetodicarboxylate, $CO \cdot (CH_2 \cdot COOEt)_2$.

If ethyl γ -cyanacetoacetate is dissolved in two or three times its weight of methyl alcohol, and hydrogen chloride is passed into the cooled liquid, crystals are obtained which melt with decomposition at 122°, and consist of the methyl-imido-ether of ethyl acetodicarboxylate plus one molecule of hydrogen chloride. When treated with silver nitrate, half the chlorine is precipitated, but the remainder can only be removed by boiling with potash. When boiled with dilute and slightly acidified alcohol, the compound yields ammonium chloride and an oily chlorinated product.

Methyl γ -cyanacetoacetate, obtained in the same way as the ethyl compound, is a somewhat thick, colourless liquid, which rapidly becomes yellow. It boils at 217—218° under normal pressure, and at 127—128° under a pressure of 20—30 mm.; it does not solidify even at a very low temperature. When treated with hydrogen chloride in presence of methyl alcohol, it yields confused white prisms which

melt with decomposition at 144° , and consist of the hydrochloride of the imido-ether of methyl acetodicarboxylate plus one molecule of hydrogen chloride. It dissolves in water and in alcohol, and with potash, acidified alcohol, and silver nitrate it behaves like the corresponding ethyl compound.

It is necessary to assume that under the conditions of experiment the alkyl cyanacetate undergoes molecular change, and behaves as an unsaturated compound. the chloro-derivatives having the constitution $\text{COOMe}\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{CHCl}\cdot\text{C}(\text{OMe})\cdot\text{NH}_2\cdot\text{HCl}$ or

O. H. B.

Mesitene Lactone and Isodehydracetic Acid. By R. ANSCHÜTZ, P. BENDIX, and W. KERP (*Annalen*, 259, 148—186).—The authors have repeated a number of experiments made by Hantzsch (*Annalen*, 222, 1) in his investigation of the condensation products of ethyl acetoacetate; they have proved that the formulæ assigned by Hantzsch to mesitene lactone and isodehydracetic acid are correct, and that the original condensation product (m. p. $61-62^{\circ}$) is a mixture of two substances and not a compound of the composition $\text{C}_{10}\text{H}_{10}\text{O}_4$, as was supposed by Hantzsch; they also obtained results at variance with those of Hantzsch in studying the action of ammonia and alkalis on ethyl isodehydracetate, as will be described below.

When the crude condensation product of ethyl acetoacetate is repeatedly extracted with cold chloroform or benzene and the extract mixed with light petroleum, isodehydracetic acid (m. p. 155°) is precipitated in a pure condition, and its ethyl salt and mesitene lactone remain in solution. The acid can be more easily isolated by dissolving the condensation product in a mixture of ether and chloroform and shaking the solution, with concentrated potassium carbonate; on acidifying the alkaline solution, the acid is precipitated in a pure condition, and the ethereal chloroform solution, on evaporation, yields the ethyl salt and mesitene lactone, the last-named compound being invariably produced when ethyl acetoacetate is treated with concentrated sulphuric acid.

Ethyl isodehydracetate and mesitene lactone can be separated from one another by fractional distillation under a pressure of about 12 to 14 mm.; the mesitene lactone passes over at $128-130^{\circ}$, the ethyl salt at 166° .

Methyl isodehydracetate, $\text{C}_8\text{H}_{10}\text{O}_4$, prepared by treating the potassium salt with methyl iodide, crystallises from ether in long, colourless needles, melts at $67-67.5^{\circ}$, and boils at 167° under a pressure of 14 mm.; it can also be obtained, together with isodehydracetic acid and small quantities of mesitene lactone, by treating methyl acetoacetate with concentrated sulphuric acid.

When a mixture of pure ethyl isodehydracetate and the free acid is crystallised from dilute alcohol, a substance is obtained which is identical in appearance with, and has the same melting point ($59-60^{\circ}$) as, the original condensation product.

Attempts to prepare the homomesaconic acid described by Hantzsch were unsuccessful; when ethyl isodehydracetate is hydrolysed with

potash, it gives varying quantities of two new acids, melting at 221° and 149° respectively, together with oily by-products. These two acids were prepared by warming the pure ethyl salt (5 grams) on the water-bath, quickly adding a solution of potash (13 grams) in boiling water (4.5 grams), and then warming the mixture for 10 minutes; 50 grams of the ethyl salt yield 13 grams of the higher melting and 2.5 grams of the lower melting compound.

The acid melting at 221° has the composition $C_8H_8O_3$, but its molecular formula is probably $C_{10}H_{12}O_4$; it is almost insoluble in ether, benzene, chloroform, and cold water, and only moderately easily soluble in boiling water, from which it crystallises in transparent, prismatic needles melting at 221° with decomposition. The *potassium* salt, $C_{10}H_{10}O_4K_2$, is a vitreous, very hygroscopic compound. The *barium* salt, $C_{10}H_{10}O_4Ba + 4H_2O$, crystallises from cold water in spherical aggregates and is moderately easily soluble (19.1 parts of anhydrous salt in 100 parts at 20°) in water. The *copper* salt, $C_{10}H_{10}O_4Cu + 3\frac{1}{2}H_2O$, is apple-green and almost insoluble in water. The *silver* salt was not obtained in a pure condition. The *methyl* salt, $C_{10}H_{10}O_4Me_2$, prepared by treating the silver salt with methyl iodide, crystallises from ether in colourless, transparent prisms, melts at 71° , and is readily soluble in ether, alcohol, benzene, and chloroform, but is precipitated from the solutions on the addition of light petroleum.

The acid melting at 149° has the composition $C_8H_{10}O_3$; it crystallises from boiling water, in which it is more sparingly soluble than the acid melting at 221° , in colourless needles, and is readily soluble in alcohol, ether, and chloroform; it decomposes about 160° . The *barium* salt, $(C_8H_9O_3)_2Ba + 2H_2O$, crystallises in microscopic needles, and is very sparingly soluble in water. The *silver* salt, $C_8H_9O_3Ag$, is moderately stable in the light.

Mesitene lactam (pseudolutidestyril,) is formed in small quantities when mesitene lactone is treated with aqueous or anhydrous ammonia under various conditions. It is best prepared by passing anhydrous ammonia for 14 or 15 hours into mesitene lactone (15 grams) heated at 150 to 160° ; the lactam (8.5 grams) thus produced is separated from the unchanged lactone (4.5 grams) by fractional distillation. The compound obtained in this way is identical with Hantzsch's pseudolutidestyril (Abstr., 1884, 1045, and 1885, 397). The *platinichloride*, $C_{11}H_{10}N_2O_2 \cdot 11PtCl_5$, separates from alcohol in dark-orange, transparent crystals.

When mesitene lactone is treated with alcoholic ammonia, a small quantity of the lactam is obtained, together with ammonium carbonate and a liquid, unstable compound, the nature of which was not determined.

Anhydrous ammonia converts ethyl isodehydracetate into the corresponding lactam, which is identical with the substance (m. p. 137°) obtained by Collie (Abstr., 1887, 501) by the condensation of ethyl β -amidocrotonate.

A compound of the composition $C_{10}H_{18}O_4N_2$ is precipitated as a colourless powder when anhydrous ammonia is passed into an alcoholic ethereal solution of ethyl isodehydracetate, moisture being carefully excluded. It melts at 104° with evolution of ammonia, being recon-

verted into ethyl isodehydracetate, and its constitution is probably represented by the formula $\text{COOEt} \cdot \text{C} \begin{smallmatrix} \text{CMe} \cdot \text{CH} \\ \text{CMe} - \text{O} \end{smallmatrix} > \text{C}(\text{NH}_2) \cdot \text{ONH}_2$; when its concentrated aqueous solution is treated with copper chloride, a dark-green, crystalline, copper compound of the composition $(\text{C}_{10}\text{H}_{14}\text{O}_4\text{N})_2\text{Cu} + \text{H}_2\text{O}$ is precipitated.

Ethyl isodehydracetate can be prepared by boiling ethyl sodacetate with a benzene solution of ethyl chlorisocrotonate; methyl isodehydracetate can be obtained in like manner.

The synthesis of ethyl isodehydracetate in this way shows that the acid has the constitution assigned to it by Hantzsch; it is probable, therefore, that the acid obtained by Collie (*loc cit.*) from the lactam, $\text{C}_{10}\text{H}_{13}\text{NO}_3$ (m. p. 137°), referred to above, has an analogous constitution, $\text{COOH} \cdot \text{C} \begin{smallmatrix} \text{CMe} \cdot \text{CH} \\ \text{CMe} \cdot \text{NH} \end{smallmatrix} > \text{CO}$, that of the acid obtained by Collie from the isomeric lactam (m. p. 165°) being probably represented by the formula $\text{COOH} \cdot \text{CH}_2 \cdot \text{C} \begin{smallmatrix} \text{CH} \cdot \text{CMe} \\ \text{NH} - \text{CO} \end{smallmatrix} > \text{CH}$. F. S. K.

Action of Methylene Iodide and Chloride on Ethyl Malonate in the Presence of Sodium Ethoxide. By S. TANATAR (*J. Russ. Chem. Soc.*, 22, 32—39).—The experiments were undertaken with the view of obtaining an acid, $\text{C}_6\text{H}_4\text{O}_8$, isomeric or identical with fumaric or maleic acid. The proportion of the substances taken was calculated from the equation $\text{C}_3\text{H}_5\text{EtO}_4 + 2\text{Na} + \text{CH}_2\text{I}_2 + 15\text{C}_2\text{H}_5\text{O}$. Sodium was dissolved in absolute alcohol and ethyl malonate was added to the solution. As on the addition of methylene diiodide, so much heat is developed that the solution will boil if care be not taken, it is advisable, to add the iodide in small portions at a time; to complete the reaction, the mixture was heated for 12 hours in a reflux apparatus. The alcohol was then removed by distillation, water added, and the oily product, which is partly soluble in water, extracted with ether. After distilling off the ether, the residue, containing some unchanged ethyl malonate and methylene iodide, was saponified with a 15 per cent. solution of potash, but part of it remained unchanged. From a solution of the potassium salt thus obtained, the acid was liberated by acidifying with hydrochloric acid and extracting with ether; the iodine was then removed from it by treatment with molecular silver. The free acid forms a honey-like syrup, which does not crystallise, but, on being kept in a desiccator for several months, becomes converted into a hard, gum-like substance. It can be further purified by converting it into the lead or silver salt and decomposing the latter with hydrogen sulphide. The calcium salt, $\text{C}_6\text{H}_4\text{CaO}_8$, is less soluble in hot than in cold water. The free acid, $\text{C}_6\text{H}_4\text{O}_8$, is called, by the author, *adipomalic acid*. The silver salt is $\text{C}_6\text{H}_3\text{Ag}_2\text{O}_8$; the barium salt, $\text{C}_6\text{H}_3\text{BaO}_8 + 2\text{H}_2\text{O}$.

That portion of the original product of the reaction which remained unchanged on boiling with 15 per cent. potash was saponified by boiling with strong potash, the potassium salt converted into the lead salt, and this, on decomposition and saturation with lime, into a salt $\text{C}_6\text{H}_4\text{CaO}_8$. From the filtrate, alcohol precipitates a calcium salt

containing a little less calcium than the salt $C_6H_8Ca_2O_8$, which shows that a mixture of acids was obtained. From a second portion, iodine was removed with silver nitrate, and the silver salt, $C_6H_8Ag_4O_{10}$, was obtained, so that probably the original acids were $C_6H_{10}O_8$ and $C_8H_{12}O_{10}$. Methylene dichloride and ethyl sodiomalonate, in like manner, yielded the compound $C_4H_8Et_2O_4$, which, on hydrolysis and conversion of the potassium salt, gave the silver salt $C_8H_8Ag_4O_8$. The free acid $C_8H_{10}O_8$, crystallises in prisms which melt at $108-109^\circ$.

B. B.

Reaction between Methylene Iodide and Ethyl Malonate. By S. TANATAR (*J. Russ. Chem. Soc.*, **22**, 39—44).—The acid $C_6H_{10}O_8$ (see preceding paper), when heated with water at 150° , undergoes no change, but if heated with hydriodic acid at 150° it yields ethyl iodide and an acid, $C_4H_6O_4$, thus:— $C_6H_{10}O_8 + HI = C_2H_5I + C_4H_6O_4$. This acid, $OH\cdot CH_2\cdot CH(COOH)_2$, the author calls (?) "*hydroxymethylmalonic acid*," whereas the original adipomalic acid, $C_6H_{10}O_8$, is regarded as *ethoxyisomuccinic acid*, $EtO\cdot CH_2\cdot CH(COOH)_2$. On heating the acid at 250° , decomposition takes place, carbonic anhydride being liberated, and a yellow oil distilling over. This is a neutral ethereal salt, which on hydrolysis yields a potassium salt, which is converted into the lead salt, $C_6H_8PbO_8$. The free acid is a thick syrup: the calcium salt is not thrown down on boiling its aqueous solution, so that the acid $C_6H_{10}O_8$ is not identical but isomeric with ethoxyisomuccinic acid, being probably dialcyllic acid, as shown by the properties of the calcium and lead salts.

B. B.

Succinamic Acid. By R. SERDA and J. WIEDEMANN (*Ber.*, **23**, 3284—3287).—Succinamic acid, $NH_2\cdot CO\cdot CH_2\cdot CH_2\cdot COOH$, prepared by treating succinimide with barium hydroxide, as described by Teuchert (*Annalen*, **134**, 139), is identical with the acid prepared by heating nitrosoglutaric acid (Wolff, *Annalen*, **260**, 114). It crystallises from hot acetone in long needles, melts at $156-157^\circ$, and is moderately easily soluble in water, but very sparingly soluble or insoluble in alcohol, benzene, and light petroleum; it is converted into ammonium succinate on prolonged boiling with water, and when heated alone at 200° , it is transformed into succinimide.

F. S. K.

Synthesis of Asparagine. By A. PIUTTI (*Gazetta*, **20**, 402—406).—When silver γ -oximidosuccinate, $OH\cdot N\begin{smallmatrix} \diagup \\ CH\cdot COOEt \\ \diagdown \end{smallmatrix}$ (Abstr., 1889, 381), is heated on the water-bath with an excess of an ethereal solution of ethyl iodide, the silver iodide removed, and the solution evaporated at $60-70^\circ$, *diethyl nitrilosuccinate*, $N\begin{smallmatrix} \diagup \\ C\cdot COOEt \\ \diagdown \end{smallmatrix} CH\cdot COOEt$ remains as a neutral, yellowish oil, which may be distilled in a vacuum with partial decomposition. When this substance is shaken with strong aqueous ammonia, *ethyl nitrilosuccinamate*, $N\begin{smallmatrix} \diagup \\ C\cdot CONH_2 \\ \diagdown \end{smallmatrix} CH\cdot COOEt$ or $N\begin{smallmatrix} \diagup \\ C\cdot CONH_2 \\ \diagdown \end{smallmatrix} CH\cdot O\cdot COOEt$ is formed; this compound crystallises from alcohol

or acetic acid in brilliant, rhombic plates, melts at 166—167°, and yields a bromide, $C_6H_7N_2O_3Br$, which melts with decomposition at about 140°.

On reducing an acetic acid solution of this amide with sodium amalgam (5 per cent. Na), care being taken to maintain the liquid acid, separating the bulk of the sodium acetate by crystallisation, and allowing the mother liquor to remain in prolonged contact with copper acetate, a crystalline deposit of insoluble copper salts is formed, which, on decomposition with hydrogen sulphide, yields a solution containing three asparagines. These may be obtained perfectly pure by precipitating their concentrated solution with alcohol and recrystallising from water. On leaving the mixture in a vacuum, the inactive α -compound loses its water of crystallisation and falls to powder; the β -asparagines may then be separated by their microscopic characters.

The author regards ethyl nitrilosuccinamate as a derivative of the nucleus $N \begin{smallmatrix} \text{CH} \\ \diagup \diagdown \\ \text{CH}_2 \end{smallmatrix}$, which he terms "etazolo," and has prepared a long series of derivatives of nitrilosuccinamic acid in support of this view.

S. B. A. A.

Amic and Anilic Acids of Fumaric Acid and Maleic Acid.

By R. ANSCHÜTZ (*Annalen*, 259, 137—148—*Maleimamic acid*, $C_6H_5NO_3$, is obtained when anhydrous ammonia is passed into a chloroform or benzene solution of maleic anhydride, and the gum-like ammonium salt which is gradually precipitated warmed with water until the evolution of ammonia is at an end; on acidifying with hydrochloric acid, the maleimamic acid is precipitated in crystals, the yield being about 70 per cent. of the theoretical. It crystallises from water in large, transparent, anhydrous plates, melts at 152—153°, and is readily soluble in hot alcohol and water, but only sparingly in hydrochloric acid, and almost insoluble in benzene, ether, and chloroform; when treated with alcoholic potash, it is converted into fumaric acid, but with aqueous alkalis and barium hydroxide in the cold, it yields salts of maleic acid.

Fumaranilic chloride, $C_{10}H_8ClNO_2$, is obtained when fumaric chloride is treated with aniline in ethereal solution, the quantity of base employed being less than is theoretically necessary to convert the chloride into fumaric acid dianilide; the dianilide and aniline hydrochloride produced are separated by filtration, the ethereal filtrate evaporated, and the residue recrystallised from ether. Fumaranilic chloride forms transparent, yellow, prismatic needles, and melts at 119—120°; with alcohols, it yields crystalline ethereal salts, and with amines, it gives amides. When treated with cold water or dilute alkalis, it is converted into an acid of the composition $C_{10}H_8NO_3$, which melts at 230—231°, and is quite different from the fumaranilic acid (m. p. 187—187.5°) previously obtained by the author and Wirtz (*Abstr.*, 1887, 934) from maleinanil in like manner; the acid melting at 187—187.5° is, therefore, in future to be termed *maleinanilic acid*, to distinguish it from the acid melting at 230—231°, which is named fumaranilic acid.

Fumaramilic acid is only sparingly soluble in boiling water, but more readily than maleïnanilic acid, and when warmed with alcoholic or aqueous potash, it is, like the latter, converted into fumaric acid.

Judging from their behaviour, the amido- and anilido-derivatives of maleïc and fumaric acids have the constitution expressed by the following formulæ:—

The article concludes with a short criticism of Bischoff's paper on dynamical isomerism (compare Abstr., 1890, 723). F. S. K.

Diglycollic Anhydride. By R. ANSCHÜTZ (*Annalen*, 259, 187—193).

—*Diglycollic anhydride*, $\text{O} < \begin{array}{c} \text{CH}_2\text{·CO} \\ \text{CH}_2\text{·CO} \end{array} > \text{O}$, is obtained when finely divided diglycollic acid is boiled with acetic chloride, or when the acid is distilled under a pressure of 11 to 12 mm. It separates from warm chloroform in long, spear-shaped crystals, melts at 97°, and boils at 120° (12 mm.); it is only sparingly soluble in ether, and is readily reconverted into the acid by cold water.

Diglycollanilic acid, $\text{C}_{10}\text{H}_{11}\text{O}_4\text{N}$, is gradually deposited in crystals when an ethereal solution of the anhydride is treated with aniline; it melts at 118°. F. S. K.

Dilactylic Acid. By S. TANAKA and CH. TCHERLEVIEFF (*J. Russ. Chem. Soc.*, 22, 107—110).—It was shown by Friedel and Wurtz that calcium lactate, when heated at 270—280°, loses 1 mol. H_2O , and becomes calcium dilactate, but neither the salt nor the acid was investigated by them. The experiment was repeated by the authors, and from the calcium dilactate obtained, the free acid, $\text{C}_6\text{H}_{10}\text{O}_6$, was separated by decomposing it with oxalic acid. The syrupy liquid obtained was purified by distillation at 170°, under a pressure of 80—90 mm. The distillate, after remaining for some time in the desiccator, was converted into monoclinic, prismatic crystals melting at 105—107°, easily soluble in water, ether, chloroform, and acetic acid, but only slightly in benzene. It gives an acid potassium salt, $\text{C}_6\text{H}_5\text{O}_6\text{K}$, and a silver salt, $\text{C}_6\text{H}_5\text{O}_6\text{Ag}_2$, which, on treatment with methyl iodide, gave the methyl salt, $\text{C}_6\text{H}_5\text{O}_6\text{Me}_2$, boiling at 260°. The

zinc salt, $C_6N_2O_8Zn + 3H_2O$, is amorphous. Hydriodic acid at 150° is without action on dilactylic acid. B. B.

Synthesis of Citric Acid. By A. HALLER and A. HELD (*Compt. rend.*, 111, 682—685).—Ethyl acetodicarboxylate is prepared from ethyl γ -cyanacetate in the manner previously described (this vol., p. 171), and the ethereal solution of the crude product from 10 grams of the cyanacetate is converted into a cyanhydrin by cooling it in a mixture of ice and salt, adding 5 to 6 grams of finely-powdered potassium cyanide, and then, drop by drop, concentrated hydrochloric acid in quantity exactly equivalent to the cyanide. The mixture is allowed to remain in a closed vessel in a cool place for 24 hours, and is then filtered, and the ether distilled off. The cyanhydrin is boiled for two or three hours with concentrated hydrochloric acid in an apparatus with a reflux condenser, the ammonium chloride is removed and the liquid, after being concentrated to expel excess of acid, is boiled with excess of potash. The liquid now contains potassium citrate and chloride with other products formed in the course of the reactions. The citric acid is best separated by means of lead acetate, the precipitate being decomposed by hydrogen sulphide, and the citric acid extracted by means of ether.

50 grams of ethyl γ -cyanacetate yield about 6.2 grams of pure citric acid, and a further quantity of about 4 to 5 grams remains in the syrupy mother liquor. C. H. B.

Action of Phosphorus Pentachloride on Citric and Aconitic Acids. By E. KLIMENKO and BUORSTAR (*J. Russ. Chem. Soc.*, 22, 96—99).—Pebal, by acting with phosphorus pentachloride on citric acid, obtained the solid hydroxychlorocitric acid and two liquid chloranhydrides. The authors have treated citric acid (1 part) with phosphorus pentachloride (3 parts) without heating; after some time, the solid contents of the vessel became converted into a liquid, which after the addition of some more citric acid became partly solid. It was then extracted with dry carbon bisulphide and Pebal's hydroxychlorocitric was left together with some citric acid; this when treated with alcohol, yielded a liquid boiling between 283° and 285° , identical with Malagutti's triethyl citrate, so that the solid chloride obtained at the beginning of the reaction is $C_6H_5Cl_5O_4$. The same chloride is contained in the liquid product of the reaction. On heating citric acid with phosphorus pentachloride, the liquid product is found to prevail, and this contains some aconitic chloride. Aconitic acid with phosphorus pentachloride gives the chloride $C_6H_5O_5Cl_4$, identical with the above bye-product, and this, on being treated with ethyl alcohol, yields Mercadante's triethyl aconitate. The formula $C_6H_5O_5Cl_2$ given to the solid chloride by Skinner and Ruhemann (*Trans.*, 1889, 235) is contradicted by the authors, who find that the solid product is not homogeneous, but always contains citric acid and probably some aconitic acid. B. B.

Alkyl Substitution Products of Ethyl Dicarboxyglutaconate, and a New Synthesis of $\alpha\alpha$ -Dialkylglutaric Acids. By M.

GUHZEIT and O. DRESSSEL (*Ber.*, **23**, 3179—3186).—The authors have already described a method by which dialkylglutaric acids containing two similar alkyl groups may be prepared (*Abstr.*, 1889, 860). To prepare disubstituted glutaric acids containing two different alkyl groups, it is necessary to start with ethyl dicarboxyglutaconate, $\text{CH}(\text{COOEt})_2\cdot\text{CH}\cdot\text{C}(\text{COOEt})_2$. When the sodium compound of this ethereal salt is heated with an excess of ethyl iodide in a sealed tube at $170\text{--}180^\circ$, it yields the *ethyl* derivative, $\text{CEt}(\text{COOEt})_2\cdot\text{CH}\cdot\text{C}(\text{COOEt})_2$, as a colourless oil boiling without decomposition at $195\text{--}202^\circ$ under 11 mm. pressure. It could not be obtained crystalline, and gives no coloration with ferric chloride. Alcohol must not be employed in the preparation of this substance, as it decomposes the sodium compound at a high temperature. The fact that the ethyl compound is volatile without decomposition, whilst the unalkylated compound decomposes on heating with formation of an α -pyrone derivative, is in full accordance with the explanation already given by the authors of the latter reaction (*loc. cit.*).

On hydrolysis, ethyl ethyldicarboxyglutaconate is converted into *ethylglutaconic acid*, $\text{COOH}\cdot\text{CHEt}\cdot\text{CH}\cdot\text{CH}\cdot\text{COOH}$, which is a white, crystalline compound melting at $118\text{--}120^\circ$. Its *silver* salt is a white precipitate, and fairly stable towards light.

Ethyl benzylidicarboxyglutaconate,

is prepared in the manner described by Conrad and Guthzeit (*Annalen*, **222**, 258), and is also volatile without decomposition, boiling at 240° (uncorr.) under 11—12 mm. pressure; it crystallises from alcohol in glassy, rectangular crystals melting at 78° . It is very slowly reduced by zinc-dust and acetic acid.

The ethyl compound, on the other hand, is readily reduced by these reagents with formation of *ethyl ethyldicarboxyglutarate*, $\text{CEt}(\text{COOEt})_2\cdot\text{CH}_2\cdot\text{CH}(\text{COOEt})_2$, which is also an oil boiling at $195\text{--}197^\circ$ (uncorr.) under 10—11 mm. pressure. On treatment with sodium ethoxide and benzyl chloride, it is converted into *ethyl ethylbenzylidicarboxyglutarate*, $(\text{COOEt})_2\text{CEt}\cdot\text{CH}_2\cdot\text{C}(\text{CH}_2\text{Ph})(\text{COOEt})_2$, which is an extremely thick oil boiling at $210\text{--}230^\circ$ under 12 mm. pressure. On hydrolysis, it yields a syrupy tetracarboxylic acid which slowly becomes crystalline, and loses carbonic anhydride on heating at $100\text{--}210^\circ$; a syrup then remains which on analysis gave numbers approximately agreeing with those required by *ethylbenzylglutaric acid*, $\text{COOH}\cdot\text{CHEt}\cdot\text{CH}_2\cdot\text{CH}(\text{CH}_2\text{Ph})\cdot\text{COOH}$. It has not yet been obtained pure or crystalline, but the neutral solution of its ammonium salt yields more or less insoluble precipitates with salts of most of the heavy metals.

H. G. C.

Thiocarbimidoacetic Acid and Thiohydantoin. By P. KLASON (*Chem. Centr.*, 1890, ii, 344; from *Oft. Königl. Vet. Akad.*, 1890, 87).—The author considers that Claus and Neuböffer's reaction of ethyl bromide on thiohydantoin is explained thus:—The ethyl bromide reacts with the alcohol with formation of hydrogen bromide, which then reacts with the thiohydantoin with formation of ammonia

and thiocarbimidoacetic acid, the latter becoming further converted into thioglycollic acid, carbonic anhydride, and ammonia. *Ethyl thiocarbimidoacetate*, $\text{CSN}\cdot\text{CH}_2\cdot\text{COOEt}$, is formed by the action of carbon thiocchloride on ethyl amidoacetate. The carbon thiocchloride is diluted with ether, and the ethyl amidoacetate added drop by drop, the mixture being kept cool; ether is then added, filtered from the ethyl amidoacetate hydrochloride, the filtrate distilled, the impure ethyl thiocarbimidoacetate distilled with steam, extracted from the water with ether, and finally distilled in a vacuum. It is thus obtained as a colourless, somewhat thick liquid, having a feeble odour of oil of mustard, boiling at 110° under a pressure of 12 mm. Sp. gr. = 1.1649 at $18^\circ/4^\circ$.

Thiohydantoin is obtained by heating a mixture of ethyl amidoacetate hydrochloride and dry potassium thiocyanate in molecular proportion at $140\text{--}150^\circ$. The mass is dissolved in water, hydrochloric acid added, and the solution evaporated. The compound has the formula $\text{CS} < \begin{smallmatrix} \text{NH}\cdot\text{CH}_2 \\ \text{NH}\cdot\text{CO} \end{smallmatrix}$. When heated with barium hydroxide, *thiohydantoic acid*, $\text{C}_2\text{H}_4\text{N}_2\text{SO}_2$, is formed, which crystallises in beautiful, colourless prisms, very slightly soluble in cold water. Mercuric oxide converts it into hydantoic acid. Ethyl hydantoate is formed in like manner to thiohydantoin if potassium cyanate is substituted for the thiocyanate, and forms beautiful prisms somewhat readily soluble in hot water, and melting at 138.5° . J. W. L.

Hydrolysis of Sulphones. By E. STUFFER (*Ber.*, 23, 3226 3241; compare Abstr., 1890, 987).—*Diisopropylsulphonedietethylmethane*, $\text{C}_6\text{H}_{12}(\text{SO}_2\text{Pr}^i)_2$, is formed in small quantities, the principal product being potassium isopropylsulphonate, when the condensation product of diethyl ketone and isopropyl mercaptan is oxidised with potassium permanganate and dilute sulphuric acid. It crystallises from hot water in small plates, melts at 97° , and is insoluble in cold water and alcohol, but readily soluble in ether, chloroform, benzene, and hot alcohol. Like diethylsulphonedimethylmethane (sulphonal), it is not hydrolysed by boiling 30 per cent. aqueous or alcoholic potash.

Potassium isopropylsulphonate, $\text{C}_3\text{H}_7\text{SO}_3\text{K}$, crystallises from hot alcohol in plates, and is readily soluble in water.

Diisobutylsulphonedimethylmethane, $\text{C}_8\text{H}_{16}(\text{SO}_2\text{C}_4\text{H}_9)_2$, prepared by oxidising the condensation product of acetone and isobutyl mercaptan, forms colourless crystals, melts at 61° , and is only sparingly soluble in hot water, but moderately easily in alcohol, and readily in chloroform, carbon bisulphide, benzene, and ether; it is not hydrolysed by boiling aqueous or alcoholic potash. The yield of the sulphone is only small, as the principal product of the reaction is the potassium salt of the sulphonic acid.

Diisoamylsulphonedimethylmethane, $\text{C}_{12}\text{H}_{24}(\text{SO}_2\text{CH}_2\text{CH}_2\text{Pr}^i)_2$, obtained in like manner from isoamyl mercaptan, forms crystalline scales, melts at 72° , and resembles the preceding compound in its behaviour with solvents and alkalis.

Diethylsulphonemethane (compare Fromm, Abstr., 1890, 55) is not

acted on by boiling alcoholic or aqueous potash or by sodium ethoxide in boiling alcoholic solution, but when heated with sodium ethoxide at a temperature above 100° , it is completely decomposed.

Diisobutylsulphonemethane, $\text{CH}_3(\text{SO}_2\text{CH}_2\text{Pr}^i)_2$, prepared by oxidising the condensation product of formaldehyde and isobutyl mercaptan, forms colourless crystals, melts at 85° , and is soluble in alcohol, ether, chloroform, benzene, and hot water, but insoluble in cold water; it resembles diethylsulphonemethane in its behaviour with alkalis. The *dibromo-derivative*, $\text{CBr}_2(\text{SO}_2\text{CH}_2\text{Pr}^i)_2$, is a crystalline compound melting at $77-78^{\circ}$.

Propylene diethyl sulphide is obtained when propylene bromide is treated with ethyl mercaptan and sodium ethoxide; it is a mobile oil, cannot be distilled, and is decomposed by oxidising agents, but without yielding propylenediethylsulphone.

Propylene diphenyl sulphide can be prepared by boiling phenyl mercaptan with propylene bromide and 10 per cent. soda for a few hours; it is a heavy oil and cannot be distilled.

Propylenediphenylsulphone, $\text{C}_6\text{H}_5(\text{SO}_2\text{Ph})_2$, is formed by oxidising the sulphide with potassium permanganate; it forms colourless, lustrous plates, melts at 113° , and is soluble in hot alcohol, benzene, chloroform, and hot water, but only sparingly soluble or insoluble in ether and carbon bisulphide, and insoluble in cold water. When boiled with dilute potash, it is decomposed into benzenesulphinic acid and a colourless oil which is probably phenylsulphonopropyl or phenylsulphoneisopropyl alcohol.

Trimethylenediethylsulphone, $\text{C}_2\text{H}_5(\text{SO}_2\text{Et})_2$, can be easily prepared by oxidising trimethylene diethyl sulphide, the condensation product of trimethylene bromide and ethyl mercaptan, with potassium permanganate and dilute sulphuric acid. It crystallises in colourless plates or needles, melts at 183° , and is readily soluble in hot water, but only sparingly in ether, chloroform, benzene, cold alcohol, and cold water; it is not decomposed by hot soda, in which it is soluble, and it is very stable towards bromine and oxidising agents.

Trimethylenediphenylsulphone, $\text{C}_6\text{H}_5(\text{SO}_2\text{Ph})_2$, obtained by heating trimethylene bromide with sodium benzenesulphinate in alcoholic solution, separates from dilute alcohol in crystals, melts at $125-126^{\circ}$, and is almost insoluble in water and cold alcohol, but moderately easily soluble in hot alcohol, benzene, and ether, and very readily in chloroform. It is not acted on by boiling soda or by oxidising agents.

A *trisulphone* of the constitution $\text{SO}_2\text{Et}\cdot\text{CH}_2\cdot\text{C}(\text{Me})_2(\text{SO}_2\text{Et})_2$ is obtained when chloroacetone is heated with ethyl mercaptan and concentrated hydrochloric acid, and the light-yellow oily product oxidised with potassium permanganate and sulphuric acid. It crystallises from hot water in needles, melts at 137° , and is readily soluble in hot alcohol; it is completely decomposed by warm soda, yielding ethylsulphinic acid.

F. S. K.

Action of Acid Chlorides on Bases in presence of Alkali.
By W. MARCKWARD (*Ber.*, 23, 3207—3208).—It has already been

pointed out by Hinsberg (this vol., p. 49) that the reaction employed by Schatten and Baumann for the preparation of benzoyl derivatives is of very general application. The author has found that a benzene solution of carbonyl chloride also acts in a similar manner on organic bases in presence of an excess of alkali, thus forming a ready method of preparing symmetrically substituted carbamides; the urethanes may also be prepared in a similar manner from the alkyl chloroformates.

In addition to the substituted carbamides which are known, the following derivatives of furylamine, $\begin{array}{c} \text{CH-O} \\ | \quad \diagup \\ \text{CH-CH} \end{array} \text{C-CH}_2\text{NH}_2$, have been prepared.

Symmetrical Difurylcarbamide, $\text{CO}(\text{NH-CH}_2\text{C}_4\text{H}_3\text{O})_2$.—To obtain this compound, a mixture of furylamine with aqueous caustic potash is shaken with a slight excess or a benzene solution of carbonyl chloride until the odour of the latter has disappeared, part of the carbamide separating out. The benzene is evaporated, the separated difurylcarbamide collected, and recrystallised from benzene. It forms small, nacreous plates which are sparingly soluble in all the ordinary solvents, melts at 128° , and has an intense odour resembling that of the dwarf plume-thistle (*Carlina acanthis*).

Ethyl furylcarbamate, $\text{C}_4\text{H}_3\text{O-CH}_2\text{NHCOOEt}$, is obtained in a corresponding manner from furylamine and ethyl chloroformate. It is extracted from the aqueous solution with ether, and remains, after distilling off the latter, as a yellowish oil which has a pleasant odour. On heating, it distils at 240° , forming a colourless liquid, which has, however, then an unpleasant odour, probably owing to the formation of traces of furylcarbamine.

II. G. C.

Rationale of Reactions in the presence of Aluminium Chloride and Bromide. By G. GUSTAVSON (*J. pr. Chem.* [2], 42, 501–507).—Friedel and Crafts (Abstr., 1889, 241) attributed the action of aluminium chloride and bromide in facilitating the displacement of the hydrogen in benzene, &c., to the formation of such compounds as $\text{C}_6\text{H}_5\cdot\text{Al}_2\text{Cl}_5$, which, however, could only be isolated in the absence of hydrochloric acid, for this decomposes them. If such be the case, the author asserts that such a compound as $\text{C}_6\text{H}_5\text{SO}_2\cdot\text{Al}_2\text{Cl}_5$ should also exist, for aluminium chloride brings about a reaction between sulphurous anhydride and benzene (*loc. cit.*); but there is no evidence that such a compound is formed when sulphurous anhydride is passed into a mixture of benzene and aluminium chloride; indeed, according to Adrianowsky (Abstr., 1879, 915), quite a different reaction takes place.

Friedel and Crafts fail to see how the compounds $\text{AlCl}_3(\text{C}_6\text{H}_5)_3$, &c., which are formed according to the author's theory (Abstr., 1885, 363), and are exothermic, can facilitate substitution; the author replies that it is equally difficult to explain how hydrogen which has combined with nitrogen in the exothermic compound ammonia should be more ready to react with methyl chloride, &c., than when in the free state. The author has obtained and analysed the compound $\text{AlCl}_3\cdot 3\text{C}_2\text{H}_5$; such compounds as this are decomposed by heat, and

will not explain those reactions which only take place at high temperatures.
A. G. B.

Meta- and Para-ethylisopropylbenzene. By P. v. D. BECKE (*Ber.*, 23, 3191—3196).—The preparation of these hydrocarbons may be readily carried out by means of Friedel and Crafts' reaction. It has been shown by Gustavson (*Ber.*, 11, 1251), Silva (*Abstr.*, 1885, 1054), and Kekulé and Schrötter, that in the presence of aluminium chloride the propyl group is converted into isopropyl, and in preparing the above hydrocarbon it is immaterial whether propyl or isopropyl bromide is employed. 300 grams of ethylbenzene were therefore mixed with 50 grams of aluminium chloride, and 450 grams of propyl bromide gradually added. After remaining for eight days, the product is washed, dried, and fractionated; the fractions 189—195° and 195—201° contain the meta- and para-ethylisopropylbenzene respectively. The fraction 150—155° is isopropylbenzene, the properties of which agree with the statements of Claus and Tonn (*Abstr.*, 1885, 903), except that the author finds the melting point of the sulphonamide to be 93—94° instead of 127°. The fraction 179—185° contains diethylbenzenes, and that boiling at 204—208° consists probably of di-isopropylbenzenes.

To obtain the pure hydrocarbons from the fractions boiling at 189—195° and at 195—201° respectively, both are sulphonated with a mixture of 1 vol. of concentrated sulphuric acid and $\frac{1}{2}$ vol. of fuming acid, the first sulphonic acid being isolated as the barium salt, and the second as the magnesium salt. These are then converted into the potassium salts, and the latter heated with hydrochloric acid under pressure.

Metethylisopropylbenzene is a colourless, pleasant-smelling liquid, which boils at 190—192°, does not solidify at -20° , and on oxidation yields isophthalic acid. *Barium metethylisopropylbenzenesulphonate* crystallises in anhydrous, fascicular aggregates of needles, sparingly soluble in water, whilst the *copper* salt crystallises with 4 mols. H_2O in blue plates which have a satin-like lustre. The *sulphochloride* and *sulphonamide* are oils.

Paraethylisopropylbenzene is a liquid which is more strongly refractive than water, boils at 197—198°, and does not become solid at -20° . On oxidation, it is converted into terephthalic acid. *Magnesium paraethylisopropylbenzenesulphonate* crystallises with 4 mols. H_2O in tablets which are sparingly soluble in water. The *copper* salt also crystallises with 4 mols. H_2O , and forms blue, satiny plates; whilst the *potassium* salt could only be obtained as an amorphous, readily soluble mass. The *sulphochloride* is an oil, and the *sulphonamide* only becomes partially solid in the exsiccator. The *sulphonanilide*, on the other hand, crystallises in nodular aggregates of prisms melting at 92—93°.

Nitroparethylisopropylbenzene is obtained by the nitration of the hydrocarbon in acetic acid solution, and forms a yellowish-brown oil which boils at 265° with partial decomposition. On treatment with zinc and acetic acid, it is slowly reduced to *amidoparethylisopropylbenzene*, the hydrochloride of which forms fascicular aggregates of

needles, becoming brown in the air. *Parethylisopropylphenol* is obtained by fusing the potassium sulphonate with caustic potash, and is a yellow oil boiling at 228—230°, almost insoluble in water, but readily soluble in alcohol and ether.

The author has also prepared *parethylpropylbenzene* according to Sempotowski's method (Abstr., 1890, 54). It boils at 199—200°, and yields, on sulphonation, only one *sulphonic acid*, the *magnesium* salt of which crystallises in small prisms containing 4 mols. H_2O , and is readily soluble in water. The *sulphonamide* crystallises from dilute alcohol in small plates which melt at 84°, and the *sulphamillide* in fascicular aggregates of slender needles melting at 97—98°.

H. G. C.

Diisopropylbenzene. By E. UHLHORN (*Ber.*, 23, 3142—3144).—A mixture of two hydrocarbons, boiling at 200—210°, is obtained in the preparation of isopropylbenzene (b. p. 153°) by Friedel and Crafts's method; the two compounds can be separated from one another by shaking the mixture with concentrated sulphuric acid, converting the sulphonic acids thus produced into their copper or barium salts, and separating the salts by fractional crystallisation.

Barium metadiisopropylbenzenesulphonate crystallises in long needles with 2 mols. H_2O , and is only sparingly soluble in water. The *copper* salt, with $4\frac{1}{2}$ mols. H_2O , forms long, bluish needles, and is readily soluble. The *magnesium* salt, with 4 mols. H_2O , crystallises in well-defined, prismatic plates, and is rather sparingly soluble in water. The sodium and the calcium salts crystallise in needles, and are very readily soluble in water.

Metadiisopropylbenzenesulphonamide crystallises in colourless plates, and melts at 145°.

Trinitro metadiisopropylbenzene forms yellowish needles, and melts at 110—111°. *Metadiisopropylbenzene*, prepared by heating the sulphonamide with hydrochloric acid at 180°, boils at 204°, and, on oxidation with dilute nitric acid, is converted into isophthalic acid.

Copper orthodiisopropylbenzenesulphonate crystallises in plates with $6\frac{1}{2}$ mols. H_2O , and is sparingly soluble in water. The magnesium, calcium, and sodium salts are very readily soluble. The *sulphonamide* melts at 102°, and yields *orthodiisopropylbenzene* boiling at 209°, which, on oxidation, is converted into phthalic acid.

F. S. K.

Nononaphthene and its Derivatives. By I. KONOVALOFF (*J. Russ. Chem. Soc.*, 22, 4—23 and 118—148).—Several years ago, Markovnikoff and Ogloblin obtained from Caucasian petroleum a series of hydrocarbons, "*naphthenes*," of the general formula C_nH_{2n} , having the properties of saturated compounds of the aromatic series. Nononaphthene was obtained from Balachana and Bibi-Eibat petroleum by treating the fraction boiling between 125—140° with fuming sulphuric acid at 40°, washing with aqueous soda and water, drying, and rectifying over sodium, and, after repeated fractional distillation, again purifying it in the same manner. The fraction boiling at 135—136° consists of the hydrocarbon *nononaphthene*, $C_{19}H_{38}$; its sp. gr., when prepared from the first-named source, is 0.7664 (20/20°), from the second 0.7647. As sulphuric acid acts on nononaphthene, it is not without reason that

Mendeléeff recommended that the use of this reagent for its purification should be avoided. With excess of sulphuric acid, nononaphthene gives pseudocumonesulphonic acids. Sulphur or antimony pentachloride at high temperatures gives indefinite mixtures of thio- or chloro-derivatives. By the action of bromine and aluminium bromide, part of the hydrocarbon is converted into tribromopseudocumene. Nitric acid of sp. gr. 1.4 is without action in the cold, but if the hydrocarbon is heated at 120—130°, with the same acid diluted with two volumes of water, nitro-derivatives are obtained such as $C_9H_{15}NO_2$; this boils at 218—220°, and on treatment with hydrochloric acid and tin, an amine, $C_9H_{15}NH_2$, isomeric with coniine is obtained. It smells like that alkaloid, boils between 172° and 177°, and gives only in a feeble degree Hofmann's reaction for primary amines. Its sp. gr. is 0.8727 at 0°, and it is a strong base, combining with acids, and absorbing carbonic anhydride from the atmosphere.

Nononaphthene was heated with hydriodic acid with the object of hydrogenating it, but nonane was not formed. By the action of chlorine, chlorides were obtained, containing principally $C_9H_{17}Cl$, boiling at 185—187°. The chloride was converted into the iodide $C_9H_{17}I$ by heating it with strong hydriodic acid at 150—160°; this boils at 108—111° under a pressure of 200 mm. On heating the chloride or the iodide with silver acetate and acetic acid, the *acetate*, $CH_3COOC_9H_{17}$, was obtained; it boils at 208.5°. This, on hydrolysis, yields *nononaphthyl alcohol*, $C_9H_{17}OH$, boiling at 189—192°; sp. gr. = 0.8972 at 20°/20°; and the alcohol, on treatment with phosphorus pentachloride, yields the chloride $C_9H_{17}Cl$, mentioned above and having the same properties. A solution of the iodide in ether, when heated with silver oxide, yields the *ether* $(C_9H_{17})_2O$, boiling at 300.5°; sp. gr. 0.8662 at 20°/20°. The elements of hydrogen chloride are easily removed from the chloride, $C_9H_{17}Cl$, with formation of *nononaphthylene*, C_9H_{16} ; this boils at 135—137°, and has sp. gr. 0.8068 at 0°. With bromine, nononaphthylene yields a dibromide, $C_9H_{16}Br_2$, which is easily split up into hydrogen bromide and the bromo-derivative $C_9H_{15}Br$, but it is impossible to saturate the compound with bromine up to the limit. Oxidation of nononaphthene and its alcohol with chromic mixture yields a complicated mixture of acids. Nononaphthene is proved to be *heptahydropsseudocumene* [b. p. 135—138°; sp. gr. 0.7667 (20/0°)]. It has hitherto been found to be impossible to convert it by hydrogenation into nonane, the corresponding saturated hydrocarbon of the fatty series.

B. B.

Caucasian Petroleum. By V. MARKOVNIKOFF (*J. Russ. Chem. Soc.*, 22, 23—26).—By fractional distillation of the lower boiling portions of Caucasian petroleum, previously purified by fuming sulphuric acid, the author has obtained a series of fractions boiling between 32° and 72°, and not further separable by fractional distillation. The relation between the boiling points and the densities shows that the higher fractions contain a comparably larger proportion of naphthenes having a higher density than the corresponding paraffins, whereas the latter are more abundant in the fractions of lower boiling point. It is shown that the portion boiling between 57° and 60° contains neither

hexanaphthene nor benzene, and that it consists principally of dipseudopropyl C_6H_{14} . The fraction 45—48° contains hexane (trimethylethylmethane) and pentane; the fraction 32—36° consists chiefly of dimethylethylmethane, whilst the fraction boiling above 60° contains normal hexane. B. B.

Action of Thionyl Chloride on the Phenols. By G. TASSINARI (*Gazzetta*, 20, 362—366).—The action of thionyl chloride on the phenols results in the formation of a mixture of variable quantities of three substances, namely (1), a compound of high melting point not examined further; (2) a dihydroxythiobenzene identical with that obtained by the action of sulphur dichloride on phenol (Abstr., 1889, 245); (3) chlorinated and sulphuretted resins. Hydrogen chloride and sulphurous anhydride are also evolved during the reaction. Thionyl chloride has a similar action on orthocresol and thymol, the only difference being that with orthocresol a good deal of the compound of high melting point is formed, and but little of the dihydroxythiobenzene, the reverse occurring with thymol; paracresol is scarcely affected in the cold, only a trifling quantity of liquid chloroparacresol being formed.

The dihydroxythiobenzene previously described (*loc. cit.*) has the following crystallographic characters. The crystals belong to the monoclinic system:— $a : b : c = 0.41564 : 1 : 0.26415$; $\beta = 86^\circ 48'$. The derived hydroxysulphonebenzide crystallises in the rhombic system:— $a : b : c = 0.78133 : 1 : 0.415568$; $\beta = 90^\circ$. S. B. A. A.

Condensation Products of Glyoxal and some Mercaptans. By E. STUFFER (*Ber.*, 23, 3241—3245).—Glyoxal combines with ethyl mercaptan in presence of hydrochloric acid, but the product cannot be obtained in a pure condition, nor can it be converted into a tetrasulphone by oxidation with potassium permanganate.

Tetraethiophenylglyoxal, $CH(SPh)_2 \cdot CH(SPh)_2$, is formed when glyoxal sodium hydrogen sulphite is warmed with phenyl mercaptan in alcoholic hydrochloric acid solution. It separates from alcoholic chloroform as a colourless powder, melts at 115°, and is very readily soluble in chloroform, but only sparingly in boiling alcohol, and insoluble in water and alkalis. It dissolves in warm concentrated sulphuric acid with a cherry-red coloration, is readily oxidised and decomposed by concentrated nitric acid, and combines with bromine, yielding a yellow, oily compound; when treated with potassium permanganate under various conditions, it is either unchanged or completely decomposed, so that the corresponding sulphone cannot be obtained. F. S. K.

Nitrometacresols. By W. STANDEL and A. KOLB (*Annalen*, 259, 208—227; compare Abstr., 1889, 497).—The two metanitrocresols which are obtained by nitrating pure cresol, prepared from thymol, can be easily separated by distillation with steam. The non-volatile compound (m. p. 129°) crystallises from water and alcohol in needles, is very readily soluble in benzene, ether, chloroform, alcohol, and hot water, and dissolves in alkaline carbonates with evolution of carb-

onic anhydride. The *ammonium* derivative forms long, yellow needles, and the *silver* derivative is a yellowish-red compound almost insoluble in water. The *potassium* derivative, $C_7H_4NO_3K + 2H_2O$, and the *sodium* derivative, with $2H_2O$, crystallise in yellow plates, and the *barium* derivative in silky needles. The ethyl derivative melts at $53-54^\circ$, and is identical with the compound obtained by nitrating metacresol ethyl ether.

Orthonitrometatoluidine $[Me : NH_2 : NO_2 = 1 : 3 : 6]$, prepared by heating nitrometacresol ethyl ether with concentrated ammonia at $140-150^\circ$, crystallises from water in slender, yellow needles, melts at 134° , and is readily soluble in alcohol, ether, and hot water; when treated with sulphuric acid and sodium nitrite in alcoholic solution, it is converted into nitrotoluene (b. p. $220-221^\circ$).

Amidometacresol $[Me : OH : NH_2 = 1 : 3 : 6]$, obtained by reducing the nitro-compound with tin and hydrochloric acid, is a grey powder melting at 174° with decomposition. The *hydrochloride*, C_7H_5ON, HCl , crystallises in colourless plates. The *acetyl* derivative, $C_7H_4NO_2$, crystallises from water, in which it is readily soluble, in colourless plates containing 1 mol. H_2O ; these melt at 80° and lose their water at $110-120^\circ$; the anhydrous compound melts at 125° , and is sparingly soluble in benzene.

Methylquinonechlorimide, C_7H_4NOCl , is precipitated when a concentrated solution of calcium hypochlorite is added to a dilute aqueous solution of amidometacresol hydrochloride. It crystallises from alcohol in golden prisms, melts at 75° , and explodes at a higher temperature.

Dinitrometacresol ethyl ether $[Me : OEt : (NO_2)_2 = 1 : 3 : 4 : 6]$ is formed when the corresponding mononitro-compound is treated with fuming nitric acid. It crystallises from dilute alcohol in colourless needles, and melts at 97° .

Dinitrometatoluidine, prepared by heating the preceding compound with ammonia at 100° , separates from xylene in yellow crystals, melts at 195° , and is only sparingly soluble in alcohol and benzene; when treated with nitrous acid under suitable conditions, it is converted into α -dinitrotoluene $[Me : (NO_2)_2 = 1 : 4 : 6]$.

Trinitrometacresol ethyl ether $[Me : (NO_2)_3 : OEt = 1 : 2 : 4 : 6 : 3]$ crystallises from alcohol in slender needles or in thick prisms melting at 75° ; it is probably identical with the compound (m. p. 72°) obtained by Nölting and von Salis from the silver derivative of trinitrocresol; when treated with alcoholic ammonia, it is converted into trinitrotoluidine (m. p. 136°).

The volatile nitrometacresol (m. p. 56°) crystallises from ether in yellow plates, and is only very sparingly soluble in water, but very readily in alcohol, ether, benzene, and chloroform. The *potassium* derivative crystallises in red needles, and is very readily soluble in water. The *ethyl* derivative, $C_7H_4NO_2$, crystallises from alcohol in colourless needles, melts at $50-51^\circ$, and is very readily soluble in most of the ordinary solvents.

Nitrometatoluidine $[Me : NH_2 : NO_2 = 1 : 3 : 4]$, prepared by heating the ethyl derivative with ammonia at $140-150^\circ$, crystallises from water in golden plates, melts at 109° , and is moderately easily

soluble in alcohol, ether, benzene, chloroform, and hot water; ethyl nitrite at 100° converts it into paranitrotoluene.

When nitrometacresol ethyl ether (m. p. 50—51°) is treated with nitric acid, it is converted into a dinitro-compound identical with that (m. p. 97°) obtained from the isomeride described above.

F. S. K.

Constitution of Thymol and Carvacrol Derivatives. By G. MAZZARA (*Gazzetta*, 20, 417—427).—*Tetracetyldiamidothymol acetate* [Me : NAc₂ : OAc : Pr : NAc₂ = 1 : 2 : 3 : 4 : 6], prepared by heating diamidothymol hydrochloride with acetic anhydride, crystallises from dilute alcohol in shining, white scales, softens at 179°, and melts at 184—186°. It is insoluble in alkalis.

a bye-product in the preparation of the preceding compound. It is prepared by heating that compound or its constituents at a temperature of 200° to 260°. It crystallises from light petroleum in large, colourless, transparent, rhombohedric tables, melts at 92—94°, and dissolves in the ordinary solvents. It is decomposed by prolonged digestion with alkalis yielding products which impart a violet coloration to the liquid. The action of dilute hydrochloric acid removes one acetyl group from this compound, leaving *monacetylamidoethenylamidothymol*, a substance which crystallises from alcohol in yellowish or violet needles melting at 132—134°. It dissolves readily in alcohol and benzene. It is reconverted into the diacetyl derivative by heating with acetic anhydride at 200°. It is decomposed by digestion with alkalis or acids.

The action of acetic anhydride on diamidothymol hydrochloride at 160° results in the formation of a mixture of *di*-, *tri*-, and *tetracetyldiamidothymol*. These compounds are all soluble in potash, forming pink solutions, from which acids precipitate the diacetyl derivative. They also dissolve in boiling water and in dilute alcohol, crystallising out in white or pale-violet scales. The tetracetyl compound melts at 216—222°, the triacetyl compound at 238—240°, and the diacetyl derivative at 260—262°.

heating diamidocarvacrol hydrochloride with excess of acetic anhydride at 210°, crystallises from alcohol in yellowish needles and melts at 190—192°. The formation of this ethenyl derivative and of the benzenyl derivative previously described (this vol. p. 48) support the author's view, that in dinitrocarvacrol the two nitroxyl groups are in the meta-position relatively to each other.

S. B. A. A.

Constitution of Rhodizonic Acid. By R. NIETZKI (*Ber.*, 23, 3136—3141).—The author agrees with Nef (*Abstr.*, 1890, 1270) that rhodizonic acid has the constitution $C_6O_4(OH)_2$ [$O_1 : (OH)_2 = 1 : 2 : 3 : 4 : 5 : 6$], and not the symmetrical constitution [$O_4 : (OH)_2 = 1 : 2 : 4 : 5 : 3 : 6$]. One of the principal facts which points to this conclusion is that croconic acid hydride, $C_6H_4O_8$, a compound which is formed from rhodizonic acid under the influence of concentrated alkalis, does not combine with orthodiamines, whereas croconic acid, $C_6H_4O_8$, is readily converted into azines. This difference in behaviour is best accounted for by assuming that the hydride has the constitution $OH \cdot CH < \begin{matrix} CO \cdot C \cdot OH \\ | \\ CO \cdot C \cdot OH \end{matrix}$, and the formation of a compound of this nature from rhodizonic acid can only be explained by assuming that the latter has the asymmetrical structure. The existence of dinitroso-resorcinoltetroxime, $C_6H_2(N \cdot OH)_4$ [$(NOH)_4 = 1 : 2 : 3 : 4$], seems to show that the quinone of the constitution $C_6H_2O_4$ [$O_4 = 1 : 2 : 3 : 4$] is also capable of formation, whereas no symmetrical paradiquinone has yet been obtained; this argument, as well as the behaviour of rhodizonic acid with orthodiamines, bears out the author's views regarding the constitution of rhodizonic acid. F. S. K.

Replacement of the Hydrogen Atoms in the Methylene Group. By O. WALLACH (*Annalen*, 259, 300—309).—The hydrogen atoms of a methylene group which is in direct combination with basic radicals are readily displaced by negative elements, more especially by sulphur; and in most cases, the reaction proceeds so well that it can be conveniently employed for the preparation of various sulphur compounds.

When benzylaniline (1 mol.) is heated with sulphur (2 atoms) at 220° until the evolution of hydrogen sulphide ceases, thiobenzanilide is formed; if, however, the temperature is raised to 250—260°, and the heating is continued, benzenylamidothiophenol (m. p. 115°) is obtained. Benzytoluidine and other benzyl bases behave like benzylaniline.

Tetramethyldiamidothiobenzophenone can be easily obtained by heating tetramethyldiamidophenylmethane (50 grams) with sulphur (15 grams) at 230° until the evolution of hydrogen sulphide is at an end; thiobenzamido can be prepared by heating benzylamine with sulphur at 180°.

Tribenzylamino combines with bromine in glacial acetic acid solution, yielding a compound of the composition $(C_7H_7)_3NBr_2$; this substance crystallises in golden needles, melts at 157—159°, is reconverted into tribenzylamino by sulphurous acid, and when boiled with water, is decomposed into benzaldehyde, dibenzylamino, and tribenzylamine.

When benzylamine is treated with bromine in glacial acetic acid solution, it yields a crystalline substance melting at 108°, which seems to have the composition $OH_2Ph \cdot NH_2Br_2$; this bromo-compound is decomposed by warm water and alcohol, and also on exposure to the air, into benzonitrile and benzylamine hydrobromide. F. S. K.

Action of Paratoluidine and Aniline on Phloroglucinol. By G. MINUNNI (*Gazzetta*, 20, 319—355).—Phloroglucinol reacts very energetically with paratoluidine or aniline forming compounds analogous to those obtained by the action of the aromatic amines on monhydric and dihydric phenols. Both symmetrical triparatolyltriamidobenzene, $C_6H_3(NH \cdot C_6H_7)_3$, the product of the action of paratoluidine on phloroglucinol, and triphenyltriamidobenzene, obtained from aniline and phloroglucinol, together with a number of their derivatives, have already been described (Abstr., 1888, 1081). The following are additional products:—The *nitrosyl* derivative of triparatolyltriamidobenzene, $C_6H_3[N(C_6H_7) \cdot NO]_3$, crystallises from boiling alcohol in slender, deep-brown needles, melts at 233—234°, and dissolves sparingly in hot benzene and in alcohol after prolonged boiling; it is readily soluble in concentrated sulphuric acid forming a dirty-green solution.

Diparatolyldiamidohydroxybenzene, $OH \cdot C_6H_3(NH \cdot C_6H_7)_2$, prepared by heating a mixture of phloroglucinol (1 mol.) and paratoluidine (2 mols.) for six hours at 140—150°, crystallises when pure from a mixture of ether and light petroleum in colourless needles, melts at 120—121°, and, on exposure to the air, turns grey at first, but becomes intensely brown after a time. It dissolves readily in cold benzene, alcohol, and ether, and in hot alkalis, but only very sparingly in boiling water and in concentrated hydrochloric acid. It is also soluble in concentrated sulphuric acid forming a colourless solution which turns brown on heating, and reddish on addition of a little potassium nitrite. The *hydrochloride* may be obtained as a yellow, flocculent, amorphous precipitate which decomposes as soon as it is removed from the acid solution. The *platinum salt*,

crystallises in brilliant, bronze-coloured scales, insoluble in ether, and only very sparingly soluble in boiling alcohol; it is decomposed by hot water; on heating to 260°, it is converted into a brown, amorphous powder.

The *acetyl* derivative, $OH \cdot C_6H_3(NAcC_6H_7)_2$, crystallises in colourless, microscopic prisms, melts at 128—129°, and dissolves in cold alcohol and benzene, and very sparingly in ether. It is also sparingly soluble in alkalis, and more readily in concentrated acids. Ammonia precipitates it unchanged from its hydrochloric acid solution.

The *benzoyl* derivative, $OBz \cdot C_6H_3(NBzC_6H_7)_2$ (P), forms a colourless, crystalline powder consisting of microscopic plates, and melts at 262—264°. It is almost insoluble in ether, and only very sparingly soluble in alcohol and benzene. It is insoluble in alkalis, but dissolves in concentrated sulphuric acid, and is reprecipitated unchanged on diluting the solution. Its composition is doubtful.

The *nitrosyl* derivative, $OH \cdot C_6H_3(NC_6H_7 \cdot NO)_2$, crystallises in brownish-red, microscopic needles which darken on heating to 230°, but do not fuse even at 260°. It is very sparingly soluble in alcohol and benzene, and almost insoluble in ether.

The *nitrosyl* derivative of triphenyltriamidobenzene, $C_6H_3(NPh \cdot NO)_3$, crystallises from alcohol in brilliant, brown needles, melts at 264—265°.

and is almost insoluble in alcohol and benzene. It dissolves in cold concentrated sulphuric acid forming a solution which appears dark-green by reflected light, and copper-coloured in the magnesium light.

Diphenylglucidoxybenzene, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{NPh})_2$, is prepared by heating phloroglucinol with aniline in the theoretical proportions for six hours at $140\text{--}150^\circ$. It crystallises from a mixture of ether and petroleum in slender, white needles which acquire a grey tinge after some time, melts at $94\text{--}95^\circ$, and dissolves readily in cold alcohol, benzene, and ether, but only sparingly in water, alkalis, and hydrochloric acid. On cooling its solution in potash, a substance separates out, readily soluble in water. It dissolves in cold concentrated sulphuric acid, and the solution turns blue on the addition of a little sodium nitrite, and brownish-red when a larger quantity is added. The *hydrochloride*, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{NPh})_2\cdot 2\text{HCl}$, is an amorphous, brownish-yellow powder which is decomposed by hot water; it melts at $85\text{--}90^\circ$, and is soluble in alcohol, but not in ether. The *platinum salt*, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{NPh})_2\cdot\text{PtCl}_4$, crystallises in large, yellowish-brown plates which darken at 230° ; it dissolves readily in boiling alcohol, but is insoluble in ether. It is decomposed by boiling water.

The *acetyl* derivative, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{NPhAc})_2$, forms a white, crystalline powder which melts at $149\text{--}150^\circ$, and dissolves readily in boiling alcohol and benzene. It is moderately soluble in hot alkalis and in cold concentrated acids. Ammonia precipitates from its hydrochloric solution a white powder soluble in excess. The *benzoyl* derivative, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{NPhBz})_2$, is obtained by treating the base with benzoic anhydride. It crystallises from alcohol in large, bright-yellow needles, melts at $184\text{--}185^\circ$, and dissolves readily in the ordinary solvents, and also in boiling alkaline solutions and in cold concentrated sulphuric acid. The *nitrosyl* derivative, $\text{OH}\cdot\text{C}_6\text{H}_3(\text{NPh}\cdot\text{NO})_2$, crystallises from boiling glacial acetic acid in bright-red needles, and blackens without melting at 250° ; it is almost insoluble in the ordinary solvents, but dissolves in cold concentrated sulphuric acid. Attempts were made to prepare a dihydroxy-derivative,

by moderating the reaction between phloroglucinol and paratoluidine, but without success, the monhydroxy-derivative being formed in every instance; a similar failure attended an attempt to prepare mixed derivatives of the type $\text{C}_6\text{H}_3(\text{NH}\cdot\text{C}_7\text{H}_7)_2\cdot\text{NHPh}$. From the foregoing results, it appears that phloroglucinol, a trihydric phenol, reacts more energetically with aromatic amines than the dihydric phenols, which in turn are more active than the monhydric compounds. The energy of reaction must, therefore, depend directly on the number of OH-groups present. Moreover, in view of the complete analogy between the action of ammonia and that of the substituted amines, it seems probable that phloramine, the product of the action of ammonia on phloroglucinol, is also a derivative of trihydroxybenzene, and not of the secondary phloroglucinol, $\begin{array}{c} \text{CH}_2\cdot\text{CO}\cdot\text{CH}_2 \\ | \quad | \\ \text{CO}\cdot\text{CH}_2\cdot\text{CO} \end{array}$, as indicated by Baeyer (Abstr., 1886, 350).

Consecutive Tetramidotoluene. By R. NITZKI and R. RÖSEL (*Ber.*, 23, 3216—3219).—A mixture of the mono- and di-nitro-derivatives of diacetylmetatoluylenediamine is obtained when diacetylmetatoluylenediamine is mixed with carbamido nitrate, and then gradually introduced into nitric acid (6 parts), which has been previously distilled with sulphuric acid, the temperature being kept at from 5 to 10°. The two compounds are precipitated with ice and hydrolysed with dilute sulphuric acid or dilute alkalis; the mono- and di-nitrometatoluylenediamine obtained in this way can be easily separated from one another, as the latter alone is soluble in alkalis, being reprecipitated on the addition of an acid.

Dinitrometatoluylenediamine, $C_8HMe(NO_2)_2(NH_2)_2$, forms slender, golden needles and melts above 300°.

Tetramidotoluene sulphate, $C_8HMe(NH_2)_4 \cdot H_2SO_4$, is obtained when the dinitro-compound just described, or tetrisonitrososorsorcinol [$Me : (NOH)_4 = 1 : 3 : 4 : 5 : 6$], is reduced with stannous chloride and hydrochloric acid; the filtered solution is treated with sulphuric acid, then mixed with a considerable quantity of alcohol, the precipitated sulphate dissolved in moderately dilute hydrochloric acid and reprecipitated with alcohol; it crystallises in small, almost colourless plates. When excess of sulphuric acid is added to a hydrochloric acid solution of this salt, a compound of the composition

is precipitated in small plates.

Tetramidotoluene cannot be obtained by decomposing one of its salts, as it rapidly oxidises on exposure to the air; solutions of its salts are coloured brown by ferric chloride and other oxidising agents, but a definite oxidation product could not be obtained.

A *quinoxaline* of the composition $C_{13}H_{24}N_4$ is gradually deposited in yellowish-red needles when tetramidotoluene sulphate is heated with benzil and sodium acetate in alcoholic solution; it melts at 222—225°, and dissolves in concentrated sulphuric acid yielding a red solution, the colour of which changes to yellow on the addition of water.

Croconic acid also combines with tetramidotoluene, yielding a dark-brown azine, which crystallises in needles, but is so insoluble in all ordinary solvents that it cannot be purified by recrystallisation.

When tetramidotoluene sulphate is heated with sodium acetate and acetic anhydride, a compound of the composition $C_{16}H_{20}N_4O_4$ is obtained; this substance crystallises in colourless needles, melts at 305°, is moderately easily soluble in hot water, and is probably a triacetylthényltetramidotoluene of the constitution

It dissolves in dilute hydrochloric acid, and on adding ammonia to the solution, a colourless, very readily soluble base melting at 282° is precipitated; judging from the analysis of the picrate, this base is probably diacetylthényltetramidotoluene. F. S. K.

Diazo-compounds. By H. GOLDSCHMIDT (*Ber.*, **23**, 3220—3222).—The author has determined the molecular weight of meta- and para-nitrodiazobenzene nitrate and of diazobenzene chloride, in aqueous solution by Raoult's method; the experiments have shown that in very dilute aqueous solutions these salts are completely dissociated, but that in more concentrated solutions the observed molecular weight increases rather rapidly, more quickly, in fact, than is the case with most metallic salts; the electrical conductivity of solutions of diazo-salts is also being investigated. F. S. K.

Aldoximes. By E. BECKMANN (*Ber.*, **23**, 3319—3331, and 3331—3341).—Salicylaldoxime (m. p. 57°) may be converted into an isomeric modification by the action of hydrochloric acid, either at the ordinary temperature or on heating. The α -benzyl ether of this compound is prepared by the action of sodium ethoxide and benzyl chloride, and crystallises from warm alcohol in slender, colourless, interlaced needles which melt at 62—63°.

The same compound is also obtained by heating an alcoholic solution of salicylaldehyde with α -benzylhydroxylamine hydrochloride and hydrogen sodium carbonate. The corresponding β -benzyl ether is formed in a similar manner from β -benzylhydroxylamine, and crystallises from dilute alcohol in pale-yellow, lustrous, rectangular plates which melt at 99—100°.

ACTION OF PHENYLCARBIMIDE ON THE BENZALDOXIMES.—The phenyl isocyanate employed in the following experiments boiled at 161—162°, and was absolutely free from hydrogen chloride. β -Benzaldoxime is dissolved in 12—14 parts of absolute ether, and treated at 5° with rather less than the calculated quantity of phenylcarbimide; a copious white precipitate is immediately formed, consisting of microscopic, quadratic plates which melt at 74—75° with evolution of gas; on boiling with dilute potash, carbonic anhydride, aniline, and diphenylcarbamide are formed. On warming equivalent quantities of β -benzaloxime and phenylcarbimide dissolved in benzene, and evaporating the solution, crystals are deposited which melt at 94° with evolution of gas; the substance is isomeric with the previous compound, and has already been prepared by Goldschmidt (*Abstr.*, 1890, 251). Carbonic anhydride and a trace of diphenylcarbamide are formed by the action of dilute potash. The first of these isomerides is very sparingly soluble, and is converted into the higher melting derivative on warming with benzene, but this latter cannot be transformed into the lower melting compound. Neither of the substances reacts with phenylcarbimide; with hydrogen chloride, both yield the compound (m. p. 134°) described by Goldschmidt (*loc. cit.*). By the action of dilute soda in the cold, the lower melting compound yields chiefly β -benzaloxime, whilst benzonitrile is the principal product from the higher melting modification.

By the action of phenylcarbimide on α -benzaloxime in ethereal solution, a compound separates which melts at 75° and is identical with the above derivative from β -benzaloxime; if this substance is removed and the solution allowed to remain for a short time, a second compound crystallises out in needles which melt at 135°; this has

previously been described by Goldschmidt. α -Benzaldoxime is, therefore, less stable than has hitherto been supposed; it is also found that by warming, or by keeping the β -aldoxime for some time, the yield of the β -derivative is increased. The author suggests that the two compounds obtained from β -benzaldoxime and phenylcarbimide are represented by the following formulæ:—

Benzalbenzamide, $\text{NHBz} \cdot \text{C}_7\text{H}_7$, is obtained by the action of benzoic chloride on β -benzaldoxime benzyl ether, and crystallises from benzene in colourless plates which melt at 105° . Acetic chloride and phosphorus oxychloride act in a similar manner, but hydrogen chloride in benzene solution causes no change. The compound may be prepared synthetically from benzylamine and benzoic chloride. On heating the amide with hydriodic acid, benzyl iodide, benzoic acid, and ammonia are formed, whilst in similar circumstances β -benzaldoxime benzyl ether yields a small quantity of benzoic acid and benzylamine. Goldschmidt prepared a compound (m. p. 121°) by the action of phenylcarbimide on β -benzaldoxime benzyl ether; this result is confirmed. On heating with concentrated hydriodic acid, benzyl iodide is formed; boiling hydrochloric acid is without action, but on heating at 140° , complete decomposition takes place; the compound is unchanged by sulphuric acid at ordinary temperatures.

By the action of sodium ethoxide on the carbanilido-product dissolved in alcohol, carbonic anhydride is eliminated, and a basic compound of the formula $\text{C}_{20}\text{H}_{18}\text{N}_2$ is obtained, which crystallises from dilute alcohol in large, flat, rectangular plates melting at 99 – 100° . The *hydrochloride* crystallises with difficulty. The same compound is formed by the action of benzanilidinido-chloride on benzylamine, and it must therefore be regarded either as symmetrical benzylphenylbenzenylamidino, or as a quinazoline derivative (see below). The compound is not acted on by hydrochloric acid and alcoholic ammonia; on heating with hydriodic acid, it yields benzoic acid, ammonia, and aniline.

On heating the carbanilido-derivative with alcoholic ammonia at 100° for an hour, benzylideneaniline is formed, together with a viscid, oily liquid which yields benzylidenephenylhydrazono on treatment with phenylhydrazine; its molecular weight is 111, as determined by Raoult's method; the compound contains two CHPh groups, together with the complex NPh , but its exact constitution is not yet determined.

Of the three formulæ for β -benzaldoxime, namely, $\text{PhC:N(OH)C}_7\text{H}_7$, $\text{OH} \cdot \text{CPh:N} \cdot \text{C}_7\text{H}_7$, and $\text{PhCH:N} \cdot \text{C}_7\text{H}_7$, the author has previously ad-

vanced the first two; the above results point, however, to the absence

of a hydroxyl group, and consequently the third one would appear to be the most probable. The compound formed by the action of phenylcarbimide would be represented by the formula $\begin{array}{c} \text{NH}-\text{CHPh} \\ | \\ \text{OCHPh}\cdot\text{O}\cdot\text{CO} \end{array} > \text{NPh}$, which would account for its great stability; by the elimination of carbonic anhydride, an amidine or quinazoline derivative would be formed, with the formula $\text{C}_6\text{H}_5\cdot\text{CH}_2\cdot\text{NH}\cdot\text{CPh}\cdot\text{NPh}$ or

respectively.

J. B. T.

Dyes of the Primuline Group. By E. TRAUTMANN (*Chem. Centr.*, 1890, ii, 440—441; from *Mon. Sci.* [4], 4, 811—820).—If dehydrothiitoluidine, prepared by heating paratoluidine with sulphur (Green, *Trans.*, 1889, 227; Gattermann and Pfizinger, *Abstr.*, 1889, 867), be heated with methyl alcohol and hydrogen chloride or iodide at 150—200°, the salts of the ammonium base

are formed; the chloride has been introduced into the market under the name *thioflavin*, and is a similar dye to auramine. The primuline base is prepared by heating thiitoluidine or dehydrothiitoluidine, or even paratoluidine, with sulphur; its constitution has not yet been established. Treatment with fuming sulphuric acid converts it into the sulphonic acid, the sodium salt of which is primulino. (For the similar dyes obtained from metaxylydine and pseudocumidine, see *Abstr.*, 1889, 602.) Dehydrothioxylidine unites with α -naphthol- α -sulphonic acid, forming the dye named "*Erika*." *Thiasole-yellow* is sodium amidoazodehydrothiitoluidinesulphonate; it dyes unbleached fibre greenish-yellow and cannot be deazotised on the fibre.

J. W. L.

Parachloracetotoluidide and Metaparanitrochloracetotoluidide. By H. ECKENROTH and A. DONNER (*Ber.*, 23, 3287—3289).—Parachloracetotoluidide has previously been obtained by the action of chloracetic chloride on paratoluidine, and may be prepared by heating paratoluidine (1 mol.) with chloracetic acid (2 mols.) at 80—90° for two hours; the product is treated with water and recrystallised from alcohol. If the temperature is allowed to rise somewhat, a second compound is formed, which is being further investigated; it is sparingly soluble in water, but dissolves in dilute potash, and is precipitated by hydrochloric acid; from alcohol, it crystallises in white needles melting above 230° with decomposition.

Nitrochloracetotoluidide, $\text{NO}_2\cdot\text{C}_6\text{H}_3\text{Me}\cdot\text{NH}\cdot\text{CO}\cdot\text{CH}_2\text{Cl}$

is prepared by the action of nitric acid at ordinary temperatures on the chloracetic derivative, and crystallises from alcohol in yellow needles which melt at 122° and yield metaparanitrotoluidine on treatment with potash.

J. B. T.

Action of Potassium Hypobromite on Phenylsuccinamide. By S. HOOGWERFF and W. A. VAN DORP (*Rec. Trav. Chim.*, 9, 33—68).—In a previous communication (Abstr., 1889, 981), the authors have shown that chlorine, bromine, hydroxyl, and nitrosyl are extremely mobile when combined with nitrogen, compounds containing such a combination readily undergoing an intramolecular change, in which the negative element or group is displaced by a more positive radicle. In continuation of these researches, they have investigated the action of potassium hypobromite on phenylsuccinamide, and the properties of the bromamido-compound thus obtained.

The phenylsuccinamide required for these experiments was prepared by the method given by Menschutkin (this Journal, 1872, 497). 15 grams of this substance is dissolved in a solution of 18 grams of potash and 12 grams of bromine in 300 c.c. of water, then diluted with 600 c.c. of water, acidified with acetic acid, and the precipitate thus obtained washed with water. The product could not be obtained pure, but was found to contain bromine, and from its reactions is undoubtedly a *bromamidophenylsuccinamide*, $\text{NHBr}\cdot\text{C}_6\text{H}_4\cdot\text{O}_2\cdot\text{NHPh}$. On warming its solution in alcohol or acetone, an intramolecular change takes place, *parabromophenylsuccinamide*, $\text{NH}_2\cdot\text{C}_6\text{H}_4\cdot\text{O}_2\cdot\text{NH}\cdot\text{C}_2\text{H}_4\cdot\text{Br}$, being formed. The latter is sparingly soluble in cold water and ether, more readily in hot water, and very easily in boiling alcohol and acetone. It crystallises in needles or plates which melt at $213\text{--}215^\circ$ with decomposition. On boiling with aqueous potash, it yields first parabromophenylsuccinamic acid and ammonia, the former decomposing on further heating with potash into parabromaniline and succinic acid. *Parabromophenylsuccinamic acid* crystallises in needles, melts at $186\text{--}187^\circ$, and is readily soluble in alcohol and acetone, sparingly in ether and water. It may also be prepared by the action of alkaline potassium hypobromite on phenylsuccinamic acid. Its barium salt forms needles or plates, and its copper salt is a pale-blue precipitate.

By the action of warm dilute potash on bromamidophenylsuccinamide, the bromine is displaced by hydroxyl, and an intramolecular change takes place at the same time. To carry out the reaction, 10 grams of phenylsuccinamide are converted into the bromamido, and the latter is dissolved in a solution of 6 grams of potash in 34 c.c. of water, 50 c.c. of concentrated potash solution is then added, and the whole warmed for $2\frac{1}{2}$ hours at $55\text{--}60^\circ$. On the addition of hydrochloric acid, a precipitate is obtained, which is purified by dissolving it in potash, reprecipitating with hydrochloric acid, reducing its alkaline solution with sodium amalgam, and recrystallising from hot water. Its composition was found on analysis to be $\text{C}_{10}\text{H}_{12}\text{N}_2\text{O}_4$. On passing hydrogen chloride into its alcoholic solution and adding sulphuric acid, it very readily yields an ethyl salt, and therefore contains a carboxyl group. It loses the elements of water on boiling with acetic chloride, forming a substance which is reconverted by alkalis into the original compound, and on fusion with potash decomposes into carbonic anhydride, aniline, and β -amidopropionic acid. From these facts, it follows that the acid has the constitution

and it may be termed *phenyl-β-ureidopropionic acid* or *phenyl-β-lacturamic acid*. It crystallises in needles or plates melting when quite pure at 171—172°, and is readily soluble in alcohol, acetone, warm water, and warm acetic acid, sparingly in ether, and almost insoluble in benzene and light petroleum. The *calcium* salt, $(C_{10}H_{11}N_2O_4)_2Ca$, forms concentrically grouped needles, and the *silver* salt, $C_{10}H_{11}N_2O_4Ag$, an amorphous, white precipitate, which is fairly stable towards light. The *ethyl* salt, $C_{10}H_{11}N_2O_4Et$, crystallises from water containing a little sodium carbonate, in needles, melts at 84—85°, and is readily soluble in alcohol, ether, and benzene, sparingly in light petroleum.

As already stated, the acid is split up on fusion with potash into carbonic anhydride, aniline, and β-amidopropionic acid. The latter is best isolated as the platinochloride of its ethyl salt, which is obtained by passing hydrogen chloride into the alcoholic solution of the acid, evaporating, and treating the alcoholic solution of the residue with platinic chloride solution. It separates in yellow needles, containing water of crystallisation which is given off at 90—100°, the salt then having the composition $(C_5H_{11}NO)_2, H_2PtCl_6$. It is readily soluble in water, melts at 193° with evolution of gas, and is identical with the compound prepared synthetically from β-iodopropionic acid. The *hydrochloride*, $C_5H_{11}NO, HCl$, forms hygroscopic crystals.

The compound obtained by the action of acetic chloride on phenylureidopropionic acid has the composition $C_{10}H_{10}N_2O_3$, and crystallises in needles which melt at 231—234°, and do not volatilise without decomposition. It stands in the same relation to phenylureidopropionic acid as hydantoin to hydantoic acid, and has, therefore, the constitution $CO < \begin{smallmatrix} NPh \cdot CO \\ NH \cdot CH_2 \end{smallmatrix} > OH_2$, and may be termed *phenylhydrouracil*. By the further action of acetic chloride at 100°, or by acting with an excess of the latter on the acid, *phenylacetylhydrouracil*, $C_{12}H_{12}N_2O_3$, is obtained, and crystallises in needles melting at 135—138°.

That phenylureidopropionic acid has really the constitution above assigned to it has been further shown by its synthetical formation from phenylcarbamide and β-amidopropionic acid. On heating these two compounds together at 135°, the following reaction takes place:—

The compound thus obtained is identical in all respects with the acid above described, but the yield is not good.

The formation of phenyl-β-ureidopropionic acid from phenylsuccinamide is very difficult, and perhaps impossible, to explain, if the latter has the symmetrical constitution usually assigned to it, namely, $NH_2 \cdot CO \cdot CH_2 \cdot CH_2 \cdot CO \cdot NHPh$. It has, however, been shown by Auger (Abstr., 1888, 952) that asymmetrical succinamide can exist, and the authors believe that phenylsuccinamide has also the asymmetrical constitution

$\begin{smallmatrix} CH_2 \cdot CH_2 \\ CO - O \end{smallmatrix} > C < \begin{smallmatrix} NHPh \\ NH_2 \end{smallmatrix}$, the bromamido-compound then be-

coming $\begin{array}{c} \text{CH}_2\cdot\text{CH}_2 \\ \text{CO} \text{---} \text{O} \end{array} > \text{C} \begin{array}{l} \text{NHPh} \\ \text{NHBBr} \end{array}$. The potassium salt of the latter undergoes an intramolecular change, forming the compound $\begin{array}{c} \text{CH}_2\cdot\text{CH}_2\cdot\text{NK} \\ \text{CO} \text{---} \text{O} \cdot \text{CBr}\cdot\text{NHPh} \end{array}$, which by the further action of potash yields $\text{COOK}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}\cdot\text{C}(\text{OH})(\text{OK})\cdot\text{NHPh}$; this then loses the elements of KOH , forming phenyl- β -ureidopropionic acid, $\text{COOK}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{NH}\cdot\text{CO}\cdot\text{NHPh}$.

When parabromophenylsuccinamide is treated with potassium hypobromite, it yields an unstable bromamide, which is readily converted into the corresponding *bromophenylureidopropionic acid*, $\text{C}_{10}\text{H}_{11}\text{BrN}_2\text{O}_3$, by the action of potash. This acid is readily soluble in warm alcohol, sparingly in ether, benzene, and hot water, and crystallises in flat needles which decompose at 229° . On fusion with potash, it yields parabromaniline, and its alkaline solution is reduced by sodium amalgam to phenylureidopropionic acid. Its *calcium* salt is a very voluminous precipitate, and its *silver* salt forms white flocks.

By the action of potassium hypobromite (1 mol.) on phenylureidopropionic acid, no monobromo-compound could be obtained, but with 2 mols. of hypobromite, a small quantity of *dibromophenylureidopropionic acid*, $\text{C}_{10}\text{H}_9\text{Br}_2\text{N}_2\text{O}_3$, was formed, crystallising in needles which melt at $201\text{--}202^\circ$ and yielding dibromaniline (m. p. $78\text{--}81^\circ$) on fusion with potash. If 3 mols. of hypobromite are employed, *tribromophenylureidopropionic acid*, $\text{C}_{10}\text{H}_7\text{Br}_3\text{N}_2\text{O}_3$, is obtained, and is also formed in smaller quantity with the dibromo-compound when only 2 mols. of hypobromite are used. It separates from acetic acid in crystals which melt at $219\text{--}220^\circ$ with decomposition, and yields symmetrical tribromaniline on fusion with potash. H. G. C.

Carbamide Derivatives of Amidocinnamic Acid. By F. W. ROTHSCHILD (*Ber.*, 23, 3341—3346).—*Orthouramidocinnamic acid*, $\text{NH}_2\cdot\text{CO}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{CH}\cdot\text{COOH}$, is prepared by the action of potassium cyanate on orthamidocinnamic acid hydrochloride, and crystallises from water in small, pale-yellow needles which dissolve in ammonia and also in hydrochloric acid; the aqueous solution has an acid reaction.

Orthamidocinnamic acid thiocyanate,

is obtained in a similar manner to the previous compound, and is deposited from water in tufts of prismatic crystals which melt at 152° with evolution of gas. On heating the compound at $110\text{--}120^\circ$ for 18 hours, *orthoithouramidocinnamic acid*,

is formed, which melts at $236\text{--}239^\circ$, and is insoluble in alcohol, but dissolves in hot glacial acetic acid or ammonia.

Orthoallylthiouramidocinnamic acid,

crystallises from a small quantity of acetic acid on the addition of water in white needles which melt at 204—208° with decomposition.

(*Orthophenylthiouramidocinnamic acid*,

crystallises from glacial acetic acid, and melts at 235—237°.

By the action of carbon bisulphide on orthamidocinnamic acid at 100°, a compound is obtained which is probably *orthocarbocinnamylthiocarbamic acid*, $\text{CSSH}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{CH}\cdot\text{COOH}$; it crystallises from water in white, microscopic prisms, melts at 185—187°, and is soluble in ammonia but insoluble in hydrochloric acid.

Metathiocyanamidocinnamic acid is prepared by the action of thiocyanic acid on metamidocinnamic acid; it crystallises from alcohol, melts at 148—149°, and is very readily soluble in water and alcohol in the cold. The corresponding *para-derivative* crystallises from water in pale, yellowish-brown needles, which remain unmelted at 272°, but decompose on suddenly heating. It yields a white silver salt. On evaporating an aqueous solution, and heating the residue for some time at 100°, *parathionuramidocinnamic acid* is obtained as a yellow substance insoluble in alcohol; it remains solid at 273°, but melts with gas evolution when heated on platinum foil. J. B. T.

Aromatic Alkyl Ketones; their Oxidation by Potassium Permanganate. By A. CLAUS (*J. pr. Chem.* [2], 42, 508—516; compare Abstr., 1890, 762, 979) —*Paracymyl methyl ketone* [$\text{Me} : \text{Ac} : \text{Pr} = 1 : 2 : 4$] is a nearly colourless oil which boils at 249—250° (uncorr.), and does not solidify at -10° . The *oxime* was obtained. The *phenylhydrazide* forms lustrous, colourless needles which melt at 134° (uncorr.). By reduction with zinc-dust in alcoholic potash, the ketone yields *paracymylmethylcarbinol* [$\text{Me} : \text{Pr} : \text{CHMe}\cdot\text{OH} = 1 : 4 : 2$], an uncrystallisable oil which boils above 300°. The constitution of this ketone is settled by the fact that it yields methylisophthalic acid [$\text{Me} : (\text{COOH})_2 = 1 : 2 : 4$] (m. p. 332°), identical with Jacobsen's β -xylidenic acid (Abstr., 1882, 188); the *potassium* (with 2 mols. H_2O), *barium* (with 2 mols. H_2O), and *silver* (with 1 mol. H_2O) salts of this acid, and the *chloride*, and the *amide* are described; further oxidation converts this acid into trimellitic acid [$1 : 2 : 4$] (m. p. 210°, uncorr.).

Paracymylglycollic acid [$\text{Me} : \text{CO}\cdot\text{COOH} : \text{Pr} = 1 : 2 : 4$], obtained by oxidising the ketone in the cold with potassium permanganate, is a thick, yellow oil; it decomposes at 220°, and dissolves in the usual solvents except water; the *calcium* (with 2 mols. H_2O), *barium* (with 1 mol. H_2O), and *silver* salts were obtained. When reduced with sodium amalgam, this acid yields *paracymylglycollic acid*

which forms crystals melting at 124° (uncorr.), and soluble in the usual solvents, except cold water; the *sodium*, *potassium*, *calcium* (with $2\frac{1}{2}$ mols. H_2O), *barium* (with 3 mols. H_2O), *silver*, *copper* (with 8 mols. H_2O), and *lead* salts are described.

By heating paracymyl methyl ketone with ammonium sulphide in a sealed tube *paracymylacetamide* [$\text{Me} : \text{Pr} : \text{CH}_2\text{CONH}_2 = 1 : 2 : 4$] is

obtained; this crystallises in thin, lustrous scales, melts at 123° (uncorr.), sublimes, and dissolves in the usual solvents, except cold water. *Paracynylacetic acid* is obtained by saponifying the amide; it crystallises in flat, lustrous, colourless needles which melt at 70° (uncorr.), and dissolve in the usual solvents, except cold water; the *sodium* (with 2 mols. H_2O), *potassium* (with $1\frac{1}{2}$ mols. H_2O), *calcium* (with 4 mols. H_2O), *barium* (with 6 mols. H_2O), and *silver* salts are described.

A. G. B.

Benzoic Fluoride. By E. GUENEZ (*Compt. rend.*, **111**, 681—682).—This compound can be prepared by Moissan's reaction. Silver fluoride and benzoic chloride in equivalent proportions are heated in a sealed tube at 190° for five to six hours. The product is distilled from the silver chloride, and even if excess of silver fluoride has been used, the liquid must be heated again in a sealed tube with more silver fluoride, in order to ensure the complete decomposition of the benzoic chloride.

Benzoic fluoride is a colourless liquid with an odour resembling that of benzoic chloride, but much more irritating. It boils at 145° , burns with a smoky flame with a blue edge, is heavier than water, by which it is decomposed into benzoic and hydrofluoric acids, and is rapidly decomposed by solutions of alkalis, especially on heating. Benzoic fluoride attacks glass with great rapidity, with formation of silicon fluoride, an alkaline fluoride, and benzoic anhydride. C. H. B.

Conversion of Cinnamic into Isocinnamic Acid. By W. ERLKENMEYER (*Ber.*, **23**, 3130—3131).—Since both α - and β -bromocinnamic acid yield benzaldehyde on oxidation, the bromine atom must be in the α -position in both compounds; it is probable, therefore, that the so-called β -bromocinnamic acid corresponds with isocinnamic acid and the α -bromo-acid with cinnamic acid. This view is rendered very probable by the fact that when the β -acid is treated with hydrogen under certain conditions, it yields isocinnamic acid and variable quantities of cinnamic acid; the iso-acid obtained in this way exhibits all the properties of the natural isocinnamic acid discovered by Liebermann. F. S. K.

Metaxylalphthalide. By E. HEILMANN (*Ber.*, **23**, 3157—3168).—Metatolnylacetic acid is prepared by heating metatolnylacetonitrile with three parts of concentrated hydrochloric acid at 100° for 4–5 hours. On fusing metatolnylacetic acid with an equal weight of phthalic anhydride, together with a small quantity of anhydrous sodium acetate, water and carbonic anhydride are eliminated, and a substance with the formula $CO < \overset{O}{\underset{C_6H_4}{\curvearrowright}} : C : CH \cdot C_6H_4Me$ is formed; if the group $CH \cdot C_6H_4Me$ is termed *xylal*, then this compound would be called *metaxylalphthalide*. It crystallises from alcohol in pale-yellow needles melting at 152 – 153° , and is very sparingly soluble in the ordinary media; the yield is 64 per cent. of the theory. On treatment with potash, xylalphthalide is hydrolysed, and the unsaturated acid which is first formed changes spontaneously into the compound $C_6H_4Me \cdot CH_2 \cdot CO \cdot C_6H_4 \cdot COOH$; this is deposited from alcohol

on the addition of water, in long, lustrous crystals which melt at 111—112°. The corresponding *oximidolactone*,

is prepared by the action of hydroxylamine on the acid, and crystallises from dilute alcohol in white, lustrous needles which melt at 133—134°, and are insoluble in alkalis.

By the action of alcoholic ammonia on xylalphthalide, *methylde-oxymetazocarbonylamide* is formed; it is difficult to isolate and readily loses the elements of water, *metaxylalphthalimidine*,

being obtained; this crystallises from alcohol in needles which melt at 165°.

Nitro-xylalphthalimidine, $\text{CO} < \begin{array}{c} \text{C}_6\text{H}_4 \\ \text{NH} \end{array} > \text{C} \cdot \text{C}(\text{NO}_2) \cdot \text{C}_6\text{H}_4\text{Me}$, is prepared by the action of nitrous acid on xylalphthalimidine; it crystallises from alcohol in yellow, lustrous needles, and melts at 157—159°. The reaction is explained by assuming that an unstable dinitro-derivative is first formed, from which the mononitro-compound is produced by the elimination of nitrous acid. *Dinitro-xylalphthalide*,

$\text{CO} < \begin{array}{c} \text{O} \\ \text{C}_6\text{H}_4 \end{array} > \text{C}(\text{NO}_2) \cdot \text{CH}(\text{NO}_2) \cdot \text{C}_6\text{H}_4\text{Me}$, is prepared by the action of nitrous acid on xylalphthalide, and crystallises from acetic acid in white, lustrous, rhombohedral plates, which soften at 125° and melt at 133° with evolution of gas. *Nitro-xylalphthalide*,

is prepared by heating the previous compound with dilute alcohol; it crystallises in yellow, lustrous needles, and melts at 144° with decomposition.

Nitro-xylalphthalide is dissolved in potash, and the solution acidified with hydrochloric acid; the product consists of a mixture of phthalic anhydride and *metatoluylnitromethane*, $\text{C}_6\text{H}_4\text{Me} \cdot \text{CH}_2 \cdot \text{NO}_2$; this compound is separated by distillation in a current of steam, and is a yellow, viscid liquid which decomposes on distillation, has a peculiar, offensive smell, and yields metaxylalamine on reduction.

Nitro-xylalphthalide is decomposed on heating at 190°, phthalic anhydride and *metatoluyyl isocyanate* being formed; the latter is a colourless, oily liquid, which boils at 190—200°, and yields metatoluy-carbamide on treatment with ammonia; the vapour rapidly attacks the eyes. By the action of phosphorus and hydriodic acid on nitro-xylalphthalide, a compound is obtained which is isomeric with xylalphthalide, and is therefore termed *iso-xylalphthalide*; it is slowly deposited from alcohol in long, slender, white crystals, which melt at 92—93°. The constitution of the compound is probably represented

by the formula $\begin{array}{c} \text{C}_6\text{H}_4 \cdot \text{OH} \\ \text{CO} \text{---} \text{O} \end{array} > \text{C} \cdot \text{C}_7\text{H}_7$.

Iso-xylalphthalimidine, $\begin{array}{c} \text{CO}-\text{NH} \\ \text{C}_6\text{H}_4 \cdot \text{CH} \end{array} > \text{C} \cdot \text{C}_7\text{H}_7$, is prepared by heating

the previous compound with alcoholic ammonia at 100° ; crystallises in small, lustrous needles, melts at 196° , and is very sparingly soluble in the ordinary media. *Metatolylchloroisoquinoline*,

is obtained by the action of phosphorus oxychloride on the previous compound; it crystallises in white, lustrous needles, and melts at $43\text{--}44^{\circ}$. On heating with hydriodic acid at 170° , and treating the product with potash, *metatolylisoquinoline*, $\text{C}_6\text{H}_4 < \begin{array}{c} \text{CH:N} \\ \text{CH:O}\cdot\text{C}_7\text{H}_7 \end{array}$, is formed as a colourless, viscid liquid, which crystallises after some time, and melts at $51\text{--}52^{\circ}$; it is deposited from methyl alcohol in long, lustrous needles. The *picrate*, *hydrochloride*, *sulphate*, and *platinochloride* are all crystalline. J. B. T.

Isogallic Acid Phenylhydrazide. By C. BÖTTINGER (*Annalen*, 259, 373—377).—The phenylhydrazine derivatives of tannin and gallic acid (Abstr., 1890, 163) are very similar in properties, and have the same reducing power as regards alkaline copper solutions; when the tannin derivative is heated with hydrochloric acid at 120° , it is decomposed into gallic acid, phenylhydrazine, and a very small quantity of a reddish-yellow, crystalline, neutral substance; the author names it, therefore, isogallic acid phenylhydrazide.

Isogallic acid phenylhydrazide is converted into an unstable acetyl derivative on boiling with acetic anhydride; it is completely decomposed by boiling alkalis, a property which it has in common with gallic acid phenylhydrazide. F. S. K.

Condensation Products of Amido-acids with Benzene-sulphonic Chloride. By S. G. HEDIN (*Ber.*, 23, 3196—3199; see also Hinsberg, this vol., p. 49).—For the preparation of the above condensation products, the amido-acid is dissolved in aqueous potash, and an equivalent quantity of benzenesulphonic chloride added in small portions alternately with caustic potash, warming and shaking well during the process. After filtering, if necessary, the liquid is acidified, and the product, being, as a rule, sparingly soluble in cold water, may then be readily purified.

Alanine yields the compound $\text{SO}_2\text{Ph}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$, crystallising from hot water in slender needles; this melts at 126° , but forms an oil under water at 100° , and is readily soluble in hot water, alcohol, ether, and ethyl acetate.

The *leucine* compound, $\text{SO}_2\text{Ph}\cdot\text{NH}\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$, crystallises in beautiful, long needles which melt at 86° , and are less soluble in water than the foregoing compound, but readily soluble in alcohol, ether, acetic acid, and chloroform.

The *aspartic acid* derivative, $\text{SO}_2\text{Ph}\cdot\text{NH}\cdot\text{C}_6\text{H}_4(\text{COOH})$, crystallises in splendid, rhomboidal crystals melting at 170° .

The *alutamine* compound, $\text{SO}_2\text{Ph}\cdot\text{NH}\cdot\text{C}_6\text{H}_4(\text{COOH})_2$, does not

separate on the addition of an acid, but must be extracted with ether, and on the evaporation of this it remains as a syrup which gradually solidifies over sulphuric acid, but is not thus obtained quite pure. It is distinguished from the other condensation products by its ready solubility in water.

Tyrosine yields two compounds, one of which is sparingly, and the other readily, soluble in water. The former has the composition $\text{SO}_2\text{Ph}\cdot\text{NH}\cdot\text{C}_2\text{H}_5(\text{C}_6\text{H}_4\cdot\text{OH})\cdot\text{COOH}$, but the latter has not been obtained pure.

Tolueneparasulphonic chloride also readily forms condensation products with amido-acids. Moreover, fibrin, after treatment with pancreatic juice, combines with benzenesulphonic chloride, forming an oil, but it is uncertain whether this is a mixture or not.

An attempt was made to prepare *benzenesulphonaglycoccine*, $\text{SO}_2\text{Ph}\cdot\text{NH}\cdot\text{CH}_2\cdot\text{COOH}$, by feeding dogs with sodium benzenesulphonate, a process corresponding to the preparation of hippuric acid from sodium benzoate. The results obtained, however, were negative, as were similar experiments in the human organism. H. G. C.

Benzenesulphinic Acid and Ethylsulphinic Acid. By W. AUTENRIETH (*Annalen*, 259, 362—364).—Pure, dry benzenesulphinic acid does not readily undergo oxidation on exposure to the air; its sodium salt is very stable, and is not decomposed to any appreciable extent when its aqueous solution is heated at 180° for 12 hours.

Ethylsulphinic acid is best prepared by oxidising ethyl mercaptan with potassium permanganate, converting the sulphonic acid thus produced into the chloride, and reducing the latter with zinc-dust in alcoholic solution. The pure acid is unstable, but the dry sodium salt is only slowly oxidised on exposure to the air. F. S. K.

Sulphone Derivatives of the Crotonic Acids. By W. AUTENRIETH (*Annalen*, 259, 332—357).— β -Phenylsulphoneisocrotonic acid, $\text{CH}_3\cdot\overset{\text{H}}{\underset{\text{H}\cdot\text{COOH}}{\text{C}}}\cdot\text{SO}_2\text{Ph}$, can be prepared by heating a moderately concentrated

aqueous solution of sodium β -chlorisocrotonate with sodium benzenesulphinate at 140 — 150° for six to eight hours, precipitating the acid with sulphuric acid, and then extracting with ether. It can also be obtained by treating ethyl β -diphenylsulphonebutyrate with cold, concentrated potash (compare next abstract); the yield is almost quantitative in both cases. It crystallises from water in needles, melts at 126 — 127° , and decomposes at a higher temperature; it is moderately easily soluble (1 in 20) in boiling, but only sparingly (1 in 390 at 15°) in cold, water. It is decomposed by tin and warm concentrated hydrochloric acid with liberation of mercaptan, and boiling alkalis decompose it completely with elimination of benzenesulphinic acid, but it is not acted on by bromine in boiling chloroform solution. The *potassium* salt, $\text{C}_{10}\text{H}_9\text{SO}_4\text{K} + 3\text{H}_2\text{O}$, crystallises from water in large, transparent, efflorescent plates, and is readily soluble in water and alcohol. The *barium* salt, $(\text{C}_{10}\text{H}_9\text{SO}_4)_2\text{Ba} + 2\frac{1}{2}\text{H}_2\text{O}$, *magnesium* salt (with 6 mols. H_2O), and *zinc* salt (with 6 mols. H_2O) crystalline wools, and are moderately easily soluble in water.

The *silver* salt, $C_{10}H_9SO_4Ag$, crystallises from water in well-defined plates, and decomposes suddenly at $240-245^\circ$. The *ethyl* salt, $C_{10}H_9SO_4Et$, is a colourless oil.

β -Phenylsulphonecrotonic acid, $\begin{matrix} SO_2Ph \cdot C \cdot Me \\ | \\ H \cdot C \cdot COOH \end{matrix}$, is prepared by

heating an aqueous solution of the sodium salt of β -chlorocrotonic acid with sodium benzenesulphonate at $160-180^\circ$ for eight hours; the yield is quantitative. It crystallises from water in lustrous plates, melts at 158° with previous softening, and is moderately easily soluble in ether, alcohol, and benzene, but only very sparingly in light petroleum; it is soluble in 262 parts of water at 15° and in 3.8 to 4 parts of boiling water. When heated at $200-210^\circ$ for 20 hours, it is completely converted into the isomeride (m. p. 127°) described above, but attempts to bring about this intramolecular change by means of sulphuric acid, iodine, alcohol, and water were unsuccessful. The *potassium* salt, $C_{10}H_9SO_4K + 1\frac{1}{2}H_2O$, is deliquescent, and does not crystallise well. The *barium* salt, $(C_{10}H_9SO_4)_2Ba + 11H_2O$, is very readily soluble in water. The *magnesium* salt (with 7 mols. H_2O) and the *zinc* salt (with 6 mols. H_2O) separate from water in large, transparent crystals. The *copper* salt forms small crystals containing 1 mol. H_2O . The *silver* salt, $C_{10}H_9SO_4Ag$, crystallises from water in very small needles, and decomposes suddenly at $198-200^\circ$.

β -Ethylsulphoneisocrotonic acid, $\begin{matrix} CH_3 \cdot C \cdot SO_2Et \\ | \\ H \cdot C \cdot COOH \end{matrix}$, can be prepared by

treating ethyl β -diethylsulphonebutyrate (compare Baumann, Abstr., 1887, 123) with potash in the cold, or by heating sodium β -chlorisocrotonate at $140-150^\circ$ with sodium ethylsulphinate in aqueous solution. It separates from cold water in well-defined crystals, melts at 98° , and is readily soluble in alcohol, ether, chloroform, and water, but only moderately easily in benzene. It is slowly decomposed by alkalis into tetrolic acid and ethylsulphinic acid, and when treated with tin and hydrochloric acid it yields mercaptan, but it is not acted on by bromine in boiling chloroform solution. The *silver* salt, $C_8H_7SO_4Ag$, forms large, well-defined crystals, and decomposes on exposure to light; the other metallic salts do not crystallise well. The *ethyl* salt, $C_8H_7SO_4$, is a colourless oil which cannot be distilled. The stereochemical isomeride of β -ethylsulphoneisocrotonic acid could not be obtained.

F. S. K.

Sulphur Derivatives of Ethyl Acetoacetate, Ethyl Methylacetoacetate, and Ethyl Ethylacetoacetate. By W. AUFENRATH (*Annalen*, 259, 365-373).—Ethyl β -diphenylsulphonebutyrate, $CMe(SO_2Ph)_2 \cdot CH_2 \cdot COOEt$, can be obtained by adding sulphuric acid and potassium permanganate to a benzene solution of ethyl β -dithiophenylbutyrate (compare Baumann and Escales, Abstr., 1886, 878) until a permanent coloration is produced. It separates from alcohol in well-defined, lustrous crystals, melts at 97° , and is readily soluble in hot alcohol, ether, and benzene, but only sparingly in cold alcohol, and insoluble in water; when treated with potash, it is converted into β -phenylsulphoneisocrotonic acid (compare preceding abstract).

Ethyl α-ethyl-β-diethylsulphonebutyrate, $\text{CMe}(\text{SO}_2\text{Et})_2\text{CHEt}\cdot\text{COOEt}$, is formed when ethyl α-ethyl-β-dithioethylbutyrate, the condensation product of ethyl mercaptan and ethyl ethylacetoacetate, is oxidised in a similar manner. It crystallises from boiling water in lustrous plates, melts at 87—88°, and is readily soluble in ether, benzene, and alcohol; it is not acted on by concentrated potash or ammonia in the cold, but on boiling with potash, it is gradually decomposed, yielding small quantities of an acid melting at 102—103°, the nature of which could not be determined.

Ethyl α-methyl-β-diethylsulphonebutyrate, prepared in like manner, crystallises from water in plates, melts at 79°, and is only sparingly soluble in cold, but readily in hot, water; it is not acted on by cold alkalis, but when boiled therewith, it is completely decomposed.

Ethyl α-ethyl-β-dithiophenylbutyrate, $\text{CMe}(\text{SPh})_2\text{CHEt}\cdot\text{COOEt}$, is obtained when hydrogen chloride is passed into a mixture of ethyl ethylacetoacetate and phenyl mercaptan. It separates from alcohol in large, transparent crystals, melts at 70—71°, and is readily soluble in benzene, alcohol, and ether, but insoluble in water.

Ethyl α-ethyl-β-diphenylsulphonebutyrate, $\text{C}_{20}\text{H}_{24}\text{S}_2\text{O}_6$, prepared by oxidising the preceding compound in the manner described above, separates from alcohol in crystals, melts at 111°, and is insoluble in water, but readily soluble in alcohol, benzene, and ether; when boiled with potash, it yields only a trace of an acid. F. S. K.

Indene and Cinnamene in Coal-tar. By G. KRAEMER and A. SPILKER (*Ber.*, 23, 3276—3283; compare *Abstr.*, 1890, 496).—The higher fractions of the light oils obtained from coal-tar contain a hydrocarbon of the composition C_9H_8 , to which the authors give the name *indene*, as it has the constitution $\text{C}_9\text{H}_7\text{CH}=\text{CH}_2$.

This compound is isolated in the following manner from the fractions boiling at 176—182°, the yield of the pure substance being about 20 per cent. of the crude oil employed:—A quantity of picric acid, sufficient to combine with the unsaturated compounds (determined by titrating a portion of the oil with bromine), is dissolved in the hot liquid, the crystalline precipitate, which contains as impurities all the naphthalene and a little cumarone, is treated with steam, and the indene in the distillate purified by precipitation with picric acid in toluene solution. The picrate is obtained in this way in golden needles melting at 98°; it decomposes slowly on exposure to the air, but quickly when heated with water, and it explodes when heated in the dry state.

Indene is a colourless oil of sp. gr. 1.04 at 15°, which turns yellowish on keeping, the colour disappearing again on exposure to light; it boils at 179.5—180.5° (corr.), is converted into a resinous compound (parindene) by concentrated sulphuric acid in benzene or ethereal solution, and into a very insoluble, infusible substance, which contains a large quantity of sulphur, by energetic treatment with concentrated sulphuric acid. On oxidation with boiling 30 per cent. nitric acid, it yields phthalic acid. The *dibromide*, $\text{C}_9\text{H}_6\text{Br}_2$, prepared by treating the hydrocarbon with the theoretical quantity of bromine in

ethereal solution, forms transparent, prismatic crystals, melts at $43-45^{\circ}$, and is readily soluble in all ordinary solvents except water and light petroleum; it readily undergoes spontaneous decomposition with evolution of hydrogen bromide and formation of a resinous substance.

Indene hydroxybromide, C_9H_7BrO , is formed when the dibromide is warmed with water or boiled with 10 per cent. alcohol; it crystallises in colourless needles, melts at $130-131^{\circ}$, and is soluble in water and alcohol.

Hydrindene, C_9H_{10} , is obtained when indene is reduced with sodium and alcohol; it is a colourless oil of sp. gr. 0.957 at 15° , and boils at $176-176.5^{\circ}$ (corr.). It forms a sulphonic acid, the salts and amide of which are very like the corresponding derivatives of benzenesulphonic acid.

Cinnamene can be isolated from coal-tar in the form of the crystalline dibromide, $C_9H_7Br_2$, by treating well-cooled, crude xylene with bromine and evaporating the solution.

The red coloration which is produced on dissolving impure naphthalene in sulphuric acid is due to the presence of indone, and the red coloration observed in the case of phenol is probably due to a similar cause.

F. S. K.

Synthesis of Indigo with Phenylglycocine. By K. HEUMANN (*J. pr. Chem.*, [2], 42, 520).—The author claims priority as to the method for the synthesis of indigo published by Lederer (this vol., p. 75), he having already patented the method. Lederer is mistaken in supposing that indigo is left when the melt is dissolved in water or dilute sulphuric acid; any that may be formed is only produced by oxidation by the air; some substance like indigo-white is the actual product of the fusion, and oxidation is necessary to convert this into indigo. The author is further investigating the subject.

A. G. B.

Synthesis of Indigo from Anilidoacetic Acid. By A. BIEBERMANN and R. LEPETIT (*Ber.*, 23, 3289—3291).—Aniline and chloroacetic acid are mixed together in molecular proportions and fused with 3—4 parts of soda, together with sufficient water to form a paste; as soon as the mass becomes orange-coloured, it is quickly cooled, dissolved in water, and the solution oxidised by means of a current of air; indigo is at once deposited, the yield being 9.5 per cent. It is probable that in the first instance anilidoacetic acid is formed; two molecules then combine together with elimination of water and hydrogen. Indigo may also be obtained by the fusion of anilidoacetic acid and sodium, the product being then oxidised with air as before. Indigo is directly prepared by the fusion of a mixture of oxanilic acid and anilidoacetic acid in molecular proportion with excess of soda; the yield is a little less than with anilidoacetic acid alone.

J. B. T.

Condensation of Cinnamene with Methylbenzene Derivatives. By G. KRAEMER and A. SPILKER (*Ber.*, 23, 3169—3174).—Crude xylene containing cinnamene is treated with concentrated sulphuric acid, when two layers of liquid are formed, the heavier of which

contains sulphonic acids. The lighter oily portion is separated, washed with soda, and distilled in a current of steam; the residue after fractionation in a vacuum, yields *phenyltoluylpentane*, $\text{C}_{11}\text{H}_{14}\text{Ph}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{C}_6\text{H}_4\text{Me}$; this is a colourless, viscid liquid which boils at $293\text{--}294^\circ$, and has a sp. gr. of 0.987 at 15° . It is probable that in the first instance cinnamene and sulphuric acid combine to form an additive compound, which then condenses with xylene according to the equation $\text{CH}_2\text{Ph}\cdot\text{CH}_2\cdot\text{SO}_3\text{H} + 2\text{C}_6\text{H}_4\text{Me}_2 = \text{CH}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{C}_6\text{H}_4\text{Me} + \text{C}_6\text{H}_4\text{Me}_2\cdot\text{SO}_3\text{H} + \text{H}_2\text{O}$. It is found that other methylbenzene derivatives condense with cinnamene in a similar manner, but benzene itself does not react in this way. On passing the vaporised substance through heated tubes, hydrogen and methane are eliminated, and methylanthracene (m. p. 200°) is formed; the yield is 62.5 per cent. of the substance employed.

Corresponding anthracene derivatives are obtained from the condensation products of cinnamene and toluene, metaxylene, and pseudocumene respectively.

The authors point out the bearing of their work on the theories regarding the formation of the higher boiling constituents of coal tar, and conclude with some polemical remarks on the Duismore process for the manufacture of coal gas. J. B. T.

Cinnamene Derivatives of Aromatic Hydrocarbons and their Conversion into Anthracene and Methylanthracenes. By G. KRAEMER, A. SPILKER, and P. EBERHARDT (*Ber.*, 23, 3269—3276; compare preceding abstract).—The compounds formed by the condensation of cinnamene with xylene are most probably $\alpha\beta$ -, and not $\alpha\gamma$ -derivatives of propane as was previously supposed; this view would explain their ready transformation into anthracene derivatives.

Meta-xylenecinnamene ($\alpha\beta$ -phenylmetatolylpropane),

prepared by gradually adding concentrated sulphuric acid to a mixture of metaxylene and cinnamene, is a colourless, feebly fluorescent oil of sp. gr. 0.987 at 15° ; it boils at 240° under a pressure of 110 mm., and at $311\text{--}312^\circ$ (corr.), and is miscible with alcohol, ether, benzene, and light petroleum, but insoluble in water. When passed through a red-hot tube, it is almost completely converted into methylanthracene (m. p. 207°).

Para-xylenecinnamene ($\alpha\beta$ -phenylmetatolylpropane), $\text{C}_{15}\text{H}_{18}$, obtained from paraxylene in like manner, boils at $302\text{--}303^\circ$ (corr.), and resembles the preceding compound very closely.

Ortho-xylenecinnamene ($\alpha\beta$ -phenylorthotolylpropane), $\text{C}_{15}\text{H}_{18}$, boils at $316\text{--}317^\circ$ (corr.).

Pseudocumene-cinnamene ($\alpha\beta$ -phenylryllylpropane),

is obtained by the condensation of cinnamene with trimethylbenzene; it boils at 324° (corr.) and is readily converted into dimethylanthracene (m. p. 235°).

Toluene-cinnamene ($\alpha\beta$ -diphenylpropane), $\text{CHMePh}\cdot\text{CH}_2\text{Ph}$, pre-

pared from toluene in like manner, is a colourless liquid boiling at 291—293° (corr.); when heated strongly, it yields only small quantities of anthracene.

Condensation products of benzene with cinnamene could not be obtained. F. S. K.

Condensation Products of Paranitrobenzyl Cyanide. By P. REMSE (*Ber.*, 23, 3133—3136).—A compound of the constitution $\text{CHPh}\cdot\text{C}(\text{CN})\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$ is formed when sodium ethoxide is gradually added to a mixture of paranitrobenzyl cyanide (1 mol.) and benzaldehyde (1 mol.) until a blue coloration is produced. It crystallises from alcohol in yellow needles, melts at 175—176°, and is soluble in glacial acetic acid, benzene, and chloroform, but only sparingly in alcohol and ether, and insoluble in water.

The condensation product obtained in like manner from orthonitrobenzaldehyde and paranitrobenzyl cyanide has the composition $\text{C}_{15}\text{H}_9\text{N}_3\text{O}_4$; it crystallises from glacial acetic acid in large, yellowish needles, melts at 184—185°, and is soluble in chloroform, benzene, alcohol, and ether, but insoluble in water.

Metanitrobenzaldehyde and paranitrobenzyl cyanide also condense to form a compound of the composition $\text{C}_{15}\text{H}_9\text{N}_3\text{O}_4$, which crystallises from alcohol in yellow needles, melts at 195°, and is soluble in most ordinary solvents except water.

A compound of the constitution $\text{OMe}\cdot\text{C}_6\text{H}_4\cdot\text{CH}\cdot\text{C}(\text{CN})\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$ can be obtained by treating anisaldehyde with paranitrobenzyl cyanide as described above; it crystallises from alcohol in yellow needles, melts at 165—166°, and is soluble in ether, benzene, and glacial acetic acid.

The condensation product of cinnamaldehyde and paranitrobenzyl cyanide has the constitution $\text{CHPh}\cdot\text{CH}\cdot\text{CH}\cdot\text{C}(\text{CN})\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$; it crystallises from glacial acetic acid in yellow needles, melts at 205—206°, and is soluble in benzene and chloroform, but more sparingly in alcohol and ether, and insoluble in water. F. S. K.

Condensation of Unsaturated Hydrocarbons with Phenols. By W. KOENIGS (*Ber.*, 23, 3144—3146).—When a mixture of isomylene and phenol is treated with a mixture of concentrated sulphuric acid (1 vol.) and glacial acetic acid (9 vols.) at the ordinary temperature for 1 to 2 days, a considerable quantity of parisonmylphenol is formed.

Hydroxydiphenylethane, $\text{CHMePh}\cdot\text{C}_6\text{H}_4\cdot\text{OH}$, is obtained when cinnamene is treated with phenol under the same conditions as those described above; the yield is about 40 per cent. The reaction product is submitted to distillation with steam and, as soon as the whole of the phenol has passed over, the receiver is changed, the residue heated to 160—170°, and the hydroxydiphenylmethane distilled with superheated steam; the oily product is then converted into the benzoyl derivative (m. p. 83°) by Baumann's method, and the latter, after recrystallisation from alcohol, hydrolysed with alcoholic potash. The phenol obtained in this way solidifies on cooling, and forms a sodium derivative which crystallises in colourless needles.

Resorcinol seems to yield condensation products with amylene and with cinnamene just as readily as phenol. F. S. K.

Diphenyl Derivatives from Alkylquinols. By E. NOELTING and P. WERNER (*Ber.*, 23, 3246—3252).—*Diethyltoluquinol*, $C_6H_5Me(OEt)_2$, can be obtained, together with the monethyl derivative, by heating toluquinol with ethyl bromide and sodium ethoxide in alcoholic solution for 5 to 6 hours at 130—140°; the two compounds are separated by treating the product with soda, in which the diethyl derivative is insoluble. It is a colourless liquid of sp. gr. 1.0134 at 15°, boils at 247—249° (corr.), and solidifies at a low temperature, melting again at 8—9°; it is insoluble in water, but miscible with alcohol, ether, benzene, and chloroform in all proportions.

Ethyltoluquinol, $C_6H_5Me(OH) \cdot OEt$, is obtained when the alkaline filtrate from the preceding compound is acidified and then extracted with cold benzene; it crystallises from dilute alcohol in plates, melts at 116—117°, and boils at 253—287°.

Diethoxydimethylidiphenylquinone (diethoxyditolylquinone),

is formed when the diethyl derivative described above is dissolved in a mixture of dilute acetic acid and sulphuric acid and a concentrated solution of sodium dichromate is gradually added. It crystallises from alcohol in greenish-black needles which melt at 139°, and, when crushed, give a reddish-brown powder; it is precipitated from its solution in boiling glacial acetic acid on the addition of water in reddish-brown flocks. It resembles very closely the cedriret-like oxidation product of the dimethyltoluquinol (compare Nietzki, *Abstr.*, 1883, 465), than which it is, however, much more readily soluble in alcohol and glacial acetic acid.

Diethyltetrahydroxyditolyl, $OH \cdot C_6H_5Me(OEt) \cdot C_6H_5Me(OEt) \cdot OH$, prepared by reducing the preceding compound with sulphurous anhydride in boiling alcoholic solution, crystallises from dilute alcohol in colourless needles, melts at 132—133°, sublimes with partial decomposition, and readily oxidises on exposure to the air; it is only sparingly soluble in water, but moderately easily in the ordinary organic solvents.

Dimethoxyditolylquinone (compare Nietzki, *loc. cit.*) and diethoxyditolylquinone are reconverted into the corresponding quinols by phenylhydrazine, phenylhydrazinesulphonic acid, and sodium hydrogen sulphite; attempts to convert the quinols into derivatives of diphenylene oxide were unsuccessful.

Diacetyldimethoxyditolylquinol,

is formed when dimethoxyditolylquinol is boiled with acetic anhydride and sodium acetate; it crystallises in colourless needles, melts at 123°, and is readily soluble in glacial acetic acid, boiling alcohol, and benzene, but insoluble in water and alkalis.

Bromodimethylquinol, $C_6H_5Br(OMe)_2$, can be obtained, together

with the dibromo-derivative and a liquid boiling at 246—260°, which is probably bromomethylquinol, by treating dimethylquinol with bromine (1 mol.) in cold glacial acetic acid solution; it is a colourless oil of sp. gr. 1.445 at 15°, boils at 262—263° (corr.), and is insoluble in water, but readily soluble in the ordinary organic solvents. When treated with potassium dichromate and sulphuric acid under suitable conditions, it yields a very small quantity of a cedriret-like compound, which, on reduction, is converted into a colourless, crystalline leuco-compound. The *nitro*-compound $\text{NO}_2 \cdot \text{C}_6\text{H}_2\text{Br}(\text{OMe})_2$, prepared by nitrating with acid of sp. gr. 1.4 in well-cooled acetic acid solution, crystallises from glacial acetic acid in orange-yellow needles, and melts at 152—153°. Warm nitric acid converts dibromodimethylquinol (Habermann, *Ber.*, 11, 1137) into a *nitro*-compound, which crystallises in orange prisms and melts at 188°.

Dibromodimethylquinol, nitrobromodimethylquinol, nitrodibromodimethylquinol, and nitrodimethylquinol cannot be converted into cedriret-like compounds.

Dimethylparaxyloquinol, $\text{C}_6\text{H}_2\text{Me}_2(\text{OMe})_2$ [$\text{Me}_2 : (\text{OMe})_2 = 1 : 4 : 2 : 5$], prepared by heating paraxyloquinol with sodium methoxide and methyl iodide in methyl alcoholic solution for 8—10 hours, crystallises from dilute alcohol in colourless plates, melts at 108°, and is soluble in ether, but insoluble in water. The corresponding diethyl derivative melts at 111—112°, and not at 105—106°, as stated by Stadel and Hölz.

Diethylmetaxyloquinol is a colourless oil boiling at 240—249°. The corresponding *ortho*-compound, $\text{C}_6\text{H}_2\text{Me}_2(\text{OEt})_2$ [$\text{Me}_2 : (\text{OEt})_2 = 1 : 2 : 3 : 4$], forms colourless plates, melts at 68—69°, and is readily soluble in alcohol, benzene, ether, &c., but insoluble in water. Cedriret-like oxidation products cannot be obtained from the xyloquinol derivatives described above. F. S. K.

Orthomethylbenzidine. By R. HIRSCH (*Ber.*, 23, 3222—3226).—Orthomethylbenzidine can be prepared in the following manner (compare D. R.-P. 54112):—A solution of nitrobenzene (1 part) and orthonitrotoluene (4 parts) in alcohol (5 parts) is boiled with sodium hydroxide (about 0.5 part) and zinc-dust added until the solution becomes grey or bright yellow; the alcohol is then evaporated, the residue carefully treated with a quantity of hydrochloric acid just sufficient to dissolve the zinc hydroxide, but not the organic bases, and the solution filtered. The residue, which consists principally of hydrazobenzene and its homologues, is then dissolved in warm dilute hydrochloric acid to convert these compounds into the corresponding benzidines, the excess of acid expelled from the filtered solution, the bases precipitated with sodium sulphate, and the sulphates decomposed with sodium carbonate. The mixture of the three bases (benzidine, orthotoluidine, and orthomethylbenzidine) obtained in this way is repeatedly extracted with boiling water, and the combined extracts carefully treated with dilute sulphuric acid to precipitate the sulphates of benzidine and orthomethylbenzidine; these salts are decomposed, and the mixture of bases again extracted (5 times)

with boiling water (20 parts), when pure orthomethylbenzidine is deposited from the first two extracts, on cooling, in lustrous plates melting at 115° . It melts at about 90° under water, forms a diacetyl derivative melting at 310° , and a benzylidene derivative, which crystallises from alcohol in yellow plates, and melts at 217° .

F. S. K.

Diphenyl Bases. By E. NOELTING and P. WERNER (*Ber.*, 23, 3252—3266).—*Ditolyline hydrochloride*, $C_{14}H_{14}N_2 \cdot 2HCl$, is obtained, together with tolidine hydrochloride and other compounds, when orthohydrazotoluene is treated with warm concentrated hydrochloric acid (4 parts). The solution is heated to boiling, then allowed to cool, the tolidine hydrochloride and azotoluene separated by filtration, and the filtrate concentrated by evaporation; after filtering again, the solution is rendered alkaline, extracted with ether, the ether evaporated, and the residue heated at 250° until free from orthotoluidine; it is then dissolved in hydrochloric acid, the ditolyline reprecipitated from the filtered solution, extracted with ether, and converted into the hydrochloride by passing hydrogen chloride into the dried ethereal solution. This salt crystallises in colourless needles, and is very readily soluble in water, but only sparingly in hydrochloric acid; in its aqueous solutions, bromine-water produces a slight, dirty-green coloration which changes to violet. The free base is a colourless, flocculent compound which rapidly oxidises on exposure to the air. The sulphate is very readily soluble. The colouring matters obtained from ditolyline do not dye cotton fibre.

Parabromazobenzene (m. p. 82°), identical with the compound obtained by Janovsky and Erb (*Abstr.*, 1887, 478) by brominating azobenzene, can be prepared from amidoazobenzene by Sandmeyer's method; when treated with stannous chloride in alcoholic solution, it is converted into bromodiphenylene (bromobenzidine).

Pariodazobenzene, $C_{12}H_9N_2I$, prepared in like manner, crystallises from alcohol in yellowish-brown needles, melts at 105° , and is soluble in ether and benzene, but insoluble in water. The corresponding hydrazo-compound crystallises in colourless needles melting at 105° — 106° .

Iododiphenylene hydrochloride, prepared by treating the azo-compound with stannous chloride in alcoholic solution, crystallises in colourless needles, and is readily soluble in water, but only sparingly in concentrated hydrochloric acid. Bromo- and iodo-diphenylene yield coloured azo-compounds which impart to unmordanted cotton only a very slight coloration.

When metadiiodazobenzene is treated with hot concentrated hydrochloric acid, it yields iodazobenzene and large quantities of benzidine. Azobenzeneparasulphonic acid is converted into hydrazobenzene-parasulphonic acid by hydrogen sulphide in ammoniacal solution, and not into benzidinesulphonic acid as stated by Griess (*Annalen*, 154, 213); on treating the ammoniacal solution with hydrochloric acid, benzidine sulphate is precipitated.

Ethoxyazobenzene, $NPh \cdot N \cdot C_6H_4 \cdot OEt$, is converted into a base of the constitution $NH_2 \cdot C_6H_4 \cdot C_6H_5 \cdot (OEt) \cdot NH_2$, when it is treated with

the theoretical quantity of stannous chloride and hydrochloric acid in alcoholic solution; the colouring matters obtained from this base do not dye unmordanted cotton.

Orthotolylazophenol, $C_6H_4Me \cdot N^2 \cdot N^1 \cdot C_6H_4 \cdot OH$, prepared by treating diazorthotolyl chloride (1 mol.) with an alkaline solution of phenol (1 mol.) and precipitating the product with an acid, crystallises from a mixture of benzene and light petroleum in dark-red or orange-yellow plates, melts at $102-103^\circ$, and is very readily soluble in alcohol, ether, benzene, and alcohol, but only sparingly in water and light petroleum.

Orthotolylidisazophenol, $(C_6H_4Me \cdot N_2)_2 \cdot C_6H_5 \cdot OH$, is obtained when a larger quantity (2 mols.) of the diazochloride is employed in the above reaction; it crystallises from alcoholic chloroform in slender, brown needles, melts at 146° , and is readily soluble in chloroform, but insoluble in water.

Orthotolylazophenetol, $C_6H_4Me \cdot N_2 \cdot C_6H_4 \cdot OEt$, prepared by treating the phenol with sodium ethoxide and ethyl bromide, crystallises from alcohol in orange plates, melts at 53° , and is only sparingly soluble in water, but readily in alcohol, ether, benzene, and chloroform; stannous chloride, in alcoholic solution, converts it into a diphenyl base from which fast dyes cannot be obtained.

Paratolylazophenetol, $C_6H_4Me \cdot N_2 \cdot O$, crystallises from alcohol in large, golden plates, melts at $121-122^\circ$, and is insoluble in water and alcohol, but moderately easily soluble in cold alcohol, and readily in boiling alcohol, chloroform, &c.

Paratolylhydrazophenetol, $C_{15}H_{18}N_2O$, prepared by reducing the preceding compound with hydrogen sulphide in ammoniacal alcoholic solution, crystallises in colourless needles, and readily oxidises on exposure to the air; it is insoluble in water, but readily soluble in boiling alcohol. Acids do not convert it into a diphenyl base, but decompose it into toluidine and amidophenetol.

Phenylazorthocresetol, $NPh \cdot N \cdot C_6H_3Me \cdot OEt$, prepared from phenylazorthocresol, crystallises from alcohol in slender, orange needles or prisms, melts at 59° , and is soluble in benzene and ether, but insoluble in water. The corresponding *hydrazo*-compound, $C_{17}H_{18}N_2O$, crystallises in colourless plates, melts at 76° , and is readily soluble in hot alcohol, but insoluble in water; it readily oxidises on exposure to the air, and it is decomposed by hydrochloric acid yielding a diphenyl base from which fast azo-dyes cannot be obtained.

Orthotolylazorthocresol, $C_6H_4Me \cdot N^2 \cdot N^1 \cdot C_6H_3Me \cdot OH$, crystallises from alcohol in red prisms, melts at 132° , and is soluble in benzene and ether, but insoluble in water. The *hydrazo*-compound, $C_{16}H_{20}N_2O$, is a colourless, crystalline substance which melts at 70° , and readily oxidises on exposure to the air; the diphenyl base, produced from the *hydrazo*-compound by intramolecular change under the influence of hydrochloric acid, does not yield any colouring matters which dye unmordanted cotton fibre.

Orthotolylidisazorthocresol, $(C_6H_4Me \cdot N_2)_2 \cdot C_6H_3Me \cdot OH$, crystallises in slender, brown needles, melts at 148.5° , and is insoluble in water,

but soluble in alcohol, benzene, chloroform, and alcoholic soda. The *ethyl* derivative, $C_{23}H_{26}N_2O_2$, prepared by treating the phenol with sodium ethoxide and ethyl bromide, crystallises in golden needles, melts at 102° , and is soluble in chloroform, benzene, and ether, but insoluble in water and alkalis.

Paratolylazorthocresol, $C_6H_4Me \cdot N^1 \cdot N^1 \cdot C_6H_3Me^3 \cdot OH^4$, forms orange crystals, melts at 163° , and is insoluble in water, but readily soluble in alcohol, ether, chloroform, and alkalis. The *ethyl* derivative, $C_{16}H_{18}N_2O$, crystallises in orange needles, melts at $73-74^\circ$, and is readily soluble in alcohol, ether, and benzene, but insoluble in water. The *hydrazo*-compound, $C_{16}H_{20}N_2O$, prepared by reducing the ethyl derivative, crystallises in colourless needles, melts at 87° , and is readily soluble in alcohol, but insoluble in water; it readily oxidises on exposure to the air, and when treated with hydrochloric acid it does not yield a diphenyl base, but is decomposed into an azo-compound and an amido-compound.

Paratolyldisazorthocresol, $C_{21}H_{20}N_4O$, forms small, prismatic crystals, melts at 164.5° , and is insoluble in water, and only sparingly soluble in alcohol. The *ethyl* derivative, $C_{23}H_{24}N_4O$, crystallises in yellow, microscopic needles, melts at $107-108^\circ$, and is soluble in hot ether, benzene, and chloroform, but insoluble in water and alkalis.

Phenylazoparacresetol, $NPh \cdot N \cdot C_6H_3Me \cdot OEt$, prepared by heating the corresponding phenol with ethyl iodide and sodium ethoxide in alcoholic solution, crystallises from alcohol in red plates, melts at 48° , and is soluble in ether and benzene, but insoluble in water and alkalis. The *hydrazo*-compound, $C_{15}H_{18}N_2O$, crystallises in colourless needles, melts at 105° , and is soluble in alcohol, benzene, &c., but insoluble in water.

Methylethoxybenzidine, $NH_2 \cdot C_6H_4 \cdot C_6H_3Me(OEt) \cdot NH_2$, is formed when phenylhydrazoparacresetol is treated with moderately concentrated hydrochloric acid, and the hydrochloride produced decomposed with ammonia. It crystallises from light petroleum in slender, colourless needles, melts at 107° , and is very sparingly soluble in water, but readily in ether and alcohol; its azo-derivatives dye un-mordanted cotton, but not so readily as the corresponding benzidine derivatives.

Orthotolylazoparacresol, $C_{14}H_{14}N_2O$, forms red needles with a blue reflex, melts at 98° , and is soluble in alcohol and chloroform, but insoluble in water and dilute alkalis. The *ethyl* derivative, $C_{16}H_{18}N_2O$, crystallises in red prisms with a blue reflex, melts at $82-83^\circ$, and resembles the preceding compound in its behaviour with solvents. The *hydrazo*-compound, $C_{16}H_{20}N_2O$, prepared by reducing the ethyl derivative with hydrogen sulphide in ammoniacal alcoholic solution, crystallises in colourless plates, melts at 138° , and is insoluble in water, but soluble in alcohol.

Dimethylethoxybenzidine, $NH_2 \cdot C_6H_3Me \cdot C_6H_3Me(OEt) \cdot NH_2$, is formed, together with a small quantity of the azo-compound, when the hydrazo-compound just described is treated with hot dilute sulphuric acid; it crystallises from dilute alcohol in colourless needles, melts at 75° , and is readily soluble in alcohol, ether, and chloroform,

but only sparingly in water; it yields coloured azo-compounds which dye unmordanted cotton fibre.

Paratolylazoparacresetoil, $C_{18}H_{19}N_3O$, crystallises from alcohol in red needles, melts at 171° , and is readily soluble in ether and benzene. The corresponding *hydrazo*-compound, $C_{18}H_{20}N_2O$, forms colourless needles, melts at 153° , and is insoluble in water, but soluble in alcohol, benzene, &c.; when treated with hydrochloric acid, it yields a base which is analogous to diphenylene, and from which azo-compounds, having only a very feeble colouring power, are obtained.

F. S. K.

Orthonitrophenylcinnamic Acid and Phenylhydrocarbo-styryl. By A. OGLIALORO and E. ROSINI (*Gazzetta*, 20, 396—402).—*Orthonitrophenylcinnamic acid*, $C_{15}H_{11}NO_4$, is prepared by heating a mixture of dry sodium phenylacetate (1 mol.), orthonitrobenzaldehyde (1 mol.), and acetic anhydride (4 mols.) for six hours at 160° . The impure acid obtained is partially purified and then converted into the *barium* salt, $(C_{15}H_{11}NO_4)_2Ba \cdot 5H_2O$, which crystallises in tufts of pale-yellow needles. The pure acid crystallises in small, pale-yellow prisms, begins to soften at 192° , and melts at 195 – 196° . It is sparingly soluble in water, but freely in hot alcohol; it also dissolves in ether and in benzene. From some of the alcoholic solutions obtained in the preparation of this acid, another barium salt may be obtained containing 8 mols. H_2O .

On reducing a diluted alcoholic solution of the acid with sodium amalgam, the product consists of a mixture of several substances which may be separated by fractional solution in water, dilute and absolute alcohol. The portion extracted by dilute alcohol crystallises in yellowish needles, melts at 173 – 174° , and has the composition of *phenylhydrocarbostyryl*, $C_{16}H_{13}NO$. It is very soluble in hot alcohol, moderately in chloroform and benzene, but only sparingly in ether and light petroleum. Attempts made to prepare hydrophenylindole from this compound by fusing it with potash were unsuccessful.

S. B. A. A.

Naphthyl Methyl Ketones. By A. OLSEN and H. THORSTENSON (*J. pr. Chem.* [2], 42, 517—519).—The crystals obtained by prolonged cooling of α -naphthyl methyl ketone below 0° (Abstr., 1887, 271) are β -naphthyl methyl ketone.

β -Naphthyl methyl ketone is best obtained by acetylising naphthalene in the cold and with exclusion of direct sunlight; the process is slow and the yield poor; it is freed from the α -ketone by crystallisation and pressure; it sublimes with steam in small, transparent leaflets, melts at 51.5 – 52° (uncorr.), boils undecomposed at 301 – 303° (uncorr.), and dissolves freely in alcohol, ether, and chloroform. The *oxime* forms colourless crystals which melt at 145° (uncorr.), and the *acetyl compound* of this melts at 134° . The *phenylhydrazide* melts at 171° (uncorr.).

α -Naphthyl methyl acetoxime melts at 114° , and α -naphthyl methyl ketone hydrazide at 146° (uncorr.; compare Abstr., 1887, 271).

β -Naphthylglyoxylic (β -naphthoylformic) acid, obtained by oxidising the ketone with potassium permanganate, is a greenish-yellow oil which slowly crystallises and melts at 75° (?); it is pretty freely

soluble in water; the *barium salt* is anhydrous; the *potassium* and *calcium salts* crystallise with 1 mol. H_2O . By reduction, it yields β -*naphthylglycollic acid*, which crystallises in small needles, sublimes in long needles, and melts at 176° (uncorr.); it is little soluble in water; its *barium salt* is anhydrous. α -*Naphthylglycollic acid* melts at 163° (uncorr.).

β -*Naphthylacetic acid* is obtained by reducing the glycollic acid with hydriodic acid; it crystallises in lustrous, silvery leaflets which melt at 142° (uncorr.); its *amide* melts at 200° (uncorr.). A. G. B.

Naphthasultonsulphonic Acids and α -Naphtholsulphonamid-sulphonic Acids. By A. BERNTHSEN (*Ber.*, 23, 3088—3096).—When naphthasultone, the “naphtholsulphonic acid-S.” of the Schollkopf Aniline and Chemical Co.’s Germ. Pat. 40571, is sulphonated with concentrated sulphuric acid, and the melt poured into water, α -naphthol- δ -disulphonic acid (“S. acid” [$\text{OH}:\text{SO}_3\text{H}:\text{SO}_3\text{H} = 1:4:1'$]) is obtained (Schollkopf Co., *loc. cit.*). The author finds that this acid is not the immediate product of sulphonation, but results from hydration of the initially-formed naphthasultonsulphonic acid- δ .

Naphthasultonsulphonic acid δ is obtained as sodium salt when 1 part of naphthasultone is gradually stirred into 8 parts of cooled 5 per cent ahydrosulphuric acid, left for about an hour until a portion is found to be completely soluble in water, and then stirred into an externally-cooled mixture of 12 parts of ice and 16 parts of saturated brine. The sodium salt, $\text{O}-\text{SO}_2 > \text{C}_{10}\text{H}_7\cdot\text{SO}_3\text{Na} + 3\text{H}_2\text{O}$, which

separates after some time, crystallises in thin scales or tables, is much more soluble in water than the sodium salt of naphthasultonsulphonic acid c (*Abstr.*, 1890, 387), and in aqueous solution gives no colour reaction with ferric chloride. On treatment with alkalis or alkaline carbonates, or by boiling with dilute (5 per cent) sulphuric acid, or prolonged boiling with water, it is converted into sodium 1:4:1'- α -naphtholdisulphonate, whilst the latter, on treatment with suitable dehydrating agents, such as concentrated sulphuric acid at 100° , yields the naphthasultonsulphonate. The solution in concentrated ammonia, on addition of hydrochloric acid, gives a precipitate of the sodium salt of *naphtholsulphonamid-sulphonic acid* δ , $\text{OH}\cdot\text{C}_{10}\text{H}_7(\text{SO}_2\cdot\text{NH}_2)\cdot\text{SO}_3\text{Na} + 2\text{H}_2\text{O}$, which crystallises in rhomb-like scales or plates, resembles the c -compound (*loc. cit.*) in properties, and forms similar azo-dyes.

The azo-dyes obtained from the salts of naphtholsulphonamid-sulphonic acid c give much bluer or redder shades, are less soluble in water, and crystallise better than those from α -naphtholdisulphonic acid c . The dyes formed by the action of diazotised xyldine, α -naphthylamine, and benzidine give respectively very blue-claret, wine-red, and bluish-violet shades, are scarcely affected by acids, and, on reduction with stannous chloride and hydrochloric acid, yield the sodium hydrogen salt of an *amidonaphtholdisulphonic acid* (probably $\text{OH}:\text{NH}_2:\text{SO}_3\text{H}:\text{SO}_3\text{H} = 1:2:3:1'$).

The azo-dyes obtained with diazotised xyldine dissolve in concen-

trated sulphuric acid with a magenta colour, which, after a short time, changes to yellow; a corresponding colour-change occurs also with the other dyes named, and is due to hydrolysis of the SO_3NH_2 radicle with the production of ammonia and the corresponding azo-colouring matters derived from α -naphtholdisulphonic acid. A more remarkable change is that brought about by alkalis. The bluish-red azo-dye obtained with diazotised xylidine, when warmed for a short time with alkalis or alkaline carbonates, changes colour to a bright reddish-yellow, and a corresponding change to yellow or red shades ensues under like conditions with the other dyo stuffs named. The azo-dyes formed can be salted out from solution, and, unlike the parent colours, are very sensitive towards acids, changing colour to blue or violet, and thus resemble many of the amidoazo-dyes. Moreover, they crystallise well, are very soluble in water containing some alkali, and in an acid bath produce shades on wool which are distinctly bluer than those from the parent dyes. On reduction with stannous chloride and hydrochloric acid, the "altered" xylidine dye, which gives a cochineal shade on wool in an acid bath, yields a sparingly soluble compound, $\text{C}_{10}\text{H}_8\text{N}_2\text{S}_2\text{O}_6 + 2\text{H}_2\text{O}$, crystallising in long, flat needles. This compound dissolves readily in alkalis, is precipitated from the alkaline solutions by acids, and by prolonged boiling with phenanthraquinol in acetic acid solution, forms an azine. It is a derivative of, but not identical with, 1:2:3:1'-orthonaphthylenediaminedisulphonic acid, and is regarded by the author as the *anhydride*, $\text{NH} \begin{smallmatrix} \text{SO}_2 \end{smallmatrix} > \text{C}_{10}\text{H}_4(\text{NH}_2) \cdot \text{SO}_3\text{H}$, of this compound, the action of alkalis on the azo-dyes obtained from naphtholsulphon-amidosulphonic acid ϵ being represented thus:—

Sodium hydrogen 1:2:3:1'-orthonaphthylenediaminedisulphonate, $\text{SO}_3\text{H} \cdot \text{C}_{10}\text{H}_4(\text{NH}_2)_2 \cdot \text{SO}_3\text{Na} + 3\text{H}_2\text{O}$, crystallises in small needles, is much more soluble than the salt of the anhydride, and forms an azine on treatment with phenanthraquinone. W. P. W.

Dinaphthyl Picrates. By R. WEGSCHEIDER (*Ber.*, 23, 3199—3201).—Of the dinaphthyl picrates, only the $\alpha\alpha$ -compound has previously been prepared. $\alpha\beta$ -Dinaphthyl picrate, $\text{C}_{20}\text{H}_{14} + \text{C}_{12}\text{H}_8\text{N}_2\text{O}_7$, may be readily obtained by mixing boiling alcoholic solutions of the hydrocarbon and picric acid, and crystallises in golden-yellow needles melting at 155—156°. For the preparation of $\beta\beta$ -dinaphthyl picrate, the constituents must be dissolved in boiling benzene; the salt separates out on cooling in microscopic, orange prisms, which have the composition $\text{C}_{20}\text{H}_{14} \cdot 2\text{C}_{12}\text{H}_8\text{N}_2\text{O}_7$. The author regards the hydrocarbon obtained by Bischoff, by the action of methyl chloride on naphthalene in presence of aluminium chloride (*Abstr.*, 1890, 1145), as probably identical with $\beta\beta$ -dinaphthyl. H. G. C.

Chrysidines. By A. PIOTET and S. ERLICH (*Chem. Centr.*, 1890, ii, 350—351; from *Arch. sci. phys. nat.*, Genève [3], 23, 552).—The

authors have pursued the investigations already commenced by Pictet (Abstr., 1890, 390), and have studied the action of heat on the two benzylidenenaphthylamines, which are obtained by heating benzaldehyde with the two naphthylamines. By passing the vapour of these compounds through a red-hot tube, two new bases, of the formula $C_{17}H_{11}N$, are obtained, the constitutional formula being, probably, $\begin{matrix} C_6H_4CH \\ | \\ C_{10}H_6N \end{matrix}$. These bases, which correspond with the phenanthridines, and are similar to them in their properties, are, therefore, α - and β -chrysidine. Their alkaline solutions have a blue fluorescence, they form yellow salts with acids, and the solutions of the latter have a green fluorescence. Reduction with tin and hydrochloric acid converts them into secondary bases. α -Chrysidine melts at 108° , β -chrysidine at 126° . J. W. L.

Turpentine. By R. G. DUNWODY (*Chem. Centr.*, 1890, ii, 241—242; from *Amer. J. Pharm.*, June, 1890).—The author finds very considerable variations in the specific rotatory power and the specific gravity of oil of turpentine. In 12 samples, the former varied from 2.60° to 36.64° in a 200 mm. tube, before rectification, and from 3.90° to 38.62° after rectification. The specific gravity at 15° varied from 0.856 to 0.876 before, and from 0.851 to 0.873 after rectification. The oils commenced to boil at 155 — 159° , and the last portions distilled between 165° and 170° : the principal part distilled at 160 — 162° . The author has not found Allen's test with castor-oil, for the detection of petroleum in turpentine, of much value, since an admixture of 65 per cent. of the former escaped detection by means of this test. In pure glacial acetic acid both petroleum and turpentine are perfectly miscible, but of acetic acid containing 1 per cent. of water, more and more is required for complete solution, the greater the proportion of petroleum which is present, as is shown in the following table:—

Petroleum	1	2	3	4	5	7	8 c.c.
Oil of turpentine.....	9	8	7	6	5	3	2 „
Acetic acid + 1 per cent H_2O	40	60	80	110	130	230	270 „

From the pitch remaining in the retort, after the distillation of the turpentine, the author has separated, with light petroleum, two well crystallised substances, the one being abietic acid, melting at 131° , and the other, a new substance, having the composition 72—72.8 per cent. carbon, 9.75—9.50 per cent. hydrogen, 18.25—17.70 per cent. oxygen; and melting at 125 — 126° . J. W. L.

Terpenes and Ethereal Oils. By O. WALLACH (*Annalen*, 259, 309—324).—*Pinole glycol diacetate*, $C_{10}H_{16}O(OAc)_2$, is formed, together with pinole and pinole glycol, when pinole dibromide is warmed with sodium or silver acetate in glacial acetic acid solution; the product is purified by fractional distillation under a pressure of 13 mm. It crystallises well from water, and melts at 97 — 98° .

Pinols glycol, $C_{10}H_{16}O(OH)_2$, can be prepared by boiling the

diacetate with very dilute sulphuric acid, or by treating the bromide with freshly precipitated silver oxide; it crystallises from light petroleum in needles, melts at 125° , is very readily soluble in chloroform, and is converted into the diacetate by boiling acetic anhydride.

Pinole hydrate, $C_{10}H_{18}O_2$, is obtained, together with cymene, when a well-cooled glacial acetic acid solution of crude pinole is saturated with hydrogen bromide, and then shaken with very dilute soda in the cold, in order to decompose the additive product; after separating the cymene by distilling with steam, the hydrate is extracted from the alkaline solution by shaking with ether. Pinole hydrate crystallises in needles or plates, melts at 131° , and is moderately easily soluble (1 in 30 at 15°) in water, but more readily in alcohol; it crystallises unchanged from boiling glacial acetic acid, but when warmed with dilute sulphuric acid, it is converted into pure pinole. It is identical with the crystalline substance which was formed, as was first observed by Sobrero (*Annalen*, 80, 106), when oil of turpentine is exposed to direct sunlight in presence of oxygen (compare Armstrong, Proc., 1890, 99). Pinole, on oxidation with potassium permanganate, yields terebic acid and considerable quantities of oxalic acid and carbonic acid; pinole hydrate, under the same conditions, gives terpenylic acid, carbonic acid, and oxalic acid; pinole glycol seems to give the same oxidation products as the hydrate.

Pure pinole is easily prepared by boiling a benzene solution of pinole dibromide with the theoretical quantity of sodium, in the form of fine wire, until decomposition is complete; the filtered solution is evaporated, and the residual pinole purified by fractional distillation.

Pinole tribromide, $C_{10}H_{15}OBr_3$, is obtained in small quantities in the preparation of the dibromide from crude pinole; it crystallises from ethyl acetate in needles, and melts at 160° with decomposition.

F. S. K.

Fenchole, an Isomeride of Camphor. By O. WALLACH and F. HARTMANN (*Annalen*, 259, 324—331).—A liquid of sp. gr. 0.934, possessing a strong odour of camphor, and boiling at 190 — 193° , can be isolated from oil of fennel; it has the composition $C_{10}H_{16}O$, and is named by the authors *fenchole*. The whole chemical behaviour of fenchole is that of a position-isomeride of camphor, as will be seen from the experiments described below; it combines with bromine in well-cooled light petroleum solution, yielding a bright-red, crystalline, unstable additive product, which is reconverted into fenchole on treatment with soda; it also yields with sodium, a solid compound, which seems to be converted into an acid by carbonic anhydride.

Fenchole oxime, $C_{10}H_{15}N \cdot OH$, crystallises from alcohol in slender needles, and from ethyl acetate in well-defined crystals, $a : b : c = 1.3047 : 1 : 0.55259$, $\beta = 76^{\circ} 20'$, which melt at 148 — 149° , and are very like those of camphor oxime in appearance. The *hydrochloride*, $C_{10}H_{17}NO \cdot HCl$, melts at 118 — 119° , and is decomposed by alcohol. The *anhydride*, $C_{10}H_{15}N$, prepared by dissolving the oxime in dilute sulphuric acid, is a colourless liquid, boiling at 217 — 219° ; it can be distinguished from the anhydride of camphor oxime by the fact that it yields a crystalline *hydrobromide*, $C_{10}H_{15}N \cdot HBr$, which is, however, very unstable.

Isofenchole oxime, $C_{10}H_{17}NO$, is formed when fenchole oxime anhydride is boiled with alcoholic potash for five to six hours; it crystallises from alcohol in plates, melts at $113-114^{\circ}$, and is readily soluble in alcohol, ether, and acids, and moderately soluble in water.

Fencholenic acid, $C_{10}H_{16}O_2$, is obtained when isofenchole oxime is boiled with alcoholic potash for four days, but some of the oxime remains unchanged. It is an almost colourless liquid, boils at $257-260^{\circ}$, and forms a sparingly soluble silver salt and a deliquescent ammonium salt.

F. S. K.

Rose-oil. By V. MARKOVNIKOFF (*Ber.*, 23, 3191).—Rose-oil consists, as is well known, of liquid constituents and stearoptene. The latter melts at 36.5° , and has all the properties of a paraffin; it is perfectly inodorous, and is, therefore, of no value with regard to the quality of the oil. The liquid portion or eleoptene boils within narrow limits, and appears to be a mixture of two substances, $C_{10}H_{20}O$ and $C_{10}H_{18}O$, one of which is an alcohol, and forms the chief constituent of rose-oil.

H. G. C.

β -Methylpyridine. By C. STOEUR (*Ber.*, 23, 3151—3157).—The product obtained by the distillation of strychnine or of brucine is not homogeneous. After purification, however, it yields β -methylpyridine, which boils at $142-143^{\circ}$, and is identical with the synthetic product from glycerol, acetamide, and phosphoric anhydride. The mercuriochloride melts at $145-146^{\circ}$, the platinosochloride at $257-257.5^{\circ}$, and the platinochloride at $201-202^{\circ}$. Ladenburg (*Abstr.*, 1890, 1432) gives three melting points for this last compound (from synthetic β -methylpyridine), which range between 191° and 198° , and it is suggested that he had to deal with varying mixtures of the two platinum compounds. Ladenburg's theory of the constitution of pyridine, so far as it is based on the existence of two β -methyl derivatives, is thus proved to be erroneous.

J. B. T.

A New Class of Acridines: Phenylcarbazacridine. By D. BIZZARRI (*Gazzetta*, 20, 407—417).—*Phenylcarbazacridine*, $C_{19}H_{11}N$, is formed when a mixture of pure carbazole (20 grams) with benzoic acid (15 grams) and fused zinc chloride (45 grams) is heated for five hours at $120-130^{\circ}$, and the alcoholic solution of the product precipitated with strong aqueous ammonia. The product when pure crystallises from alcohol in minute, white scales, turns green on heating to 150° , and melts at 186.5° . It dissolves in most of the ordinary solvents, but only sparingly in absolute alcohol, and not at all in water. It crystallises from benzene in groups of rectangular laminae, and from xylene in peculiar, spherical tufts. With acetic acid, it forms an intense green solution, which is dichroic when concentrated (0.25 per cent.), appearing emerald-green by reflected, and garnet-red by transmitted light. It is not affected by boiling with alkalis, and only partially decomposed by heating with soda-lime. It is dissolved by benzoic chloride, but not further affected.

The *methiodide*, $C_{19}H_{11}N, MeI$, prepared by heating the base with methyl iodide at 140° , crystallises in brownish-yellow plates, soluble in

~ 2

alcohol and acetic acid. From these solutions, the base is reprecipitated on the addition of water. Boiling alcoholic potash decomposes it into the free base, methyl alcohol, and potassium iodide. On gently heating, it is similarly split up into the base and methyl iodide.

The *hydrochloride* forms emerald-green scales, soluble in acetic acid and in alcohol, but not in water. It dissociates even in alcoholic solution, and is only stable in presence of an excess of free hydrochloric acid. It is completely decomposed by boiling water. The *sulphate* forms a green, shining mass, soluble in acetic acid and in alcohol, but not in water. It is gradually decomposed by boiling water, and the alcoholic solution is unstable in the absence of free sulphuric acid. The *picrate* and *hydriodide* crystallise in green plates decomposed by water, and forming unstable alcoholic solutions. The *chromate* crystallises in scales decomposed by water and alcohol.

Benzoylcarbazole, $C_{15}H_{13}NO$, is obtained by heating carbazole with benzoic anhydride at 240° . It crystallises from alcohol in white, acicular prisms, melts at 95.5° , dissolves in benzene, ether, &c., but only sparingly in alcohol. It is decomposed by alcoholic potash into carbazole and benzoic acid. Its formation and decomposition, together with the analogy to acetylcarbazole, establish for this compound the constitution $C_{15}H_{13}NBz$. On heating it with zinc chloride at $130-150^{\circ}$, phenylcarbazacridine is formed.

prepared by reducing phenylcarbazacridine with zinc-dust, crystallises in yellowish leaves which turn brown and melt at 172° , and dissolves in acetic acid, alcohol, and ether, but not in water. It reduces silver nitrate in alcoholic solution, and picric acid imparts to it an orange coloration. It has no basic properties, but acids and potassium permanganate convert it into phenylcarbazacridine.

When carbazole is heated with benzoic acid and zinc chloride at $150-160^{\circ}$, there is formed, besides the acridine described and resinous products, a compound of unknown constitution, which crystallises from boiling alcohol in tables which melt at 210° , and are stained yellow by picric acid. At $200-210^{\circ}$, no phenylcarbazacridine is formed, the products consisting mainly of resins. At 280° , the mass is gradually carbonised.

S. B. A. A.

Thiazoles. By K. HURACHER (*Annalen*, 259, 228—253; compare Hantzsch, *Abstr.*, 1889, 413, 723, and 1890, 1238).—*Thiopropionamide*, C_3H_5NS , can be prepared by treating propionamide with phosphorus pentasulphide, as described by Hantzsch (*loc. cit.*) in the case of thiacetamide; the yield is, at the most, 10 per cent. of the amide employed. It crystallises in yellowish plates, melts at $42-43^{\circ}$, and is very readily soluble in benzene, but only sparingly in ether, alcohol, and water.

α -Methyl- μ -ethylthiazole, $\begin{smallmatrix} CH-S \\ | \\ CMe-N \end{smallmatrix} \gg CEt$, is obtained when thiopropionamide is treated with chloroacetone in alcoholic solution, and the

product decomposed with soda. It is a colourless liquid, boils at $159.5\text{--}160^\circ$ (728.5 mm.), has an odour of pyridine, and is miscible with alcohol and ether, but is only sparingly soluble in cold water. The *platinochloride*, $(C_6H_5NS)_2H_2PtCl_6$, forms small, yellowish-red crystals, and melts at 177° with decomposition.

α-Phenyl-μ-ethylthiazole, $C_{11}H_{11}NS$, is formed when thiopropionamide is treated with bromacetophenone in like manner; the product is dissolved in dilute hydrobromic acid, and the crystalline hydrobromide, which is deposited from the filtered solution, decomposed with soda. The base is a colourless oil, of agreeable odour, boils at 295° (729 mm.), and is insoluble in water, but miscible with alcohol and ether. The *platinochloride*, $(C_{11}H_{11}NS)_2H_2PtCl_6$, forms light-yellow, microscopic crystals, and melts at $128\text{--}129^\circ$ with decomposition. The *hydrobromide*, $C_{11}H_{11}NS.HBr$, crystallises in colourless needles, melts at $68\text{--}70^\circ$, and is decomposed by cold water or when kept over sulphuric acid.

μ-Phenylthiazole, C_6H_7NS , is formed when thiobenzamide is heated at 100° for several hours with dichlorether and sodium acetate in alcoholic solution; the dark, resinous product is extracted with dilute hydrochloric acid, the base liberated with soda, and distilled. It is a colourless oil boiling at $266\text{--}268^\circ$ (732 mm.). The *hydrochloride*, $C_6H_7NS.HCl + 2H_2O$, crystallises from dilute hydrochloric acid in plates, melts at $61\text{--}62^\circ$, loses its water over sulphuric acid, and is immediately decomposed by water. The *platinochloride*, $(C_6H_7NS)_2H_2PtCl_6 + 2H_2O$, is a yellow, crystalline compound melting at $173\text{--}175^\circ$ with decomposition; it loses its water at 110° . The picrate crystallises in yellow needles, melts at $124\text{--}125^\circ$, and is only very sparingly soluble in water, but readily in hot alcohol.

α-Methyl-μ-phenylthiazole, $C_{10}H_9NS$, prepared by treating thiobenzamide with chloracetone in alcoholic solution, is an oil boiling at $277.5\text{--}278^\circ$ (724 mm.).

αμ-Diphenylthiazole, $C_{13}H_{11}NS$, obtained from thiobenzamide and bromacetophenone in like manner, crystallises from alcohol in colourless plates, melts at $92\text{--}93^\circ$, boils above 360° without decomposition, and is readily soluble in alcohol and ether; it is a very feeble base, but its salts are unstable and cannot be obtained in a pure condition.

Ethyl α-methyl-μ-phenylthiazolecarboxylate, $\begin{matrix} \text{CPh}\cdot\text{S} \\ \text{N}\cdot\text{CMe} \end{matrix} \text{ > C}\cdot\text{COOEt}$, is

obtained when thiobenzamide is warmed with ethyl chloroacetate, and the salt thus produced decomposed with soda; it crystallises from ether in yellow needles, and melts at 43° . The corresponding acid, $C_{11}H_9NS$, prepared by hydrolysing the ethereal salt with alcoholic potash, crystallises in colourless needles, melts at $202\text{--}204.5^\circ$, and, when heated more strongly, sublimes in long needles, being at the same time partially decomposed into carbonic anhydride and methylphenylthiazole. It is readily soluble in alcohol, but only sparingly in ether, and almost insoluble in water; in its neutral solutions many metallic salts produce a precipitation.

A mixture of various compounds, which contains α-chloropropaldehyde

hyde, can be obtained by gradually adding sulphuryl chloride to an ethereal solution of propaldehyde in which barium carbonate is suspended; the ethereal solution is washed with water and sodium carbonate consecutively, dried, and then submitted to fractional distillation; the portion passing over between 60° and 150° was employed in some of the experiments described below.

$\beta\mu$ -*Dimethylthiazole*, $\begin{array}{c} \text{CMe}\cdot\text{S} \\ | \\ \text{CH}\cdot\text{N} \end{array} > \text{CMe}$, is formed in small quantities when crude α -chloropropaldehyde is warmed with thiacetamide, the product boiled with hydrochloric acid, and then treated with soda; it is purified by distilling with steam, and then submitted to fractional distillation. It is a colourless liquid, boils at 148–150° (734 mm.), and is sparingly soluble in water, but readily in ether and alcohol. The *platinochloride*, $(\text{C}_2\text{H}_4\text{NS})_2\cdot\text{H}_2\text{PtCl}_6$, crystallises in prisms and melts at 202°; the picrate crystallises in small, yellow needles, melts at 166–167°, and is sparingly soluble in water.

β -*Methyl- μ -amidothiazole*, $\text{C}_4\text{H}_6\text{N}_2\text{S}$, is obtained by heating crude α -chloropropaldehyde with thiocarbamide; it crystallises from water in yellowish plates, melts at 94–95°, and is readily soluble in alcohol, but less readily in ether, and only sparingly in cold water. The *platinochloride* forms nodular, crystalline aggregates, and melts at 181–182° with decomposition.

$\alpha\beta$ -*Diphenyl- μ -amidothiazole*, $\text{C}_{11}\text{H}_{12}\text{N}_2\text{S}$, can be prepared by warming bromodeoxybenzoin with thiocarbamide and decomposing the product with dilute sodium carbonate. It crystallises from alcohol in yellowish needles, melts at 185–186°, and is readily soluble in alcohol, but only sparingly in ether, and insoluble in water. The *hydrobromide*, $\text{C}_{11}\text{H}_{12}\text{N}_2\text{S}\cdot\text{HBr}$, crystallises in needles, melts at 215–217° with partial decomposition, and is only sparingly soluble in dilute hydrobromic acid.

$\alpha\beta$ -*Diphenyl- μ -methylthiazole*, $\text{C}_{16}\text{H}_{14}\text{NS}$, can be obtained by treating an alcoholic solution of thiacetamide with bromodeoxybenzoin; it is purified by means of the hydrochloride, a crystalline compound melting at 96–97°. The base crystallises in colourless needles, melts at 51–52°, and is insoluble in water, but readily soluble in alcohol and ether.

Triphenylthiazole, $\text{C}_{21}\text{H}_{18}\text{NS}$, prepared from thiobenzamide and bromodeoxybenzoin, crystallises in colourless, well-defined prisms, melts at 86–87°, and is readily soluble in ether, but more sparingly in alcohol, and insoluble in water. It crystallises unchanged from hot concentrated hydrochloric acid, in which it is only very sparingly soluble.

Phenylhydroxythiazole (m. p. 204°) is formed when bromoacetophenone is treated with xanthogenamide under various conditions. The *ethyl* derivative of phenyloxypseudothiazole is obtained when phenylhydroxythiazole is treated with sodium ethoxide and ethyl iodide at 140–150°. It crystallises from ether in colourless plates, melts at 71°, and is decomposed by concentrated hydrochloric acid at 220° yielding ethylamine; it has, therefore, the constitution expressed

by the formula $\begin{array}{c} \text{CH}\cdot\text{S}\cdot\text{CO} \\ | \\ \text{CPh}\cdot\text{NEt} \end{array} >$.

F. S. K.

Trimethylthiazole, Methylene-thiazole, and Thiazolecarboxylic Acids. By T. ROUBLEFF (*Annalen*, 259, 253—276).—*Ethyl α -chloromethylacetoacetate*, $\text{COMe}\cdot\text{CMeCl}\cdot\text{COOEt}$, is obtained when sulphuryl chloride is gradually added to well-cooled ethyl methylacetoacetate. It is a colourless liquid of sp. gr. 1.0591 at 16.5°, with a pleasant, rather pungent odour, and boils at 192—194° (corr.). It does not yield a salt with copper acetate under any conditions; the corresponding bromo-compound, obtained by brominating ethyl methylacetoacetate, gives a copper salt, and can be readily converted into thiazole derivatives. It is evident, therefore, that chlorine and bromine, at the ordinary temperature, displace different hydrogen atoms in ethyl methylacetoacetate (compare Hantzsch, *Abstr.*, 1890, 1238; it has, however, been stated by Genvresse (*Compt. rend.*, 107, 187) that both α - and γ -chloro-derivatives are formed when ethyl acetoacetate is treated with chlorine at 170°.

Trimethylthiazole, $\begin{array}{c} \text{CMe}\cdot\text{S} \\ | \\ \text{CMe}\cdot\text{N} \end{array} > \text{CMe}$, is formed when crude methyl chlorethyl ketone, prepared by hydrolysing ethyl α -chloromethylacetoacetate with 40 per cent. hydrochloric acid, or by chlorinating methyl ethyl ketone with sulphuryl chloride, is warmed with thiacetamide; the product is boiled with dilute hydrochloric acid, the filtered solution mixed with soda, and the precipitated oil extracted with ether. Trimethylthiazole can also be obtained by brominating methyl ethyl ketone in etheral solution, and treating the methyl bromethyl ketone produced with thiacetamide. It is a colourless liquid of sp. gr. 1.0130 at 16°, boils at 166.5—167.5° (corr.), and is moderately easily soluble in cold water. The *platinochloride*, $(\text{C}_6\text{H}_5\text{NS})_2\cdot\text{H}_2\text{PtCl}_6$, crystallises in orange prisms, and melts at 232—233° with decomposition. The *hydrochloride* is a crystalline, deliquescent compound melting at 173—174°. The *anrochloride* is sparingly soluble in boiling water, from which it crystallises in yellow needles melting at 155—156°. The *picrate* crystallises from hot water in yellow prisms melting at 133°, and the *mercuriochloride* crystallises in small plates melting at 118—119°.

Ethyl bromomethylacetoacetate, $\text{CH}_2\text{Br}\cdot\text{CO}\cdot\text{CHMe}\cdot\text{COOEt}$, prepared by brominating ethyl methylacetoacetate, is an oil of sp. gr. 1.1981 at 16.5°, with a disagreeable, pungent odour; its alcoholic solution gives a reddish-violet coloration with ferric chloride, and a green, crystalline precipitate with copper acetate.

Ethyl methylthiazolepropionate, $\begin{array}{c} \text{CMe}\cdot\text{N} \\ | \\ \text{S}-\text{CH} \end{array} > \text{C}\cdot\text{CHMe}\cdot\text{COOEt}$, is formed when thiacetamide is treated with ethyl bromomethylacetoacetate; it is a thick, dark-brown oil, and on hydrolysis with alcoholic soda, it yields an oily acid which, when distilled with lime, is converted into μ -methyl- α -ethylthiazole.

μ -Methyl- α -ethylthiazole, $\text{C}_6\text{H}_5\text{NS}$, purified by fractional distillation, is an oil boiling at 169—171° (corr.). The *platinochloride*,

forms reddish-yellow prisms, and melts at 182—183° with decom-

position. The *picrate* crystallises from water in well-defined, lemon-yellow prisms, melting at 114—115°, and the *mercurichloride* crystallises in prisms melting at 138—139°.

α,μ-Dimethylthiazole-β-carboxylic acid, $\begin{array}{c} \text{N-Me} \\ | \\ \text{C-Me-S} \end{array} \Rightarrow \text{C-COOH}$, is obtained

when the ethyl salt (compare Hantzsch, Abstr., 1869, 724) is hydrolysed with alcoholic potash. It crystallises from hot water in long, colourless needles or small prisms, melts at 227° with evolution of gas, sublimes without decomposition, and is only moderately easily soluble in hot water, but more readily in alcohol and ether. The salts of the alkaline earths are readily soluble in water, but in neutral solutions of the ammonium salt, many metallic salts produce a precipitation. The *silver* salt, $\text{C}_5\text{H}_7\text{NS}\cdot\text{COOAg}$, crystallises from boiling water in colourless needles, and quickly darkens on exposure to light. The *hydrochloride*, $\text{C}_5\text{H}_7\text{O}_2\text{NS}\cdot\text{HCl}$, crystallises from cold dilute hydrochloric acid in transparent plates, and is decomposed by water, or when heated at 70°. The acid is completely destroyed by potassium permanganate, but it is not acted on by boiling concentrated nitric acid.

μ-Methylthiazole-dicarboxylic acid, $\begin{array}{c} \text{S-C-COOH} \\ | \\ \text{C-Me-N-C-COOH} \end{array}$, can be obtained

by warming ethyl chloroxalacetate, prepared by treating ethyl oxalacetate with sulphuryl chloride, with thiacetamide, and hydrolysing the product with alcoholic soda. It crystallises from warm water in long, colourless needles with 1 mol. H_2O , sublimes below 100°, melts at 169° with evolution of carbonic anhydride, and is readily soluble in cold water and alcohol, but very sparingly in ether, carbon bisulphide, benzene, &c. The *barium* salt, $\text{C}_5\text{H}_7\text{NSO}_4\cdot\text{Ba} + 2\text{H}_2\text{O}$, crystallises in colourless needles, and loses the whole of its water at 130°. The *mercury* salt, $\text{C}_5\text{H}_7\text{NSO}_4\cdot\text{Hg} + 3\frac{1}{2}\text{H}_2\text{O}$, is colourless and crystalline, and loses its water at 115°. Most of the other salts, except those of calcium, magnesium, and the alkalis, are sparingly soluble in water.

μ-Methylthiazole-β-carboxylic acid, $\text{C}_5\text{H}_7\text{O}_2\text{NS}$, is formed with evolution of carbonic anhydride, when the dicarboxylic acid just described is heated for some time at 170—172°. It crystallises from water in small, colourless needles or prisms containing 1 mol. H_2O , loses its water at 70—80°, and melts at 144—145°; it is readily soluble in cold water, but more sparingly in alcohol, ether, and chloroform, and almost insoluble in carbon bisulphide and benzene. The salts are all readily soluble, except those of silver, copper, and mercury.

Ethyl μ-amidothiazole-dicarboxylate, $\text{C}_8\text{H}_{12}\text{O}_4\text{N}_2\text{S}$, is obtained in the form of the hydrochloride when ethyl chloroxalacetate is mixed with thiocarbamide; when the crystalline salt, which is only very sparingly soluble in water, is treated with potassium carbonate, the base is liberated, and can be purified by crystallisation from ether-alcohol. It forms well-defined prisms which contain $\frac{1}{2}$ mol. $\text{C}_2\text{H}_5\text{O}$, and melt at 90°, the alcohol-free compound melting at 112°.

μ-Amidothiazole-dicarboxylic acid, $\text{C}_8\text{H}_8\text{N}_2\text{SO}_4$, prepared by hydrolysing the ethyl salt with alcoholic soda, crystallises from hot water

in yellowish needles with 1 mol. H_2O , loses its water at 150° , melts at $229\text{--}230^\circ$ with complete decomposition, and is only sparingly soluble in most ordinary neutral solvents. Attempts to convert this acid and its ethyl salt into $\alpha\beta$ -thiazoledicarboxylic acid by means of nitrous acid were unsuccessful.

F. S. K.

Diazo-compounds of the Thiazole Series. By M. WOHMANN (*Annalen*, 259, 277—300).—A compound of the composition $\text{C}_7\text{H}_5\text{N}_3\text{O}_3\text{S}$, which seems from its behaviour to be the diazo-hydrate

of ethyl methylthiazolecarboxylate, $\text{COOEt} \cdot \text{C} \begin{smallmatrix} \text{S} - \text{C} \cdot \text{N} \cdot \text{N} \cdot \text{OH} \\ \text{CMe} \cdot \text{N} \end{smallmatrix}$, is

formed when ethyl methylamidothiazolecarboxylate (10 grams), prepared as described by Zürcher (Abstr., 1889, 725), is dissolved in a mixture of 33 per cent. hydrochloric acid (30 c.c.) and water (200 c.c.), and sodium nitrite (25 grams), dissolved in water (100 c.c.), gradually added to the cooled solution; after expelling the nitrous acid with a stream of air, the precipitate is quickly separated by filtration, washed with very dilute nitric acid, alcohol, and other consecutively, and then recrystallised from cold ether, from which it separates in small, yellowish plates. It melts and explodes at $99\text{--}100^\circ$, is rather unstable, gives Liebermann's reaction, and is moderately easily soluble in glacial acetic acid, alcohol, benzene, and light petroleum, but more sparingly in ether. In some respects, it behaves like an aromatic diazo-compound, being soluble in alkalis and cold concentrated acids, and giving dyes with phenols; in others, it behaves like a nitroso-derivative, and, when treated with most ordinary reducing agents, is reconverted into the amido-compound.

Ethyl hydrazomethylthiazolecarboxylate is obtained in an impure condition by carefully reducing the diazo-compound described above with zinc-dust and dilute ammonia. It is a crystalline, very unstable compound, which reduces Fehling's solution in the cold, and combines readily with aldehydes and ketones in acetic acid solution, yielding crystalline compounds; the condensation product obtained with acetone forms bright-yellow needles and is unstable.

Ethyl methylchlorothiazolecarboxylate, $\text{C}_7\text{H}_5\text{O}_2\text{NSCl}$, can be prepared by gradually adding the diazo-compound to warm 15 to 18 per cent. hydrochloric acid, and heating the mixture until the evolution of nitrogen ceases; the solution is then diluted with water, the product distilled with steam in order to separate it from the azimido-compound described below, and then treated with dilute hydrochloric acid to free it from ethyl methylamidothiazolecarboxylate. It crystallises from alcohol in transparent prisms, melts at $50\text{--}51^\circ$, has a sweet, sharp taste, and a fruity odour; it is soluble in concentrated hydrochloric acid and dissolves freely in most ordinary organic solvents, but is insoluble in water.

Ethyl methylbromothiazolecarboxylate, $\text{C}_7\text{H}_5\text{O}_2\text{NSBr}$, prepared by treating the diazo-compound with hydrobromic acid in a similar manner, crystallises from alcohol in large, colourless plates, melts at $70\text{--}71^\circ$, and resembles the chloro-derivative in chemical and physical properties. The corresponding iodo-compound, $\text{C}_7\text{H}_5\text{O}_2\text{NSI}$, is formed

in small quantity when the diazo-compound is treated with 2 to 3 per cent hydriodic acid, the principal product, however, being regenerated amido-compound; it separates from alcohol and glacial acetic acid in crystals melting at 86—87°, and resembles the chlorinated derivative very closely. The yield of the iodo-compound is only 5 to 10 per cent., whereas in the case of the chlorinated and brominated derivatives the yield is 60—70 per cent. of the ethyl methylamidothiazolecarboxylate employed.

Ethyl methylazimidothiazolecarboxylate, $C_{14}H_{17}O_4N_3S_2$, is gradually deposited in orange-red needles when the diazo-compound is boiled with alcohol or heated for a long time with almost any neutral solvent. It separates from alcohol and glacial acetic acid in crystals, melts at 224—225°, and is moderately easily soluble in benzene and light petroleum, but more sparingly in ether; it dissolves freely in mineral acids, but it is only very sparingly soluble in, and is decomposed by, alkalis. On reduction with zinc-dust and hydrochloric acid, it is converted into ethyl methylamidothiazolecarboxylate, and on hydrolysis with alcoholic potash it is converted into the corresponding acid, $C_{10}H_8O_4N_3S_2$, which crystallises in slender, yellowish-red needles, melts at 214° with decomposition, and is almost insoluble in all ordinary neutral solvents.

Methylchlorothiazolecarboxylic acid, $C_6H_4O_2NSCl$, is obtained when the ethyl salt described above is hydrolysed with cold alcoholic potash, but the product is always mixed with some methylhydroxythiazolecarboxylic acid, from which it can only be imperfectly separated by fractional crystallisation. It seems to melt at about 144—148°, and is very readily soluble in all organic solvents, but only moderately easily in hot water. The silver salt, $C_6H_3O_2NSClAg$, crystallises in colourless needles.

The bromo-acid, $C_6H_4O_2NSBr$, and the iodo-acid, $C_6H_4O_2NSI$, were also obtained in an impure condition; the former seems to melt at about 162—164°, the latter at about 174—176°, with decomposition.

Methylhydroxythiazolecarboxylic acid, $C_6H_5O_4NS$, is formed when methylchlorothiazolecarboxylic acid is heated at 170°, but it is best prepared by fusing the ethyl salt of the chlorinated acid with concentrated potash. It crystallises from alcohol in small needles, melts at 222° with decomposition, and is moderately easily soluble in alcohol and hot water, but only sparingly in ether, and almost insoluble in benzene and light petroleum. The ammonium salt, $C_6H_5O_4N_2S$, crystallises from water in large prisms with 3 mols. H_2O , and melts at 138° with liberation of carbonic anhydride, being transformed into methylhydroxythiazole (m. p. 102°); this hydroxy-compound is also obtained when the acid is carefully heated.

Ethyl methylthiazolecarboxylate, $C_7H_7O_2NS$, can be easily prepared by treating the chlorinated derivative with zinc-dust and acetic acid at a temperature below 50°. It crystallises in transparent prisms, melts at 27—28°, boils at 232—233° (726 mm., thermometer entirely in vapour), is volatile with steam, and is very readily soluble in all ordinary solvents except water. The corresponding acid, $C_6H_5O_4NS$, prepared by hydrolysing the ethyl salt with alcoholic potash, crystallises from hot water in nacreous plates, and from alcohol in small

needles, melts at 257° with decomposition, and is almost insoluble in benzene and light petroleum; most of the salts of the heavy metals are insoluble. F. S. K.

Synthesis of a Diamidocarbazole from Benzidine. By E. TAUBER (*Ber.*, 23, 3266—3269).—*Diamidocarbazole sulphate*, $C_{12}H_{11}N_3H_2SO_4$, can be obtained by heating metadiamidobenzidine hydrochloride (compare Abstr., 1890, 782) with 18 per cent. hydrochloric acid (6 parts) for 10 hours at 180 — 190° , and treating the filtered solution of the product with excess of hot dilute sulphuric acid; it crystallises in colourless needles and is almost insoluble in boiling water. The base, $C_{12}H_{11}N_3$, crystallises from hot alcohol in flat, lustrous needles, and turns black at 200° , but without melting; it is not identical with the diamidocarbazole obtained by nitrating carbazole and reducing the product (compare D. R.-P., No. 46438). The hydrochloride is moderately easily soluble in water but is precipitated from the solution in crystals on the addition of hydrochloric acid. The tetrazo derivatives of the base dye unmordanted cotton very readily, the shades being the same as those obtained with the corresponding benzidine dyes. F. S. K.

Tritopine and other Rare Opium Bases. By E. KAUDER (*Arch. Pharm.*, 228, 419—431).—The rarer alkaloids were sought for in large quantities of the mother liquor, obtained in the preparation of morphine, &c., on a manufacturing scale. The results largely confirm and extend those previously obtained by Hesse. After removing the relatively large quantities of morphine, codeine, narceine, thebaine, papaverine, and narcotine still present in the mother liquor, a considerable amount of cryptopine was the first product. The mother liquor, diluted with water, warmed to 60° , and poured into water containing excess of sodium hydroxide, gave a dark, resinous precipitate. The filtrate, further treated with hydrochloric acid, ammonia, &c., gave only narcotine and laudanine. Lanthopine and codamine were not detected. Laudanine, whilst soluble in sodium hydroxide, can also be methylated, so that it ranges with morphine. The methyl ether of laudanine, melting at 113° , is not identical with laudausine. The dark, resinous precipitate above described was dissolved in a little alcohol, treated with ether until precipitation ceased, the ether filtered off, and treated with acetic acid water. Excess of potassium iodide added to this solution precipitates almost the whole of the alkaloids, with much resin. After 24 hours, the mother liquor was poured off, the residue mixed with a little alcohol and set aside for several days. Large quantities of iodides thus crystallised out, which were pressed and washed with a little alcohol. No more crystals could be obtained from the tenacious mother liquor containing most of the resin. The iodides were converted into the free bases, and these dissolved in hydrochloric acid and concentrated. After the addition of an equal volume of alcohol and then alcoholic ammonia, crystals of protopine, and a new base, tritopine, separated. The filtrate from these was treated with much ether, the ether agitated with oxalic acid water, the aqueous solution concentrated and treated with more oxalic acid.

After 24 hours, a few hard crystals of protopine and cryptopine binoxalate had formed. Further treatment of the mother liquor with potassium iodide, &c., separated small quantities of cryptopine, protopine, and tritopine, whilst still further concentration yielded laudanose, easily purified by crystallising from light petroleum. *Tritopine*, $C_{28}H_{44}N_2O_7$, melts at 182° . It is easily soluble in chloroform, slightly in ether; 1 part dissolves in 40 parts of boiling alcohol, from which it crystallises in transparent prisms. Several salts of this base are described. The relative amounts of the bases found were approximately, laudanose, 1; tritopine, 2; protopine, 3.5; laudanine, 20; cryptopine, 70. J. T.

Atropamine. By O. HESSE (*Chem. Centr.*, 1890, ii, 446—447; from *Pharm. Zeit.*, 35, 471).—The author has separated an alkaloid from the roots of *Atropa belladonna*, which he has named *atropamine*. At ordinary temperatures, it is solid, but is quite liquid at 60° . It is precipitated from solutions of its salts by potash or soda as an oil; it is readily soluble in alcohol, ether, and chloroform. It has the formula $C_{17}H_{21}NO_2$; it contains 1 mol. H_2O less than atropine, hyoscyamine, and hyoscyne, and is isomeric with belladonnine. It forms haloid salts, which crystallise very beautifully; this distinguishes it from belladonnine and other atropa alkaloids.

It is optically inactive. A 2 per cent. solution of the hydrochloride has, according to Berlin, no mydriatic action. Protracted boiling with alcoholic solution of barium hydroxide causes a decomposition with formation of tropine and an acid which is neither tropic, atropic, nor isatropic acid. By the action of hydrochloric acid, atropamine is converted into belladonnine, and is then further transformed as by heating with alcoholic barium hydroxide. Atropamine is very readily decomposed by acids, and hence it has been overlooked in the past. The acid above referred to, the nature of which has not been determined, sometimes causes a smell of bitter almond oil if mixed with potassium permanganate, a reaction which is not produced with atropamine. J. W. L.

Root Constituents of *Scopolia atropoides*. By E. SCHMIDT (*Arch. Pharm.*, 228, 435—441). A new investigation, in which the bases were precipitated as aurochlorides, yielded hyoscyamine, but only a very small amount of atropine, and a minute quantity of aurochloride, which agreed as to its melting point, 198 — 199° , and analysis with the hyoscyne compound. Scopoletin has been proved to be identical with methylæsculetin by Takahashi (*Abstr.*, 1889, 255). F. Schmidt has found by the application of Zeisel's method (heating with hydriodic acid, &c.) that scopoletin contains only one methoxyl group. The æsculetin produced by this reaction was isolated and analysed. The methylæsculetin of Tie-mann and Will melts at 184° , whilst scopoletin melts at 199 — 200° , so that one is probably the α - and the other the β -methylæsculetin; but which is which has not been determined. J. T.

Alkaloids of *Chelidonium majus*. By F. SELLE (*Arch. Pharm.*, 228, 441—462).—Besides the two alkaloids chelidonine and chelerythrine, E. Schmidt found strong evidence of the presence of α -homochelidonine, β -homochelidonine, and a third base seemingly identical with *protopine*, an alkaloid obtained by Hesse from opium. The author has separated and investigated these three new bases. The following general method is used to extract the bases from the root of the plant. The dried and pulverised material is repeatedly extracted with alcohol containing acetic acid; after filtration and dilution with water, the alcohol is distilled off and the resin separated is removed by another filtration. The filtrate is treated with ammonia and shaken up with chloroform; the chloroform solution on evaporation leaves a residue which is dissolved in the least possible amount of alcohol containing hydrochloric acid. After cooling, the alcoholic solution is separated by filtration from the undissolved and crystalline portion, consisting of chelidonine and protopine hydrochlorides. The alcoholic solution is diluted with water, freed from alcohol, strongly diluted with hydrochloric acid water, filtered, and treated with ammonia in excess. The filtrate contains β -homochelidonine, which may be extracted by shaking up with alcohol. The precipitate contains α -homochelidonine and chelerythrine; the latter can be obtained by long digestion with ether.

β -Homochelidonine, $C_{18}H_{15}(OMe)_2NO$, appears as well formed, colourless, seemingly monoclinic crystals, which melt at 159° . A solution (1 : 100) gives a white precipitate with mercury chloride, phosphotungstic acid, and potassium cadmium iodide; yellowish-white with potassium mercury iodide and phosphomolybdic acid; yellow with bromine-water; reddish-yellow with potassium bismuthiodide. Concentrated sulphuric acid gives a beautiful violet coloration. Froehde's reagent yields a transient yellow, violet, and green coloration, which becomes a beautiful blue, and finally an intense moss-green. Erdman's reagent gives a yellow, passing quickly to a beautiful violet, which gradually becomes dirty-violet. Concentrated nitric acid produces a yellow colour. Vanadium sulphuric acid gives yellow, violet, and intense blue; after a time this becomes green. The alkaloid is easily soluble in hydrochloric, sulphuric, nitric, and acetic acids. The hydrochloride, platinochloride, and aurochloride are described.

α -Homochelidonine, $C_{18}H_{15}(OMe)_2NO$, forms large, rhombic crystals, when recrystallised from its solution in ethyl acetate, which melt at 182° . Its solution (1 : 100) yields precipitates similar to those given by the β -base, with the addition that tannin gives a white precipitate, soluble in excess. Concentrated sulphuric acid dissolves the base, with the gradual formation of pale-yellow streaks. Concentrated nitric acid gives a yellow coloration. Froehde's reagent produces a dirty brownish-green and then brownish-yellow tint. Erdmann's reagent and vanadium sulphuric acid yield a reddish-yellow coloration. The hydrochloride, platinochloride, and aurochloride are described and analysed.

Protopine (?) was finally obtained in colourless crystals from its solution in a mixture of much chloroform with little ethyl acetate; its melting point is 207° . The amount obtained was insufficient to

admit of a determination of its formula, but $C_{20}H_{17}NO_5$ is indicated, and Zeisel's method does not indicate the presence of methoxyl groups. Its reactions with precipitants are the same as those given for α -homochelidonium. J. T.

Alkaloids of the Rhizome of *Veratrum album*. By G. SALZBERGER (*Arch. Pharm.*, 228, 462—483).—Besides the three crystallisable bases, jervine, rubijervine, and pseudojervine already known, the author has isolated two new ones, *protoveratrine*, an extremely powerful poison, and *protoveratridine*. Two methods of extraction were followed: one, the baryta method, is relatively rapid, and gives jervine, rubijervine, and protoveratridine, but no protoveratrine; the other, the metaphosphoric acid method, yields protoveratrine and pseudojervine, with small amounts of jervine and rubijervine. The yield varies considerably, and the method of drying the rhizome is not without influence on the result. The moderately pulverised rhizome was mixed with barium hydroxide and water, and extracted with ether. The extract was freed from ether at the lowest possible temperature in a gentle current of hydrogen. The dark-green syrup thus obtained gave a crop of crystals mainly consisting of jervine. Recrystallisation from alcohol separated a little protoveratridine, and further treatment by Wright and Luff's process with dilute sulphuric acid yielded a small amount of rubijervine. The mother liquor from the crude jervine by further treatment yielded a little more protoveratridine and rubijervine, and other uncrystallisable and decomposition products. Protoveratrine can be easily extracted from the drug by cold water, but cannot be obtained in a crystalline form by this means. To obtain the crystalline base, the rhizome is freed from fatty and resinous compounds by treatment with ether, and an alcoholic extract of the residue is prepared. This extract is freed from alcohol in a vacuum, mixed with much acetic acid water, quickly filtered from the insoluble residue, and treated with solid metaphosphoric acid, until no further precipitate appears. The voluminous precipitate contains much amorphous matter, besides insoluble compounds of jervine and rubijervine. The filtrate is treated with excess of ammonia, filtered, and shaken up with ether, and from the ether extract the protoveratrine crystallises out when the ether is distilled off. By recrystallisation from strong alcohol, the base is purified and separated from some little remaining rubijervine and jervine. The yield was about 0.3 gram per kilo. The ammoniacal solution, after removal of ether, was further treated with chloroform, when pseudojervine was obtained. Protoveratridine is not obtained by this metaphosphoric acid process, which would indicate this base to be a decomposition product of protoveratrine.

Protoveratrine, $C_{28}H_{41}NO_{11}$, crystallises from dilute solutions in microscopic four-sided plates, which melt with charring at $245-250^\circ$. The base is insoluble in water, benzene, and light petroleum; chloroform and boiling 96 per cent. alcohol dissolve it somewhat; cold ether scarcely touches it, boiling ether takes up a little more. Dilute acids, with the exception of acetic acid, dissolve it. The base is exceedingly poisonous; a minute amount applied to the nose causes violent

sneezing. Concentrated sulphuric acid dissolves the alkaloid slowly with the production of a greenish colour, which passes to cornflower blue, and after some hours becomes violet. With the same acid and sugar, the first formed greenish colour becomes olive-green, then dirty green and finally dark brown; this is very different from the colours yielded by veratrine. When warmed with the strong acid, the solution is first light, then dark cherry-red, and exhales the odour of isobutyric acid. Concentrated hydrochloric and phosphoric acids give the same reaction. Dilute solutions of salts of this base are quantitatively precipitated by ammonia; precipitates are also produced by Nessler's test, gold chloride, potassium mercury iodide, potassium cadmium iodide, phosphotungstic acid, and picric acid, whilst no precipitate is produced by tannin, platinic chloride, or mercuric chloride. The aurochloride, a golden-yellow, amorphous compound, was obtained and analysed.

Protoveratridine, $C_{26}H_{45}NO_8$, occurs as colourless, four-sided plates, which melt at 265° . It is almost insoluble in alcohol, chloroform, methyl alcohol, and acetone, and insoluble in benzene, light petroleum, and ether. It is not poisonous, and does not cause sneezing, but its solution in dilute acids has a very bitter taste. Concentrated sulphuric acid gives first a violet, then a cherry-red colour. Its solution in concentrated hydrochloric acid becomes light-red on warming, as is the case with veratrine, but with a decided odour of isobutyric acid. Dilute acids readily dissolve the base, and the solutions give crystalline precipitates with ammonia. The sulphuric acid solution gives copious precipitates with phosphotungstic, picric, and tannic acids, and with potassium mercury iodide, but gives no precipitate with platinum chloride, potassium cadmium iodide, or with Millon's reagent. *Protoveratridine platinochloride*, $(C_{26}H_{45}NO_8)_2 \cdot H_2PtCl_6 + 6H_2O$, was precipitated as large, six-sided plates on adding alcohol to a mixed solution of platinum chloride and a salt of the base. Pseudojervine has been already described by Wright and Luff; they found its melting point to be 299° ; the author makes it $300''$ to 307° . Jervine, $C_{28}H_{47}NO_8$, melts at 238° to 242° , Wright and Luff found 237° . The hydrochloride, nitrate, platinochloride, and aurochloride are described. Wright and Luff's formula is confirmed, and not the one given by Tobien. Rubijervine, $C_{28}H_{45}NO_8 + H_2O$, melts at 240° to 246° ; Wright and Luff found 236° . Five basic compounds have thus been determined with certainty in white hellebore root. J. T.

Cytisine. By A. PARTHEIL (*Ber.* 23, 3201—3203).—The alkaloid prepared by Husemann and Mariné from the seeds of the laburnum and other kinds of *Cytisus*, to which they gave the name of cytisine, may be readily obtained in the following manner. The coarsely-powdered seeds are extracted with alcohol containing hydrochloric acid, the alcohol distilled off, the residue treated with water, and filtered through a wet filter to remove any fatty oil, the filtrate treated with lead acetate, and after separating the precipitated colouring matter, made alkaline with caustic potash, and shaken with amyl alcohol. The latter solution is then extracted with dilute hydrochloric acid, the solution evaporated, the crude cytisine hydrochloride

thus obtained treated with dilute alcohol to remove colouring matters, and recrystallised several times from water. The salt then forms well-developed, colourless, transparent prisms. Its *platinochloride* crystallises in golden-yellow needles, which have the composition $C_{11}H_{14}N_2O, H_2PtCl_6 + 2\frac{1}{2}H_2O$, are tolerably soluble in water, and decompose on heating without melting. The *aurochloride*, $C_{11}H_{14}N_2O, HAuCl_4$, crystallises in short, reddish-brown, hook-shaped needles, which melt at $212-213^\circ$ (uncorr.) with evolution of gas. From the analyses of these double salts, it follows that cytisine has the composition $C_{11}H_{14}N_2O$, and not $C_{20}H_{27}N_3O$ as given by Husemann and Marmé. The same formula has already been given by Gerrard to ulexine, obtained from the seeds of *Ulex europæus* (Abstr., 1886, 1048), which, as Koberth has already suggested, on physiological grounds (*Deutsch. Med. Wochenschr.*, 1890, 406) may be identical with cytisine. Both compounds are being at present further investigated.

H. G. C.

Products of the Artificial Digestion of Glue. By F. KLUG (*Chem. Centr.*, 1890, ii, 318-319; from *Centr. Physiol.*, 4, 189-191).—Glue, obtained from the refining of fine French gelatin, is precipitated from its solution by picric acid, chromic acid, tannin, platinic chloride, mercuric chloride and iodide, potassium iodide, and hydrochloric acid. These precipitates dissolve in hot water, and are reprecipitated on cooling. Alcohol, phosphotungstic acid, and hydrochloric acid, basic lead acetate, and ammonium sulphate also precipitate it, the precipitates being, however, insoluble in hot water. With sodium hydroxide and copper sulphate, its solution is coloured violet-blue. Acetic acid and potassium ferrocyanide cause no precipitation. Millon's reagent causes a flocculent precipitate, soluble in the hot liquid; if the solution be boiled, it is coloured red. Nitric acid and sodium hydroxide colour hot glue solutions slightly yellow; copper sulphate causes a blue coloration. Glue, therefore, may be distinguished from egg albumin by the precipitate obtained with picric acid dissolving on heating and by the biuret reaction, whereas with nitric acid neither precipitation nor yellow coloration ensues. It is to be noted, however, that concentrated solutions of sodium chloride, ammonium sulphate, and gallic acid form precipitates with picric acid which dissolve in warm liquids. By artificial digestion, glue becomes converted into three substances, *glucose* and *glutinopeptone*, which dissolve, and *apoglutin*, which remains in the liquid as a flocculent re-*s*idue, to the amount of 5.69 per cent.

Apoglutin dissolves completely in sulphuric acid, but only imperfectly in the other mineral acids and in acetic acid. When boiled with nitric acid, it becomes coloured yellow; sodium hydroxide and copper sulphate colour it violet; boiled with Millon's reagent, it is coloured red; it is not digested by pancreatic juice.

Glucose is precipitated from the solution of digested glue by the addition of ammonium sulphate or alcohol, and it may be precipitated, after re-solution in water, by addition of sodium chloride, and then acetic acid and concentrated solution of sodium chloride. That part which is precipitated by salt has been named by the author *protoglucose*; the remaining portion, which is separated on the addition of acetic acid

and sodium chloride, he names *deutero-glucose*. Glucose, precipitated by 95 per cent. alcohol, separates as a sticky, white mass. It is also precipitated by picric and chromic acids, phosphotungstic acid and hydrochloric acid, mercuric iodide, potassium iodide and hydrochloric acid, platinic chloride, and mercuric chloride; all these precipitates, that by phosphotungstic acid excepted, are dissolved on warming the solutions, and are again precipitated on cooling. When boiled with nitric acid, it is neither precipitated nor coloured yellow; but if sodium hydroxide is added, the solution becomes yellow. Sodium hydroxide and dilute copper sulphate colour the solution violet-red; copper sulphate alone colours it blue.

Glutino-peptone is also obtained by the digestion of glucose, and may be precipitated by means of a mixture of alcohol and ether. When dried on the water-bath and in the desiccator, it appears as a yellow, brittle mass, very readily soluble in water, which distinguishes it readily from glucose. Picric acid causes a precipitate only with concentrated solutions, which redissolves in an excess of the reagent, and also by heating; chromic acid and platinic chloride cause no precipitation; sodium hydroxide and highly dilute copper sulphate solution cause a rose-red coloration; copper sulphate alone, a green coloration; Millon's reagent causes a milkiness, which redissolves on boiling. It becomes precipitated by saturating the solution with either sodium chloride or ammonium sulphate. The following are the elementary analyses of glue, apoglutin, and glucose.

	C.	H.	N.	O and S.	Ash.
Glue.	42.75	7.00	15.61	34.64	0.88
Apoglutin ...	48.39	7.50	14.02	30.09	5.22
Glucose	40.06	7.02	15.86	37.06	2.14

Physiological Chemistry.

Proteid Absorption. By R. NEUMISTER (*Zeit. Biol.*, 27, 309—373).—Many observers have found that a proteid may be absorbed without previous conversion into peptone; for instance, in the case of nutrient cnemata. It also appears that a first stage in the action of the digestive juices is simply to dissolve the proteid; changes of the nature of hydration then follow. Hasebroek (*Abstr.*, 1887, 609) showed that this was the case with fibrin. It is equally true for coagulated white of egg, although whether the dissolved albumin is the same as the original albumin is uncertain; it is certainly not a globulin; serum albumin, vitellin, and other proteids are also similarly simply dissolved, in the first instance, by the gastric and pancreatic secretions. Casein and hæmoglobin are exceptions to this rule. Casein is first converted into an insoluble curd by the rennin of the stomach, and hæmoglobin is decomposed into hæmatin and a proteid residue.

When various proteids are introduced directly into the blood stream, there are differences again noticeable. Casein and hæmo-

globin solutions act like foreign substances, and are excreted by the kidneys. Egg albumin is similarly got rid of; but in case of blood transfusion, there is no albuminuria; the same is true for the injection of serum, or of solutions of pure serum albumin, of syntonin (prepared either from white of egg or myosin), and of crystalline phyto-vitellin. These proteids, among which are to be noted several which are not normal constituents of the blood, are thus directly assimilable, without having undergone peptonisation.

In fact, it is well known that albumoses and peptones introduced into the circulation are not assimilable, but, like other foreign substances, are excreted by the kidneys (compare Abstr., 1888, 516). Dextrose is similarly got rid of, if its percentage in the blood is higher than normal; the question thus arises, whether peptone should be considered as on all fours with dextrose in this respect. That it cannot be, but that it is an absolutely foreign substance is shown by the fact that practically it all appears in the urine, and that in normal blood no peptone or peptone-like substance is present. The word peptone may here be conveniently employed to include the albumoses, for all these products of proteolysis are in this respect the same (including hetero-albumose and atmidalbumin, concerning which experiments are now, for the first time, given).

Peptone thus disappears rapidly from the blood after injection; this occurs also when none can escape from the kidneys, either by ligaturing the ureters, or by injecting such a large amount that the lowering of blood pressure so produced stops urinary secretion. Under these circumstances, it is discharged into the intestinal canal.

Peptone is therefore a form of proteid not assimilable by living cells. Previous experimenters have attempted to answer the question where the peptone formed in the alimentary canal is reconverted into normal proteids. Salvioli could find none in the blood circulating in the stomach walls, although the stomach was full of peptone. Hofmeister corroborated this; and in the present research a number of observations, in which an artificial circulation was kept up, led to the same conclusion that some element, either in the interior of the alimentary canal or in the wall of the same, effects the disappearance of peptone; no other tissue produces this change. The general outcome of these experiments is as follows; without doubting the existence of micro-organisms which cause the disappearance of peptone (*M. restituens* of J. Brinck, Abstr., 1889, 632; compare also N. Popoff, Abstr., 1889, 632), it is probable that the regeneration of albumin from peptone occurs not before, but concomitantly with, absorption. The methods of Brinck and Popoff were not carefully conducted from a chemical standpoint; no doubt their peptone was mixed with albumin; they put this mixture into the stomach, and withdrew it after half-an-hour; by that time the peptone had been absorbed, and the fluid, *minus* its peptone, was now able to keep the frog's heart beating; whereas, their conclusion was that the peptone had been converted into serum albumin. The question then arises, do the lymphoid cells or the epithelium cells of the stomach and intestinal walls produce this effect? The fact that the white blood corpuscles are not able to effect the change when peptone is injected

into the blood stream is considered sufficient to refute the conclusion arrived at by others that the lymph cells are the active agents; in fact, most physiologists are now pretty well agreed that it is the epithelial elements with which, in this connection, we have to reckon, and their dehydrating action on the peptones is comparable to that of the liver cells in converting sugar into glycogen.

The question whether the liver cells have any action on peptone is an interesting one. In most animals, artificial circulation of fluid containing peptone through the recently-removed and still-living organ led to a negative result; but in the case of the rabbit, the liver cells were found to possess the power seemingly limited in other animals to the columnar cells of the wall of the alimentary canal. It cannot be, however, supposed that weighty conclusions can be drawn from an exceptional case; and even in the rabbit, the liver cells cannot normally fulfil this function, since the portal vein is always free from peptone, as in other animals. Such observations are also of importance in view of Seegen's remarkable conclusion that the formation of sugar in the liver occurs, not at the expense of the hepatic glycogen, but of the peptone brought to the liver by the portal vein (Abstr., 1888, 172). Much of the present paper is devoted to an examination of Seegen's work, and the general nature of the criticisms, and of the experiments performed to negative his assertions, will be gathered from what has preceded this.

Throughout this paper, great care is taken to point out the methods to be adopted in the separation of peptones and albumoses from one another, and from other proteids, and the fallacious results obtained before the time of the introduction of ammonium sulphate as a reagent for this purpose. Among the points taken up, it is shown that a so-called peptone described as existing in eggs (W. Fischel, Abstr., 1886, 166) is not a true peptone. The name *pseudopeptone* is suggested for it.

W. D. H.

Cystin in Pancreatic Digestion. By E. KÜLZ (*Zeit. Biol.*, 27, 415—417).—The question, as to what becomes of the sulphur of proteids during digestion has never been completely answered. In the present examination of the products of an artificial pancreatic digestion, no hydrogen sulphide was evolved. The insoluble products were removed by filtration, and the filtrate concentrated; during this process, a precipitate formed, but after removal this was not found to contain cystin. The final filtrate, after a time, deposited a white precipitate insoluble in water, but soluble in ammonia. The ammoniacal solution was diluted with large quantities of water, and six-sided crystals separated, which, after purification by recrystallisation, gave all the reactions of cystin. Whether this is always the case, or if bacteria are concerned in the process, are questions that have still to be settled.

W. D. H.

The so-called Liver of *Helix pomatia*. By M. LEVY (*Zeit. Biol.*, 27, 398—414).—The chief intestinal gland of the snail *Helix pomatia* is a digestive gland, but is not analogous to any of the abdominal glands of the higher animals. The weight of its organic

constituents is very constant, being the same in summer and winter, and in great measure they are the same in kind in all periods of the year. The alcoholic extract of the gland shows the chlorophyll spectrum (MacMunn's enterochlorophyll). The digestive ferments present are a diastatic, a peptic, but not a tryptic one. The peptic ferment appears to be identical with Krukenberg's helicopepsin. The diastatic ferment disappears during the winter sleep; it is capable of digesting raw starch, but has no effect on cellulose. A fat emulsifying action is shown by the secretion in the summer time, but this also disappears during hibernation.

The ferment by means of which this action is brought about is not identical with the one described by Schmiedeberg (*Arch. exper. Path. Pharm.*, 14) as histozyme. Histozyme, which was separated from pigs' kidneys, is concerned in the splitting up of hippuric acid. The snail's ferment has no such action.

Glycogen with sinistrin is generally present in the organ, but all tests for bile gave a negative result. Jecorin was also absent.

A list of the substances separable from the organ is as follows:—

(1.) In the alcoholic extract: Chlorophyll, lecithin, oleic acid, fatty acids, ash, chlorine, and phosphoric and sulphuric acids.

(2.) In the ethereal extract: A trace of fat.

(3.) In the aqueous extract: Sugar, globulin (coagulating at 66°), glycogen, sinistrin, hypoxanthine, and other bases precipitable by phosphotungstic acid; in the ash, potassium, sodium, calcium, magnesium, iron (traces), manganese, chlorine, and phosphoric and sulphuric acids. In winter animals, silica was found in addition.

W. D. II.

Organic Basis of Various Shells. By W. ENGEL (*Zeit. Biol.*, 27, 374—385).—Numerous previous researches have been directed to the determination of the inorganic constituents of egg shells, but those relating to their organic constituents are scanty.

The shells of a number of snakes, which were preserved for microscopic purposes in Kleinenberg's solution, were freed from picric acid by prolonged washing with water, alcohol, and ammonia. Elementary analysis of their organic substratum gave the following percentage results:—C, 54.68; N, 16.37; H, 7.24; O, 21.1. These coincide very well with the percentage composition of elastin, as worked out by previous investigators. The reactions of this substance are, moreover, identical with those of elastin; some slight differences in solubility, especially in alkalis, are not considered sufficient to negative the general conclusion that the material in question is elastin, since elastin prepared from various sources itself exhibits similar differences in solubility.

The cover of the incubating cells of wasps was next investigated; and although the quantity of material available was not sufficient for elementary analysis, the colour tests and solubilities of the substance are so like those of fibroin, with which it was carefully compared, that the conclusion is drawn that the material in question is fibroin.

Lastly the egg shells of the *Aplysia* were examined; their organic constituent appeared to be allied to keratin by its reactions, and in

elementary analysis it was found to be intermediate between conchiolin and elastin. The general conclusion drawn is that the substance in question is one of the keratins.

W. D. H.

Action of Yeast on the Animal and Human Organism. By J. NEUMAYER (*Chem. Centr.*, 1890, ii, 247—248; from *Inaug. Diss. München. Hygien. Inst.*).—The author finds that the various yeasts pass through the alimentary canal without suffering any change, and are not acted on by the gastric juice, and that they may be eaten without any harm to the animal, provided that all fermentable substances are absent, otherwise inflammation of the stomach ensues. This injurious action is not due to the yeasts, or the principal products of their fermentive action, but to abnormal fermentation products formed at the high temperature of the body; if the fermentation proceeds at low temperatures, these injurious products are not formed at all, or only in insignificant amount. Subcutaneous injection of the yeasts causes their destruction, without, however, producing any ill effects on the animal.

J. W. L.

Chemistry of Vegetable Physiology and Agriculture.

The Antiseptic Properties of Sodium Fluoride. By O. HEWELKE (*Chem. Centr.*, 1890, ii, 248; from *Deut. Med. Wiss.*, 16, 477—478).—The author experimented with alkaline sodium fluoride on the ferment, and the alkaline fermentation of urine. *Torula cerevisie* did not grow in the presence of 1 part of sodium fluoride in 100 to 300 parts of urine; in presence of 1 : 600 to 3000 the fermentation was distinctly checked, and this was noticeable, although in a minor degree, when the proportion of sodium fluoride was reduced to 1 : 4000. In the case of urine without any sodium fluoride, the fermentation commenced at the end of 3 to 5 days; the addition of 1 part to 2000 of urine prevented fermentation until the 14th—15th day; 1 : 600 till the 60th day; 1 : 100 over a month. Blood, with the addition of 1 part of sodium fluoride to 80—160, remained good for a long period, and a disagreeable odour was first developed at the end of several weeks.

In nutrient substances containing 1 of sodium fluoride : 150 to 200, neither pathogenic nor non-pathogenic organisms developed, and even when the proportion of the salt was reduced to 1 : 600, evidences of a checked growth were observable. Some organisms proved more susceptible than others, for instance 1 : 300 prevented the growth of *Bacillus anthracis*. In general, the pathogenic organisms proved the most susceptible.

J. W. L.

Catalytic Reduction of the Sulphonic Group. By O. LOEW (*Ber.*, 23, 3125—3126).—As, in all probability, the sulphur in albuminoids is not present in the form of a sulphonic group, it must be assumed that hydrogen sulphide is formed from sulphates in the

vegetable organism, and that at the moment of its formation it is further converted into an organic compound, that is to say, it takes part in the production of albuminoids.

The most plausible explanation of this phenomenon is, that the intense atomic vibrations in the active albumin are communicated to the sulphates and to the dissolved organic matter, causing them to act on one another in such a way that the oxygen of the sulphuric acid acts on the organic matter, the hydrogen of the latter combining with the sulphur; in other words, it may be supposed that oxidation and reduction take place simultaneously under the influence of a catalytic action.

Experiments which were made with various sulphates in presence of platinum black did not give the expected results; sodium hydroxymethylenesulphonate (formaldehyde sodium hydrogen sulphite), on the other hand, is reduced moderately easily. On warming a solution of this organic salt (5 grams) and crystalline sodium carbonate (10 grams) in water (100 grams) with platinum black (16 grams), in a flask which is almost completely filled with the solution, an odour of leeks is observed after some hours, and the solution then gives the nitroprusside reaction for sulphides; on acidifying with acetic acid, hydrogen sulphide is evolved, showing that sodium sulphide has been formed by reduction, whilst a corresponding quantity of the sodium hydroxymethylenesulphonate must have undergone oxidation. When the quantity of the organic sodium salt and platinum black is increased, the solution gives off an odour very like that of decomposing albuminoids, probably owing to the formation of methyl mercaptan; if platinum black is not added to the solution, reduction does not take place. The above reaction is not due to nascent hydrogen, as this gas is not evolved when a dilute solution of formaldehyde is warmed with platinum black and sodium carbonate.

F. S. K.

Chemical Composition of Vegetable Cell Membranes. By E. SCHULZE (*Ber.*, 23, 3175; compare Abstr., 1890, 1456).—The author explains that he did not mean it to be inferred that cellulose is the only constituent of the cell envelope which is insoluble in dilute acids.

J. B. T.

Crystalline Constituents of the Seeds of *Cataputia minoris*. By Y. TAHARA (*Ber.*, 23, 3347—3351).—The seeds are carefully freed from oil, extracted repeatedly with alcohol, the alcohol evaporated, the residue washed with ether, and boiled with alcohol; on cooling the solution, brown crystals of ausculetol are deposited, which may be purified by treatment with lead acetate.

If the oil is allowed to remain for some time in a closed flask, a substance separates which crystallises from alcohol in colourless, odourless prisms melting at 193°; it is insoluble in water, alkalis, or acids, and has not yet been further investigated.

J. B. T.

Kesso Oil. By J. BERTRAM and E. GILDEMEISTER (*Arch. Pharm.*, 228, 483—492).—Kesso is the Japanese name for *Valeriana officinalis*

var. angustifolia; the oil obtained by distilling the root of this plant with steam has a sp. gr. of 0.996, whilst the sp. gr. of oil of valerian is 0.945.

A large quantity of kesso oil was divided into three portions by distillation with steam. The first portion was fractionated into six portions. 1. Up to 155°, contained much acetic and valeric acids, but no formic acid. Probably some valeraldehyde was present, judging by the odour. 2. That boiling between 155° and 160° was relatively small in amount, and consisted of lævopinene, the rotation in Wild's apparatus, with a column 100 mm. long, being 53° 5' to the left. 3. That boiling between 160° and 170° is not given. 4. That boiling between 170° and 180° consisted of dipentene, as shown by the formation of its hydrochloride and hydrobromide. 5. That boiling between 180° and 200° is not given. 6. That boiling between 200° and 220° contained terpinol, $C_{10}H_{17}\cdot OH$. On shaking it up with a strong aqueous hydriodic acid solution, the compound $C_{10}H_{16}\cdot 2HI$ was obtained, which melted at 76°. This fraction also contained borneol.

The second portion, boiling between 220° and 290°, yielded a fraction below 260°, composed of borneol with acetic and isovaleric acids. The fraction boiling between 260° and 280° was a clear liquid, consisting, apparently, of sesquiterpene.

The third portion of the distillate was heavier than water, and boiled about 300°. This was saponified, and yielded acetic acid, a bluish oil, whose composition has not yet been made out, and *kessyl alcohol*, $C_{14}H_{24}O_2$. This alcohol is odourless, insoluble in water, easily soluble in alcohol, ether, chloroform, benzene, and light petroleum. It melts at 85°, and boils under a pressure of 11 mm. between 155° and 156°, and at the ordinary pressure at 300—302° without decomposition. A 10 per cent. solution in alcohol has a rotatory power of 3° 39' to the left in a column 100 mm. long. It readily forms well-shaped, rhombic crystals from its solution in alcohol or ether [$a : b : c = 0.9936 : 1 : 0.4369$]. *Kessyl alcohol* alone, or dissolved in dry ether, in contact with acetic chloride or phosphorus pentachloride, develops heat, evolves hydrogen chloride, and produces a splendid, dark, cherry-red solution. *Kessyl acetate*, $C_{14}H_{22}O_2\cdot Ac$, was obtained by heating the alcohol with acetic anhydride and some anhydrous sodium acetate. It can also be obtained by fractional distillation of the kesso oil, but is impure when thus produced. The pure acetate is a thick, colourless oil, of very faint odour, which does not solidify at -20°. It is insoluble in water, easily soluble in ether, alcohol, chloroform, and light petroleum. Its is lœvorotatory to the extent of 70° 6' in a column 100 mm. long. Oxidation products of *kessyl alcohol* have not yet been fully investigated. J. T.

Poisonous Action of Hydrazine. By O. LOEW (*Ber.*, 23, 3203—3206).—Hydrazine exerts an extremely poisonous action on organisms of the most varying description. In a solution containing, in addition to food substances, 0.2 gram of hydrazine sulphate per litre, the shoots of the helianthus and of barley were rapidly killed. Algae, fission organisms, moulds, *Schizomycetes*, and lower water organisms were also rapidly destroyed by its dilute solution. A dose

of 0.1 gram of hydrazine sulphate neutralised with sodium carbonate, and administered subcutaneously to a guinea-pig, caused death in $2\frac{1}{2}$ hours, and a dose of 0.5 gram, administered to a puppy in a similar manner, brought about the same result in $2\frac{1}{2}$ hours. H. G. C.

Composition of Sorghum Seed. By H. W. WILBY (*Biol. Centr.*, 1890, 678—680).—The following is the mean percentage composition of 24 samples sorghum seed, hulled and unhulled:—

	Unhulled.	Hulled.
Moisture	9.93	9.63
Albuminoids.....	10.54	11.39
Light petroleum extractive	3.72	3.16
Ether extractive	0.61	0.54
Absolute alcohol extractive	2.44	1.46
80 per cent. alcohol extractive ..	2.91	1.78
Fibre	3.17	1.83
Ash	2.05	1.69
Carbohydrates	64.62	68.86

This seed, compared with wheat, maize, and oats, appears to be equal in feeding value to maize and oats, and only rather poorer than wheat.

The seed hulls contain a colouring matter which, however, is not harmful to cattle, nor does it contain any tannin. E. W. P.

Analytical Chemistry.

Gas Apparatus, &c. By W. E. ADENEY (*Chem. News*, 62, 196—199; 204—206).—In this apparatus, the pressure and measuring tubes are placed some little distance apart, the latter only being surrounded by a water-jacket; they are connected at their lower extremities (which are bent at right angles for the purpose, the measuring tube being likewise narrowed) by wired india-rubber tubing and a glycerol joint. The pressure tube is furnished near the bend with a side tube connecting with the mercury reservoir, and terminates at the top with a Friedrich's patent glass stop-cock, so that it can be used either open or closed; it is 1000 mm. high. The measuring tube, 640 mm. long, is wide for about two-thirds of its length, but is narrower at the upper portion, to which a Friedrich stop-cock is attached, and this is connected with two capillary, double right-angled tubes, one of wider bore, for the admission of the gas to be examined, or other object; the second and narrower one passing to the laboratory vessel, which is furnished at the top with a cup, into which the tube fits, and is rendered air-tight by an india-rubber collar. The laboratory vessel, which may be of any convenient capacity, is provided with platinum wires for explosions, and, moreover, terminates below in a narrow cylindrical portion, which may be used

open, or be closed with a cork, and to which is attached a side tube, connecting with an independent mercury reservoir to facilitate filling with mercury, transferences, &c. A suitably bent tube, with india-rubber attachment, is fitted to the cork, and serves for the admission of reagents. Behind the whole length of the pressure tube a long, narrow mirror, graduated in millimetres on an unsilvered portion, is fixed at such an angle as to reflect a good image of the mercury column and meniscus. The whole apparatus is mounted on a wooden support, with necessary clamps, attachments, &c.; the mercury reservoirs being placed behind. The apparatus serves for all kinds of gas measurements, as an air-pump, and for distillations under reduced pressure or in a vacuum.

D. A. L.

Lacmoid. By O. FORSTER (*Zeit. ang. Chem.*, 1890, 163—167).—Commercial lacmoid is of very variable character. Some specimens are almost wholly insoluble in water, and are unsuitable as indicators. Others colour boiling water intensely blue, and are fit for use. To prepare the pure blue indicator, the finely-powdered crude material is extracted with boiling water, but stopping short of complete exhaustion, so as to avoid dissolving a sparingly soluble red substance. From the cooled and filtered blue solution, the colour is precipitated by feebly acidifying, and after some hours is collected on a filter and washed with cold water, then dried at a low temperature (since some decomposition takes place if it be dried at 100°), or dissolved in alcohol, and the solution evaporated on the water-bath. Purified in this way, it gives, with pure distilled water, a blue solution, having a slight tendency to violet, and exceeds all other indicators in sharpness. In water containing carbonic acid or an ammonium salt, it gives an exceedingly sharp change with a quantity of alkali, which has scarcely any effect on litmus. To prepare blue lacmoid paper, sulphuric acid is added to an alcoholic solution of lacmoid, until white paper dipped into the liquid is coloured red. This will become blue on drying. The depth of blue should be that of the forget-me-not. For red paper, the paper should be dipped in very dilute sulphuric acid and dried before staining. It must be preserved in well stoppered bottles, and is an extremely sensitive indicator for alkalis.

A somewhat more ready mode of purification is as follows:—8 parts of finely-powdered crude lacmoid is gently warmed for a quarter of an hour with 100 parts of 20 per cent. alcohol, and the liquid filtered after cooling. After ascertaining the amount of matter in solution by evaporating a portion, there should be added an alcoholic solution of 14 parts of malachite green to 86 parts of the lacmoid. This addition does not impair the indication with acids, whilst it increases enormously the sharpness of the change to blue with an alkali. The liquid is filtered from a precipitate which forms, and is then mixed with an equal volume of absolute alcohol. It should be kept in black bottles.

M. J. S.

Estimation of Free Hydrochloric Acid in Stannous Chloride Solutions. By W. MINOR (*Zeit. ang. Chem.*, 1890,

25—26).—Precipitation as silver chloride cannot be resorted to in consequence of the co-precipitation of tin compounds. A measured quantity (100 c.c.) of the solution is, therefore, saturated hot with hydrogen sulphide, and filtered into a litre flask. Half of the filtrate is boiled to expel hydrogen sulphide, and the total acid then titrated with standard alkali. The amount of tin is now ascertained by titration with iodine, and the corresponding quantity of hydrochloric acid deducted from the total. M. J. S.

Detection of Hypochlorous Acid in Chlorine Water. By T. SALZER (*Chem. Centr.*, 1890, ii, 472; from *Pharm. Zeit.*, 35, 457).—The author recommends the method of Lunge and Næff, devised for the determination of hypochlorous acid in the presence of chlorine, which depends on the fact that chlorine reacts with potassium iodide and hydrochloric acid, forming potassium chloride, iodine, and hydrochloric acid, whereas hypochlorous acid produces, under the same circumstances, no hydrochloric acid. If, therefore, the solution is first titrated with decinormal alkali and then with thiosulphate solution, the amount of the chlorine and hypochlorous acid may be calculated. Of neutral chlorine water, the author recommends 25 c.c. should be acidified with 10 c.c. of decinormal hydrochloric acid, 1 gram of potassium iodide added, and titrated with thiosulphate. Pure chlorine water should require exactly 10 c.c. of decinormal hydrochloric acid. Chlorine water, containing acid, is not to be recommended as an eye-wash. J. W. L.

Detection of Traces of Iodine in the Presence of much Chlorine. By A. JOHNSTONE (*Chem. News*, 62, 153, 169).—The solution to be tested is treated with a saturated solution of silver nitrate in strong ammonia; a yellow precipitate indicates the presence of an iodide. To confirm this, add concentrated sulphuric acid, and agitate with carbon bisulphide; the latter becomes coloured by any liberated iodine. D. A. L.

Separation and Estimation of Tellurium. By E. DONATI (*Zeit. ang. Chem.*, 1890, 214—217).—Precipitation by sulphurous acid is complete but tedious. Kastner's grape-sugar method (*Abstr.*, 1876, 440) is accurate and expeditious. Precipitation by stannous chloride or an alkaline stannite is not suitable, since the precipitate always contains tin. Tellurium is very rapidly precipitated from acid solutions by hyposulphurous acid. The yellow solution obtained by shaking scrap zinc with aqueous sulphurous acid is filtered, and added to the cold concentrated hydrochloric acid solution of the tellurium compound. Precipitation is complete in 15 minutes. The washed precipitate, which may contain some tellurium sulphide, is rinsed into a tared capsule, oxidised with strong nitric acid, and, after gentle ignition, weighed as tellurium dioxide.

For the attack of ores containing tellurium, 3 or 4 grams of the impalpable powder is treated in a basin with small quantities of concentrated nitric acid, and from the pasty mass obtained, the excess of acid is completely evaporated at a temperature which will not decom-

pose the metallic nitrates. The dry mass is powdered in the basin, moistened with strong soda solution, and digested for half an hour. Water is then added, the filtrate boiled for 20 minutes with pure grape-sugar, and the precipitated tellurium weighed as dioxide, as above.

M. J. S.

Estimation of Hypophosphorous, Phosphorous, and Hypophosphoric Acids. By L. AMAI (*Compt. rend.*, 111, 676—679).—In a warm acid solution, hypophosphoric acid reduces mercuric chloride to the mercurous salt, and is itself completely converted into phosphoric acid, probably in consequence of an intermediate conversion into phosphorous and phosphoric acids. About 1 gram of the substance is mixed with 10 c.c. of concentrated hydrochloric acid, evaporated almost to dryness in order to promote the decomposition of the hypophosphoric acid, redissolved in a small quantity of water, and mixed with a solution containing 68 grams of mercuric chloride and 20 to 40 c.c. of concentrated hydrochloric acid per litre. The mixture is allowed to remain for 24 hours at 80°, and the mercurous chloride is collected and weighed.

Potassium permanganate can be employed in the manner indicated by P. de St. Gilles, the substance being oxidised by excess of the permanganate and the excess determined by means of oxalic acid. The oxidation is more rapid, the more concentrated the solution, the greater the proportion of free acid, and the higher the temperature. At a high temperature, a small quantity of permanganate may be decomposed, and at a low temperature, especially in dilute solutions, oxidation is incomplete; careful attention to the conditions is therefore necessary.

The permanganate employed should be equivalent to a solution containing 63 grams of oxalic acid per litre, and the quantity of substance taken for analysis should reduce about 20 c.c. of the permanganate. The substance is dissolved in 20 c.c. of water, mixed with 3 c.c. of concentrated sulphuric acid, cooled, mixed with 35 c.c. of permanganate, and heated at 50° for half an hour. 20 c.c. of oxalic acid solution is then added, and after the liquid has become colourless and the brown precipitate has completely dissolved, the excess of oxalic acid is determined by means of permanganate. The method is applicable to phosphites, pyrophosphites, and hypophosphites. In the case of hypophosphates, the liquid is first heated with the sulphuric acid at 80—100° for half an hour, and then cooled and mixed with the permanganate.

The mercuric chloride method, although the more tedious, is the more accurate of the two.

C. H. B.

The "Citrate Method" of Phosphoric Acid Estimation. By O. REITMAIR (*Zeit. ang. Chem.*, 1890, 19—25, 196—210; continued from *Abstr.*, 1890, 416).—Comparing the results yielded by the citrate method, under a great variety of conditions, with those furnished by precipitation by molybdate, the author has investigated the amount of the error of deficiency due to imperfect precipitation of the phosphoric acid, and that of the error of excess due to contamination of the precipitate by impurities. His conclusions are as follows:—In

all modifications of the citrate method, the precipitation of the phosphoric acid is incomplete, and with large proportions of citrate and a small amount of magnesia, it may be very seriously so. In the most favourable cases, about 2 milligrams of magnesium pyrophosphate passes into the filtrate. On the other hand, when calcium, iron, aluminium, or manganese is present, a variable portion of those bases will always be found in the precipitate, and, if enough magnesia mixture has been used, a compensation of errors is possible. The use of a minimum quantity of ammonium citrate, in accordance with the procedure of Brassier and Glaser (*Abstr.*, 1885, 837), is not permissible; an excess is always requisite. The quantity of magnesia mixture must, however, always be proportioned to the amount of citrate. The bases which chiefly contaminate the precipitate are calcium and manganese. Both are precipitated in the form of ammonio-phosphates, which are converted into pyrophosphates on ignition. Of iron and aluminium, there are usually only traces precipitated; the principal effect of these metals in the solution is to retard the precipitation of the magnesium ammonium phosphate. Grupe and Tollens have stated that magnesia, or a basic magnesium salt, is precipitated together with the ammonio-phosphate. This is certainly true, since the ignited precipitate always shows the reaction of an orthophosphate with silver nitrate, but if the magnesia mixture has been added by drops to an ammoniacal solution (2.5 per cent. of ammonia), the magnesium oxide in the precipitate will be scarcely weighable. But, using nearly neutral solutions, and especially when salts of sodium or potassium are present, the amount may be very considerable. The use of hydrochloric acid for dissolving phosphates containing silica is disadvantageous; the magnesium precipitate will always be strongly contaminated with silica, and the amount of foreign bases precipitated will also be increased. Even when sulphuric acid is used, and the solution is consequently freer from silica, it is to be expected that about 1 milligram will be found in the precipitate. The presence of sulphates has, however, the tendency, other things being equal, to increase the error of deficiency. Moreover, since the use of sulphuric acid removes a large part of the lime as sulphate, less ammonium citrate is needed than would otherwise be the case.

Using the process for estimating the phosphoric acid in the soluble portion of a superphosphate, and working upon 1 gram of substance, with 5 grams of citric acid, 25 c.c. of magnesia mixture, and ammonia equal to 2.5 per cent. of the solution, a loss of about 2 milligrams, equal to 0.128 per cent. of phosphoric acid, may be assumed. On the other hand, when examining basic slag, or raw phosphates, the error will be in excess. If silica and manganese are absent, the amount of the error may be small, but no estimate of its average magnitude can be formed.

M. J. S.

Reduction of Arsenic Acid in Analysis. By F. A. GOOCH and P. E. BROWNING (*Amer. J. Sci.*, 40, 66—71).—The authors endeavour to shorten the process of reduction of arsenic acid by employing hydriodic acid, instead of sulphurous acid, as the active agent. The process recommended may be summarised as follows:—To the arsenate

in solution are to be added potassium iodide in excess of the amount needed, according to the equation, to complete the reduction, and 10 c.c. of half and half sulphuric acid. The liquid is to be diluted to about 100 c.c., and boiled rapidly until the volume is decreased to 40 c.c. The colour of the free iodine is to be bleached by cautious additions of sulphurous acid, and the liquid immediately diluted with water and neutralised, first with normal potassium carbonate and afterwards with the hydrogen salt. The whole is to be cooled and titrated with iodine in the usual manner, starch being used as an indicator. The advantage of this method is in the rapidity with which it may be executed, the whole operation being completed in half an hour. The average error of the process amounts to 0.13 per cent. of the amount taken.

B. H. B.

Estimation of Peroxides of the Alkaline Earths. By G. KASSNER (*Arch. Pharm.*, 228, 432—435).—A weighed amount of the peroxide (0.2 in the case of the barium compound) is ground with a little water and washed into a beaker; then excess (about five times as much) of pure potassium ferricyanide is added. Oxygen is at once evolved, and the reaction is complete when the gas ceases to come off; the reaction may be accelerated by gently warming the beaker. A considerable amount of water is now added, and excess of sulphuric acid; the greenish colour which may now appear does not affect the result. The solution is finally titrated with potassium permanganate solution. Thus, 0.2 gram of peroxide required 17.2 c.c. of permanganate (1 c.c. = 0.00576 gram of Fe); hence the peroxide contained 74.7 per cent. of peroxide. The old direct process gave 75.13 per cent. The new process may prove useful in cases where an acid solution would be inadmissible; it is only necessary to filter off an aliquot part of the solution before the acid is added, and then titrate and calculate.

J. T.

Estimation of Ferric Oxide and Alumina in Phosphatic Manures. By A. STUTZER (*Zeit. ang. Chem.*, 1890, 43—44).—The author, whilst admitting the superiority of Glaser's method (*Abstr.*, 1890, 420) over that depending on the insolubility of the iron and aluminium phosphates in acetic acid, prefers to weigh the ferric oxide and alumina as such, and not as phosphates. To this end, the solution of 1 gram of the phosphate in hydrochloric acid is made alkaline with ammonia, and then feebly acid with acetic acid. The precipitate is collected and partially washed; the filter with its contents is returned to the same beaker, and digested with 150 c.c. of molybdate solution. The solution filtered from the yellow precipitate is made feebly alkaline with ammonia, and warmed for 10 minutes on the water-bath. The precipitate sometimes contains traces of molybdic acid, but if dissolved in hydrochloric acid and reprecipitated by ammonia, the ferric oxide and alumina are obtained free from all impurities.

M. J. S.

Valuation of Pyrolusite by means of Hydrogen Dioxide. By A. BAUMANN (*Zeit. ang. Chem.*, 1890, 72—79).—The reaction $\text{MnO}_2 + \text{H}_2\text{O}_2 = \text{MnO} + \text{O}_2$, which occurs in acid solutions, yields equally good results by gravimetric, volumetric, or gasometric

methods. The last has already been employed by Lunge (Abstr., 1885, 1162). For accurate work, an ordinary 50 c.c. nitrometer is scarcely large enough, since not more than 0.18 gram of manganese dioxide could be used, and an error of 0.1 c.c. in reading the volume of the gas would equal 0.2 per cent. in the result. The endiometer should be able to measure at least 100 c.c. of gas, and should be surrounded by a water-jacket, that the temperature may be known with exactness. Water may be used in the endiometer instead of mercury. In case the pyrolusite should resist attack, the reaction flask may be warmed to 70°. 1 c.c. of oxygen at 0° and 760 mm. is equal to 0.003885 gram of MnO_2 .

Gravimetrically, the estimation may be made by weighing the oxygen evolved. Almost any of the forms of carbonic acid apparatus for the estimation by loss of weight may be used. From 2 to 6 grams of the pyrolusite, in impalpable powder, is placed in the reaction flask with 30 c.c. of sulphuric acid (1 part to 3 of water), and 40 c.c. of commercial hydrogen peroxide is placed in the inner tube. Warming should be avoided.

For volumetric estimation, an acidified hydrogen peroxide (containing about one-tenth of sulphuric acid) should be made of strength corresponding approximately with a standard permanganate (10 grams per litre). The relation of the solutions is accurately found, and then 0.4 to 1 gram of the pyrolusite is treated with 50 c.c. of the hydrogen peroxide in the cold, and after half an hour with occasional shaking, the excess is titrated back with the permanganate. The presence of ferrous compounds in the pyrolusite leads to high results, since they consume hydrogen peroxide; in Bunsen's and the ferrous sulphate processes, the error is in the opposite direction. M. J. S.

Titration of Permanganate and of Bleaching Powder by Hydrogen Peroxide. By L. VANINO (*Zeit. ang. Chem.*, 1890, 80—83).—To facilitate calculation of the results from the volume of oxygen evolved, tables are given of the weight of 1 c.c. of oxygen and of chlorine respectively, over a sufficiently wide range of temperature and pressure. The author's practice differs in three points from that of Lunge (*Zeit. ang. Chem.*, 1890, 7); he prefers an azotometer to the nitrometer; in the analysis of bleaching powder, he uses feebly acid, instead of alkaline, hydrogen peroxide; and he compares his results with those of the iodometric method, rather than with Ponot's, and finds a closer agreement than did Lunge with the latter. The titration by permanganate of the residual hydrogen peroxide gives unexceptionable results in the assay of bleaching powder. M. J. S.

Dry Assay of Tin Ores. By H. O. HOFFMANN (*Chem. News*, 62, 157—159; 169—170).—This section of the author's paper on the dry assay of tin ores deals with methods depending on fusion with potassium cyanide, of which various modifications have been investigated, with and without a salt cover, in chalk- or charcoal-lined crucibles, in porcelain crucibles, with charcoal intermixed with the cyanide, with various qualities of cyanide, &c. The chief source of error appears to be due to the tin, instead of forming a button, being disseminated through

the mass of slag, when it cannot subsequently be thoroughly separated. To obviate this, it is recommended to ram a lot of potassium cyanide into the bottom of the crucible before putting in the ore and flux, so as to form a fused mass for the tin to fall through and accumulate beneath to form a button. As regards impurities, iron passes into the cyanide, alkaline sulphates and carbonates cause low results owing to the formation of tin sulphides in the first case, and of stannates in the second. Impure cyanide gives low and irregular results.

D. A. L.

Estimation of Vanadic Acid in Vanadotungstates. By A. ROSENHEIM (*Ber.*, 23, 3208—3210).—The statement attributed to the author by Rothenbach (*Ber.*, 23, 3050; and this vol., p. 18) that sulphurous acid is capable of reducing tungstic acid when present as phosphotungstic acid is incorrect, as he has shown (*Abstr.*, 1889, 762) that no reducing action takes place. Rothenbach further states that the violet coloration produced when sulphurous acid is added to a mixture of phosphoric and vanadotungstic acids is not due to the reduction of the tungstic acid, as vanadium tetroxide free from sulphurous acid also yields the coloration with phosphotungstates. This fact, however, really proves the contrary of Rothenbach's statement, for vanadium tetroxide, as shown by its action on ferric oxide and ammoniacal silver solutions is a reducing agent, and this is the compound which actually causes the reduction of the tungstic acid, as is shown by the fact that the intensity of the coloration is dependent on the quantity of tungstic acid present, and not on that of the vanadium tetroxide.

H. G. C.

Estimation of Ferrocyanides. By R. ZALOZIECKI (*Zeit. ang. Chem.*, 1890, 210—214).—When a solution of an alkaline ferrocyanide is treated with zinc carbonate and a stream of carbonic anhydride, the whole of the ferrocyanogen is precipitated in the form of a double salt of the alkali metal and zinc. If the operation is performed at the boiling temperature, the reaction takes place according to the equation $3M',FeCy_2 + 2ZnCO_3 = 2Zn_2FeCy_6.M',FeCy_2 + 4M',CO_3$, and the amount of alkaline carbonate produced may be employed as a measure of the ferrocyanide originally present. The zinc carbonate should be prepared by the addition of sodium carbonate to a hot solution of zinc sulphate, as it then subsides and washes readily. It is preserved in the pasty state, and if the quantity added contains an amount of zinc approximately equal to the weight of alkaline ferrocyanide, it will be amply in excess. The mixture is heated to boiling, and a stream of carbonic anhydride is passed through it for a half to one hour. It is then cooled, diluted to a known volume, filtered, and an aliquot part of the filtrate is titrated with standard acid, using methyl-orange as indicator. If the original solution had contained alkaline carbonates or sulphides, the amount of these should be ascertained by titration, and the acid they consume deducted from the total quantity required after treatment with zinc carbonate. Sulphates and chlorides have a disturbing influence, but this can be counteracted by the presence of an excess of alkaline carbonate; thiocyanates and the other constituents of prussiate "metal" are without influence.

M. J. S.

Estimation of Sugar in Blood. By J. SEEGLIN (*Chem. Centr.*, 1890, ii, 478—479; from *Centr. Physiol.*, 4, 217—222).—The author has found that if, in the estimation of sugar in blood, the coagulum, caused by the addition of iron acetate, be not thoroughly and repeatedly pressed and washed, considerable quantities of sugar may be retained by it, although he has not found the error to be nearly so great as stated by Schenk and by Rohmann. In his first experiments, 5—8 per cent. was retained, and he considers that the sugar may be entirely washed from the coagulum independently of any choice of precipitating agent. J. W. L.

Examination of Oils, Fats, and Allied Substances. By T. T. P. B. WARREN (*Chem. News*, 62, 125; 179—180).—The sulphur chloride test recommended in various communications by the author indicates the character but not the probable quantity of the oils in a mixture; it is, therefore, now suggested to ascertain the latter factor by taking the iodine absorptions, with Hubl's reagent, of the individual constituent oils as well as of the mixture, and from the data obtained to determine the proportions present, for which purpose methods of calculating are described. D. A. L.

Estimation of Formic Acid in presence of Acetic and Butyric Acids. By A. SCALA (*Gazzetta*, 20, 393—396).—The liquid containing the formate is weighed out into a deep beaker, an excess of a saturated solution of corrosive sublimate added, the whole covered with a clock glass and heated for two hours on the water-bath. The precipitated calomel is collected on a weighed filter, washed with warm water, dried at 100°, and weighed. When the acid is present in the free state, it is neutralised before proceeding as above. This method gives trustworthy results, and is very sensitive, formic acid precipitating more than 10 times its weight of calomel. S. B. A. A.

Modification of Jaffé's Indican Test. By F. OBERMEYER (*Chem. Centr.*, 1890, ii, 273—274; from *Centr. Physiol.*, 4, 155).—The author precipitates the urine with plumbic acetate, avoiding too large an excess, filters through a dry filter, agitates the filtrate with an equal volume of fuming hydrochloric acid, in which 2 to 4 parts of ferric chloride are dissolved in 1000 parts, and extracts finally with chloroform. The indigo produced by the oxidation of the indican may then be determined colorimetrically in the chloroform solution. Ferric chloride has the great advantage over others, as an oxidising agent of indican, that it does not affect the indigo produced. J. W. L.

General and Physical Chemistry.

Circular Polarisation of certain Tartrate Solutions. By J. H. LONG (*Amer. J. Sci.* [3], 40, 275—283; compare Abstr., 1890, 313).—The specific rotation of potassium antimony tartrate is considerably reduced by the admixture of carbonates, borates, phosphates, or acetates in amounts insufficient to produce immediate precipitation. Investigation of this behaviour leads to the conclusion that on mixing solutions of alkaline phosphates, acetates, carbonates, or borates with the tartrate in the cold, there is probably first formed a temporarily stable antimony salt, with a corresponding amount of alkaline tartrate. The observed rotation is due to this plus that of the unchanged potassium antimony tartrate.

The specific rotation of potassium ammonium tartrate is but slightly affected by the presence of ammonium or potassium salts, but is considerably diminished by the addition of a sodium salt. This behaviour may also be explained on the general hypothesis of replacement in the tartrate molecule by excess of inactive salts.

H. C.

Phosphorescence of Lithium Compounds in Vacua, and Spectra of Coated Terminals. By E. E. BROOKS (*Chem. News*, 62, 239).—Various lithium salts and minerals exhibited the following phosphorescence phenomena and continuous spectra showing a concentration of light in certain parts, when examined by Crookes' method in the negative discharge in a vacuum:—Sulphate, a bright lilac-blue; phosphate, bright, light Cambridge blue, when fused with sodium carbonate the colour became bright emerald-green, and, unlike the other cases, the glow was prolonged for a second or two after the circuit was broken: chloride, moderately brilliant, pale lavender-blue; fluoride, moderately brilliant, very light flesh-colour; silicon-fluoride, deep blue with darker spots, not so brilliant as the sulphate; spodumene, golden-yellow; lepidolite, very brilliant, deep-red, with traces of blue; petalite, very brilliant, rich yellow; amblygonite, trace of white glow; the nitrate, carbonate, hydroxide, and rubellite and indicolite did not phosphoresce; but the nitrate, fused in a glass tube, produced an opaque, enamel-like appearance at surfaces of contact, by which the inherent yellowish phosphorescence of the German glass became yellow.

By coating with, or simply placing on, aluminium or platinum negative terminals, lithium, thallium, sodium, calcium, or barium salts, and submitting them to a discharge in a vacuum of moderate tenuity, the flame spectra of the respective metals were obtained; other metals gave very faint spectra, or even none, with the 1-inch-spark coil employed. Those spectra disappear in high vacua.

D. A. L.

Crystalline Liquids. By O. LEHMANN (*Ann. Phys. Chem.*, 41, 525—537).—The author has drawn attention to the fact that certain

liquids exist which behave optically as if they had a crystalline structure (Abstr., 1890, 106). These liquids are chemically homogeneous, and the anisotropy is not produced by external force. He now asks the question whether isotropic liquids are non-crystalline, or whether they belong to the regular system, and concludes that in view of the very general miscibility of liquids they are non-crystalline, for otherwise they would only have the power of mixing with isomorphous substances. This conclusion he supports by experiments on the miscibility of crystalline liquids with each other and with solid crystals. Liquid crystals, when heated between cover glasses slightly above the point where they pass into ordinary liquids, retain on cooling the original direction of their optical axes, owing probably to condensation and consequent higher "melting" point of a layer on the surface of the glass. Isomorphous liquid crystals exhibit the phenomena of diffusion, and thus the capability of solids to form mixed crystals appears to correspond exactly with the process of mixing or diffusion in liquids (compare van't Hoff, Abstr., 1890, 1041).

J. W.

Passive State of Iron and Steel. By T. ANDREWS (*Proc. Roy. Soc.*, 48, 116—125).—Steel magnetised by hand or by a coil exhibits a small E.M.F., almost always positive with respect to non-magnetised steel, when both are immersed in nitric acid of sp. gr. 1.42 at the ordinary temperature. As the temperature is raised, the E.M.F. varies somewhat, but remains small, not exceeding 0.03 volt. At about 90°, however, the magnetised steel is attacked violently by the acid, and the E.M.F. rises suddenly to as much as 0.3 volt.

J. W.

Effect of Pressure on the Electrical Conductivity of Liquids. By C. BARUS (*Amer. J. Sci.* [3], 40, 219—222).—For commercial mercury subjected to pressures between 10 and 400 atmos. isothermally, $-\delta R/R = 30 \times 10^{-6} \delta P$, where $\delta R/R$ is the decrement of the specific electrical resistance R , corresponding with the pressure increment δP . If v is the volume, then from the results of Grassi and others, $-\delta v/v = 3 \times 10^{-6} \delta P$, and hence $\delta R/R = 10 \delta v/v$. If θ be the symbol of temperature, the following approximate results apply, isopiastically, at ordinary temperatures and pressures: $\delta R'/R' = 800 \times 10^{-6} \delta \theta$, and $\delta v/v = 180 \times 10^{-6} \delta \theta$. Hence $\delta R'/R' = 4.4 \delta v/v$, where R' refers to electrical resistance considered in its thermal relations. For a concentrated solution of zinc sulphate subjected to pressures from 10 to 400 atmos., similar expressions apply with somewhat less accuracy.

Expressing the results graphically, the pressures in atmospheres or volume decrements per unit of volume are found to be linear functions of the corresponding decrements or increments of electrical resistance per unit of resistance. The curves for thermal change of resistance $\delta R'/R'$ coordinated with volume decrement are also rectilinear. In order to bring the compression loci into coincidence with the thermal loci, the former must be rotated in each case around the origin in a direction contrary to the hands of a watch. The angle of rotation is considerably greater for zinc sulphate solution than it is

for mercury. From this, follows the remarkable result that, both in the case of the metal and of the electrolyte, the effect of isothermal compression is a decrement of resistance nearly proportional to pressure, and by deduction, that the immediate electrical effect of rise of temperature, $\delta R'/R' - \delta R/R$, is a decrement of specific resistance, both in the case of the metal and of the electrolyte. This points out an inherent similarity between the metallic and the electrolytic conduction in this instance.

H. C.

Electrical Conductivity of Boric Acid Solutions in Presence of Dulcitol. By G. MAGNANINI (*Gazzetta*, 20, 441—448).—The author has applied his new method of studying the constitution of solutions (see Ab-tr., 1890, 1357) to the investigation of the molecular composition of the compounds existing in solutions of boric acid and dulcitol. The variations of the molecular conductivity of boric acid solutions in presence of dulcitol are precisely of the same character as those which occur in presence of mannitol, with this difference, however, that from the observed values of the conductivity in the case of dulcitol, no simple relation for the molecular composition of the electrolytic compound or compounds can be calculated. This renders it probable that several compounds of boric acid and dulcitol exist together in the solution.

S. B. A. A.

Determination of Boiling and Freezing Points by means of the Platinum Thermometer. By E. H. GRIFFITHS (*Proc. Roy. Soc.*, 48, 220—225).—Eight thermometers, varying somewhat in construction, were compared. The best form was found to be the following:—A coil of fine platinum wire is wound on a roll of asbestos paper, and slipped into a thin tube of hard glass. Thick platinum wires run from this coil to the top of the instrument, and the unimmersed portion of the stem is surrounded by the outer tube of a condenser, through which tap-water is kept flowing. The diameter is less than 3/16ths of an inch, and the length about 18 inches. The instruments were graduated at the boiling points of water, naphthalene, benzophenone, and sulphur, and the freezing point of water. From the determinations of the boiling points of various substances, it was found that although the curves for the different thermometers vary considerably in form, intermediate temperatures deduced from them are in practical agreement (less than 0.1°) up to 500°.

J. W.

Heat of Combustion of Organic Compounds. By F. STOHMANN (*Zeit. physikal. Chem.*, 6, 334—357).—In this paper are collected and systematically arranged the heats of combustion of over 400 organic compounds. The tables include all the determinations made from 1852 until Angström, 1890, with the exception of the experiments of Frankland, Ramsay, von Rechenberg, and Danileffski. Many hitherto unpublished determinations by the author and his pupils are also included. In the various columns are given the heat of combustion per gram in small calories; the heat of combustion per gram-molecular weight in great calories (both at constant pressure

and constant volume); the heat of formation in great calories; the observer; and the reference to the original source. In calculating the heats of formation, the author assumes the following heats of combustion:—C, 94 Cal.; H₂, 69 Cal.; and S, 69·3 Cal. J. W.

Relations of the Heats of Combustion of Solid Bibasic Acids to those of the Gaseous Hydrocarbons. By F. STOHMANN (*J. pr. Chem.* [2]. 42, 248—259; compare Abstr., 1889, 1096, and Abstr., 1890, 100)—If A is the heat of combustion of any bibasic acid, and B that of the gaseous hydrocarbon from which it is derived, then the ratio A/B is practically a constant. A mean value for this constant obtained from the determinations of the heats of combustion of 22 different acids is 0·97692. Hence, if the heat of combustion of a molecule of a gaseous hydrocarbon is taken as unity, that of the corresponding bibasic acid will be 0·97692, or the heat of combustion of the hydrocarbon is obtained by dividing that of the acid by 0·97692. A comparison between numbers thus calculated and those observed shows a very satisfactory agreement.

The difference B — A is equal to the sum of two numbers x and y , the first of which is the loss of heat in the passage of the hydrocarbon from the gaseous to the solid condition, and the second the heat evolved in the conversion of the solid hydrocarbon into the corresponding acid. In some cases x is already known, and for others it may be calculated without serious error on the assumption that the heats of fusion and vaporisation of unit weight of all hydrocarbons are the same. The value of x being known, y the heat of formation of the acid from the hydrocarbon is then easily calculated.

The following table gives values of y for different acids calculated by the above method:—

	y. Cal.	K.		y.	K.
Malonic acid	2·5	0·17100	Fumaric acid	9·5	0·09300
Methylmalonic acid....	1·7	0·08700	Phthalic acid	5·7	0·12100
Ethylmalonic acid. ...	5·5	0·12700	Isophthalic acid	8·5	0·02870
Dimethylmalonic acid..	8·1	0·07700	Salicylic acid	2·8	0·10200
Succinic acid	9·7	0·00665	Metahydroxy benzoic acid	3·3	0·00807
Methylsuccinic acid ...	8·2	0·00860	Parahydroxybenzoic acid	6·4	0·00286
Ethylsuccinic acid.....	7·4	0·00860	α -Naphthoic acid	1·0	0·02040
Glutaric acid	6·2	0·00475	β -Naphthoic acid.....	4·2	0·00678
Pimelic acid.....	8·1	0·00857			
Adipic acid.....	10·7	0·00871			
Maleic acid	3·3	1·17000			

In the second column of the table, are given the values of Ostwald's affinity coefficients, between which and the heats of formation there is an evident relation, for acids of similar constitution the affinity coefficient being smaller the greater the heat of formation. Methylmalonic acid occupies an exceptional position in the malonic acid series. By analogy with the other acids of this series, the heat of

formation should be between 2.5 Cal. and 5.5 Cal., and the affinity coefficient between 0.171 and 0.127. Instead of this, the numbers are 1.7 Cal. and 0.087.

H. C.

Compressibility of Mixtures of Air and Carbonic Anhydride.

By U. LALA (*Compt. rend.*, 111, 819—821).—The author has investigated the compressibility of mixtures of air and carbonic anhydride containing 11 to 56.92 per cent. of the latter, at pressures extending to 1613.96 cm. of mercury. When the proportion of carbonic anhydride does not exceed 22 per cent., the compressibility lies between that of air and carbonic anhydride, and is, at first, nearer to that of air, but approaches more closely to that of carbonic anhydride as the pressure increases. The greater the proportion of carbonic anhydride, the lower the pressure at which the compressibility becomes equal to that of carbonic anhydride alone. As the proportion of this gas increases, the compressibility becomes greater than it would be if no air were present, but beyond a certain point it decreases and tends to revert to the compressibility of pure carbonic anhydride.

C. H. B.

Experiments on Vapour Density. By E. P. PURMAN (*Proc. Roy. Soc.*, 48, 45—59).—This investigation was undertaken mainly to ascertain if bromine dissociates at low pressures and moderate temperatures. The apparatus employed is figured in the accompanying cut. *A* is a glass globe of known capacity (about $\frac{1}{2}$ litre) blown inside a larger globe, *B*. The liquid which produces the

vapour-jacket is boiled in *C*, and condensed in *D*, which may be specially cooled if necessary. *F* is a tube containing a liquid to absorb the bromine vapour, a few drops being also introduced into

the bulb-tube *G*. *M* is an air reservoir, and *O* a pressure gauge, the tube *P* being attached to a water-pump.

A is first exhausted, and then there is introduced into it a little liquid bromine, air being excluded. The tube above *E* is fused on to *F*, the liquid in *O* boiled, and the bromine allowed gradually to blow out over the potash solution in *F*. The tube above the globe must be heated gently with a Bunsen flame. The apparatus is now exhausted as far as possible, the stopcock *E* turned off, the tube above cracked and removed. more bromine admitted as at first, the tube fused together again, and the bromine driven out as before until the vapour in *A* has the atmospheric pressure at the temperature of the boiling liquid in *O*. The absorption-tube *F* is then filled with strong solution of potassium iodide, and the whole apparatus connected up as in the figure. *M* is exhausted to the requisite degree, and the pump cut off by the screw-clip *R*. Bromine vapour is allowed to escape from *A* by cautious manipulation of the stopcock *E* until equilibrium is attained. The pressure is then read off, the stopcock *L* closed, and the contents of the absorption-tube washed into a stoppered bottle to be afterwards titrated with thiosulphate. The experiment is then repeated at lower pressures until the series is complete.

By adding together the residual quantity of bromine and the quantities removed, the weight of bromine in the globe at each pressure is found, and as the volume occupied is already known, all data required are available.

It was found that at temperatures ranging from 15° to 280°, and at pressures from 15 mm. to 760 mm., bromine vapour exhibited the normal density without any indication of dissociation.

Iodine, when vaporised in a similar apparatus, did not yield constant results, so experiments with it were conducted by means of an apparatus for determining the speed of sound in the vapour. Finely-divided precipitated silica was used to ascertain the wavelength. The density of the saturated vapour at 132 was found to be normal. The author finds (in contradiction to J. J. Thomson, *Abstr.*, 1887, 1013) that the passage of electric sparks through the vapour does not alter its density.

A few experiments were made with the vapour of sulphuric anhydride. The author considers that his results prove the formula of this substance to be SO_3 and not S_2O_6 .

The vapour density of aqueous hydrochloric acid shows that the acid and water do not combine at the temperature employed (132°).

J. W.

Variation of the Density with the Concentration of Weak Aqueous Solutions of Certain Salts. By J. G. MACGREGOR (*Chem. News*, 62, 223—224, 232—234).—The densities of the various solutions were, in these experiments, determined in a specific gravity bottle at 20°, and, as a rule, at least two solutions of different strengths of each salt were prepared from weighed quantities of the recrystallised pure crystalline salt of commerce and weighed quantities of water, the intermediate solutions being obtained by dilution. With ferrous sulphate, however, all solutions were made directly from the salt and

water; in this case, also, air was eliminated from the water as far as possible by boiling.

In all the salts tested, in concentrations varying from 1 per cent. to about 5 per cent. of anhydrous salt, the excess of density of a solution over that of water at the same temperature is directly proportional to the percentage of salt in the solution, and may be represented symbolically by the equation

$$Dt = d_t + kp,$$

in which D_t and d_t are the densities at the same temperature t of a solution and of water respectively, p the percentage of anhydrous salt in the solution, and k a constant for all sufficiently dilute solutions of any one salt. Data are furnished showing the close agreement between the numbers calculated from the formula and those obtained from actual observations. In the following table, the value of k is given, and the maximum observed concentration up to which it holds good for each salt.

Salt.	t .	k .	Maximum concentration per cent.	Observer.
ZnSO ₄	20·0°	0·0103918	3 0	MacGregor.
MgSO ₄	20 0	0 010324	2 0	
MgSO ₄	23·0	0 0098176	between 2 0 and 2·5	Schiff."
FeSO ₄	20·0	0 0099496	above 2·6	MacGregor.
OsO ₄	18 0	0 0097329	about 3·0	Grottrian.
CuSO ₄	18 0	0 0098427	below 2 0	Gerlach.
Al ₂ (SO ₄) ₃	12·5	0·0092083	2·5	Hassenfratz.
AlK(SO ₄) ₂	20·0	0·0095187	{ at least 1·7 possibly 2·5 }	MacGregor.
K ₂ SO ₄	15·0	0·0081600	2·5	Gerlach.
K ₂ SO ₄	12·5	0 0085950	2·5	Hassenfratz.
Na ₂ SO ₄	15·0	0·0091875	4·0	Ostwald.
Na ₂ SO ₄	15·0	0·0091267	4 0	Gerlach
KHO.....	18 0	0 0093717	over 5·0	Thomsen.
NaHO.....	18·0	0·0145630	about 2·0	Thomsen.

The formula seldom applies to concentrations below 1 per cent., exceptions being magnesium, copper, and potassium aluminium sulphates.

D. A. L.

Dissociation Hypothesis of Arrhenius. By J. TRAUBE (*Ber.*, 23, 3519—3530).—The author raises a number of objections to the hypothesis of Arrhenius of the dissociation of electrolytes in dilute aqueous solution (*Abstr.*, 1888, 896). The hypothesis contradicts our ordinary conceptions of chemical affinity, since even the most stable compounds are assumed to dissociate when dissolved in water. All explanations of reactions in solution based on the assumption of a so-called nascent condition become impossible under the new hypothesis. To explain the fact that the ions which are assumed to exist in the free state in aqueous solutions cannot be separated from one another by diffusion, the further assumption is made that the ions are

endowed with charges of opposite sign, and are, in consequence, so dependent one on another that they cannot be separated without the application of energy from the outside. This is, however, to assume a dissociation where none really occurs. According to the hypothesis, the colour of any particular ion in solution should always be the same, whereas an atom of iron in the thiocyanate is red, in Prussian blue is blue, in ferrous sulphate is green, and in ferric chloride is yellow. The additive properties of dilute solutions, which Arrhenius regards as of so much importance in support of the hypothesis, are rather to be looked on as a weak point. For were the hypothesis correct, all the properties of dilute solutions would be of an additive nature, and this is by no means the case. The freezing point reduction of a mixed solution is either equal to or less than the sum of those of its constituents, according as there is no action between the salts or the formation of a double salt. On the dissociation hypothesis, the former only would be the case. The hypothesis also contradicts in every way the hydrate theory, ignoring the fact that from the properties of solutions the existence of hydrates has been predicted which have subsequently been obtained in the free state. We should be compelled to assume that even in solutions of 10 per cent. to 15 per cent. concentration, salts exist in a dissociated condition, and if we accept the Arrhenius reasoning, that in a 65 per cent. solution of silver nitrate this salt is completely dissociated.

Ostwald (Abstr., 1898, 1020, 1142) applies the laws of gaseous dissociation to electrolytes, but the formula he obtains, $m^2/(1-m)r = C$, which should be applicable to all binary electrolytes, only holds for organic acids of low conductivity. Although, therefore, the formula holds for some hundreds of acids, there are an equally large number of compounds to which it is absolutely inapplicable. The application of the gaseous laws by Arrhenius to electrolytes leads to the conclusion that the dissociation is attended in some cases with a development of heat, a result which cannot be reconciled with the idea that energy is required to separate the ions from one another. The phenomena of electrolytic conduction are opposed to the dissociation hypothesis. For since many indifferent organic compounds have a molecular conductivity, which like that of the acids decreases with the concentration, it would be necessary to assume for these also an electrolytic dissociation, which, however, is impossible. In the same way, all the abnormal results for the osmotic pressure, and lowering of the freezing point of organic compounds, would have to be taken as indicating that these also undergo electrolytic dissociation.

Objections are raised to Arrhenius' method of calculating the value of α from the conductivity (*loc. cit.*). The values of α are calculated for solutions containing 1 gram of the dissolved substance in a litre of water. The freezing point determinations, on the other hand, apply to normal or half-normal solutions. The error, therefore, in the latter series of numbers must be at least 20 per cent. The value $\alpha = 0$ is assumed for non-electrolytes, but the author cannot see any reason why the law of Kohlrausch $\lambda = u + v$ should be applied at all to non-electrolytes.

H. C.

Surface Tension of the Halogens. By A. A. TRUNSEWITSCH (*Zeit. physikal. Chem.*, 6, 360—361).—The author, in this preliminary communication, gives the results he obtained from measurement of the capillary elevation of bromine and liquid chlorine. He finds for bromine $\gamma = 4.11$, and for chlorine $\gamma = 2.72$. J. W.

Influence of Mass on Chemical Processes. By F. K. HERMANN (*J. pr. Chem.* [2], 42, 134—142).—The author gives some further instances in support of the view that he put forward in a former paper (*Abstr.*, 1890, 484), that not only the laws of chemical affinity, but also the atomic or molecular weight of the replacing atom or radicle dominates or directs the position which it takes up in any compound. The above assumption serves to explain the fact that many compounds, such as benzil-dioxime, are capable of existing in stereochemically different forms, whereas other compounds of analogous constitution, such as diacetyloxime, exist only in one form.

H. C.

Affinity Constants of Organic Acids, &c. By R. BADER (*Zeit. physikal. Chem.*, 6, 281—318).—The author, in this paper, communicates his determinations of the dissociation constants of some 60 organic substances of acid character. The chief compounds investigated are the hydroxybenzenes, their derivatives, and certain cyanamide compounds.

The mono- and poly hydroxybenzenes are extremely feeble acids, so much so that it is impossible to obtain a constant for them at all. When alkyl radicles, however, are introduced into the benzene nucleus, the acid properties increase markedly, the cresols, for example, giving definite though still very small constants. The introduction of a chlorine atom exerts no great influence on the phenols; the nitro-group, on the other hand, is extremely active, nitrophenol and the dinitrophenols being moderately strong acids. The position of the substituent groups with regard to the hydroxyl here plays a great part in determining the strength of the compound. Trinitrophenol (picric acid) is quite comparable to the mineral acids. Nitrodi- and trihydroxy-derivatives are stronger than the corresponding nitro-mono-hydroxy-compounds, but are still dissociated only as monobasic acids.

Cyanamide in aqueous solution scarcely conducts electricity at all, is thus feebly dissociated, and shows no distinct acid properties. Its derivatives of the type $\text{CN}\cdot\text{NHR}'$, where R' is a univalent acid radicle, are, however, in many cases strong acids, being usually much more powerful than the corresponding carboxylic acids themselves. Thus, whilst acetic acid has the constant $K = 0.0018$, acetylcyanamide, $\text{CN}\cdot\text{NH}(\text{C}_2\text{H}_3\text{O})$, has $K = 0.015$. When the substituting radicle is that of a sulphonic acid, the resulting substance, though acid, is by no means so powerful as the corresponding compound derived from a carboxylic acid: for example, we have for $\text{CN}\cdot\text{NH}(\text{C}_6\text{H}_4\cdot\text{CO})$, $K = 0.186$; but for $\text{CN}\cdot\text{NH}(\text{C}_6\text{H}_4\cdot\text{SO}_3)$, $K = 0.0013$. The replaceability of the hydrogen atom of the imido-group is evidently conditioned by the simultaneous presence of the cyanogen group and an acid radicle in the molecule. An acid radicle alone is insufficient to impart

strongly acid properties to the group NH , succinimide, $\begin{matrix} \text{CH} \cdot \text{CO} \\ \text{CH} \cdot \text{CO} \end{matrix} > \text{NH}$, for instance being practically a non-conductor of electricity in aqueous solution

Other acids investigated were β -naphthoic acid and its reduction products, σ thiophenic acid (stronger than benzoic acid), tetrahydro- α -thiophenic acid, phenylglyoxylic acid (very powerful) and its ketotime, isocinnamic acid (much stronger than ordinary cinnamic acid), dimethylglutaric acid, and α - and γ truxillic acids

Coefficient of Mineral Condensation in Chemistry. By T S HUNT (*Amer Chem J*, 12, 565—585) —Solid or liquid mineral species (including under the designation of minerals all distinct forms of unorganised matter) are formed by intrinsic condensation or polymerisation from simpler chemical species, often themselves gaseous. There is at present no method of fixing the amount, or, in other words, of determining the coefficient, of the condensation, often very considerable, which results in the production of such mineral species. The author proposes, however, to do this by assuming that for all species, whether gaseous, liquid, or solid, the molecular weight varies as the density, taking that of hydrogen under normal conditions as the unit. Dealing with solids and liquids, the density of which is referred to water as unity, it will be necessary to multiply this density by about 21400, the number expressing the density of liquid water with respect to hydrogen, in order to obtain the molecular weight of a substance in the solid or liquid state. Dividing the number so obtained by the ordinarily accepted molecular weight, deduced chemically or from the gaseous density, we get the coefficient of mineral condensation. Thus for quartz, $\text{SiO}_2 = 60$, the density of which is 2.65 the coefficient of mineral condensation will be $2.65 \times 21400/60 = 945$ approximately, and for other substances it may be calculated in like manner.

The coefficient of mineral condensation expresses the degree of polymerisation necessary in the conversion of the simple gaseous chemical species into the liquid or solid mineral species. The author quotes a number of facts in favour of the view that solid molecules are built up by condensation from the gaseous molecules, and that the above reasoning is therefore perfectly justifiable. All the facts that have up to the present been ascertained with regard to the molecules of solid substances point to their being of great complexity, as would be the case if the views above explained are correct.

H C

Reactions at High Temperatures and Pressures. By W HAMPEL (*Ber*, 23, 3388—3392) —The author describes an apparatus consisting of a steel cylinder A, containing a porcelain tube G in which the substance under examination is placed. Down the middle of the tube, a thin rod of carbon F passes and fits into a carbon block E, it may be heated by the electric current, passed by means of the copper wires D and K, the head B of the steel cylinder screws on airtight, and provision is made for pumping in gas through the valve C,

until the desired pressure is obtained. Experiments with this apparatus show that the quantity of cyanides obtained from carbon,

nitrogen, and alkaline oxides increases as the pressure becomes greater, potassium cyanide being much more readily formed than barium cyanide. The production of boron nitride from boric anhydride, carbon, and nitrogen follows the same rule.

J. B. T.

Apparatus for Fractional Distillation in a Vacuum. By H. SCHULZ (*Ber.*, 23, 3568—3570).—The apparatus described in this paper resembles in many respects that recently described by H. Wislicenus (this vol., p. 146), but differs from it, inasmuch as the bell-jar covering the vessels for the collection of the distillate is the part which is made to rotate. It is very simple in construction, and can readily be made of any size, and is, therefore, suitable for technical purposes.

H. G. C.

Error in the Principle of the Ordinary Exsiccator. By W. HEMPEL (*Ber.*, 23, 3566—3568).—In the ordinary exsiccators, the material used for absorbing the moisture is always placed at the bottom, the result of which is that diffusion of dry air takes place very slowly, owing to the fact that dry air is heavier than moist air at the same temperature. If the drying material be placed above the

substance which is to be dried, a much more rapid evaporation will take place, the dried air falling to the bottom, and thus causing rapid currents within the apparatus. To determine the difference in the desiccating action, two dishes, each containing 10 c.c. of water, were placed in two similar exsiccators, the one being above and the other below the dish containing the sulphuric acid. In the first case, the water took nine days to evaporate, and in the second only three days.

The author recommends the employment of an ordinary bell-jar exsiccator, in which the dish of drying material is fixed as high as possible on an iron tripod, and the substance to be dried placed underneath. If sulphuric acid is employed, it is advisable to place in the liquid large pieces of glass, porcelain, or pumice stone. The last named substance must previously be boiled with sulphuric acid to remove the chlorides it contains.

The drying action may be further increased by cooling the highest portion of the bell-jar with a freezing mixture, which causes the formation of stronger currents inside the exsiccator. Notwithstanding the presence of the sulphuric acid, the moisture separates out at the coolest places in the form of snow. H. G. C.

Absorption Plates of Wood Wool. By W. CAMERER (*Zeit. anal. Chem.*, 1890, 576).—This material is a very advantageous substitute for the porous clay and plaster of Paris plates hitherto used for drying precipitates, &c. A coating of cellulose gives a smoother surface. M. J. S.

Inorganic Chemistry.

Molecular Weights of Sulphur, Phosphorus, and Iodine in Solution. By J. HERTZ (*Zeit. physikal. Chem.*, 6, 358—359).—Phosphorus dissolved in benzene gives a depression of the freezing point corresponding with the formula P_4 . The numbers obtained with sulphur dissolved in naphthalene point to the existence of molecules S_8 , in accordance with the results obtained by Beckmann, who employed carbon bisulphide as solvent (*Abstr.*, 1890, 447). The red solution of iodine in naphthalene yields numbers corresponding with the molecule I_2 . J. W.

Action of Metals on Sulphuric Acid. By A. DITTE (*Ann. Chim. Phys.* [6], 19, 68—92).—The author has investigated the action of a number of metals on sulphuric acid of different degrees of concentration and at various temperatures; the following general conclusions may be drawn from the results of the experiments:—

The metals attacked by sulphuric acid can be classed in two groups.

The one contains those metals which are acted on only when the

acid is concentrated and hot; the reaction is very regular in all cases, and sulphurous anhydride alone is evolved, no secondary reactions taking place. To this class belong silver, mercury, copper, lead, and bismuth.

The second group embraces those metals which are acted on more or less readily by sulphuric acid of all degrees of concentration. The most constant product of the reaction is hydrogen, this gas being always evolved in the cold, and almost always at a high temperature also; when the temperature is not very high, hydrogen is the sole gaseous product, whatever the degree of concentration of the sulphuric acid employed. Sulphurous anhydride is only produced when the acid is hot and concentrated; the temperature at which the evolution of sulphurous anhydride commences varies with the metal employed, and, generally speaking, its quantity increases in proportion to the rise of temperature, the quantity of hydrogen decreasing to a proportionate extent, and sometimes, when the temperature is very high, disappearing altogether. When the concentration of the sulphuric acid decreases, the formation of sulphurous anhydride also decreases, so that, even at a high temperature, it is not obtained free from hydrogen; when a certain degree of dilution of the acid is reached, sulphurous anhydride ceases to be formed. Between certain limits of temperature and concentration, which vary with the nature of the metal employed, the action of sulphuric acid gives rise to a mixture of hydrogen and sulphurous anhydride, so that by choosing a suitable temperature and an acid of suitable strength, a mixture of the two gases, in any required proportion, could be obtained.

This is true in the case of metals, like magnesium, which only yield hydrogen when treated with sulphurous acid, as the reducing action of the hydrogen on the sulphurous acid under the conditions of the experiment may be neglected. When, however, the metal employed decomposes sulphurous acid, yielding a sulphide, secondary reactions set in, and hydrogen sulphide is formed; in such cases, larger or smaller quantities of this gas are formed according as the action of the metal on the sulphurous acid is rapid or slow, and according as the sulphide produced is readily or slowly acted on by the sulphuric acid. The hydrogen sulphide thus produced decomposes, and is itself decomposed by, some of the sulphurous acid, and it also reduces the sulphuric acid causing a deposition of sulphur, which, in its turn, acts on the sulphuric acid. When, however, the metal is treated with sulphuric acid under such conditions that sulphurous acid is not produced, the formation of hydrogen sulphide and other secondary reactions cease, and pure hydrogen is evolved. To the second of these two groups belong magnesium, manganese, nickel, cobalt, iron, zinc, cadmium, aluminium, tin, thallium, and probably also the alkali metals. In the case of the last named, it was only possible to study the behaviour with sulphuric acid in the cold, and under these conditions hydrogen is evolved, but, considering the close relationship between the alkaline metals and thallium, it is very probable that, like the latter, they would yield sulphurous anhydride on treatment with sulphuric acid at a high temperature.

F. S. K.

Selenites. By BOUTZOUREANO (*Ann. Chim. Phys.* [6]. 18, 289--351).—The author has prepared the following selenites:—

SELENITES OF BIVALENT METALS.—*Basic selenites*:— $2\text{CuO}, \text{SeO}_2$, clinorhombic. *Normal selenites*:— $\text{MgO}, \text{SeO}_2 + 6\text{H}_2\text{O}$, cubic. $\text{MgO}, \text{SeO}_2 + 2\text{H}_2\text{O}$, clinorhombic. ZnO, SeO_2 , orthorhombic. CdO, SeO_2 , orthorhombic. $3(\text{CuO}, \text{SeO}_2) + \text{H}_2\text{O}$, clinorhombic. $3(\text{CoO}, \text{SeO}_2) + \text{H}_2\text{O}$, clinorhombic. $2(\text{NiO}, \text{SeO}_2) + \text{H}_2\text{O}$, orthorhombic. *Acid selenites*:— $\text{MgO}, 2\text{SeO}_2$, rhombohedral. $\text{ZnO}, 2\text{SeO}_2 + 3\text{H}_2\text{O}$, clinorhombic. $2\text{CdO}, 3\text{SeO}_2 + \text{H}_2\text{O}$, clinorhombic. $\text{CdO}, 2\text{SeO}_2$, orthorhombic. $\text{CuO}, 2\text{SeO}_2 + \text{H}_2\text{O}$, clinorhombic. $\text{CuO}, 2\text{SeO}_2 + 2\text{H}_2\text{O}$, clinorhombic. $\text{CuO}, 2\text{SeO}_2 + 4\text{H}_2\text{O}$, clinorhombic. $2(\text{MnO}, 2\text{SeO}_2) + \text{H}_2\text{O}$, clinorhombic. $\text{MnO}, 2\text{SeO}_2 + 5\text{H}_2\text{O}$. $\text{CoO}, 2\text{SeO}_2 + 3\text{H}_2\text{O}$, clinorhombic. $\text{CoO}, 2\text{SeO}_2$, clinorhombic.

SELENITES OF QUADRIVALENT METALS.—*Basic selenites*:— $\text{Mn}_2\text{O}_3, 2\text{SeO}_2$, clinorhombic. $\text{Fe}_2\text{O}_3, 2\text{SeO}_2$, clinorhombic. *Normal selenites*:— $\text{Fe}_2\text{O}_3, 3\text{SeO}_2 + 10\text{H}_2\text{O}$, clinorhombic. $\text{Fe}_2\text{O}_3, 3\text{SeO}_2 + 3\text{H}_2\text{O}$, cubic. $\text{Fe}_2\text{O}_3, 3\text{SeO}_2 + \text{H}_2\text{O}$, clinorhombic. $\text{Al}_2\text{O}_3, 3\text{SeO}_2 + 7\text{H}_2\text{O}$, hexagonal. $\text{Al}_2\text{O}_3, 3\text{SeO}_2 + 3\text{H}_2\text{O}$, cubic. $\text{U}_2\text{O}_3, \text{SeO}_2$, cubic. *Acid selenites*:— $\text{Fe}_2\text{O}_3, 4\text{SeO}_2 + \text{H}_2\text{O}$, orthorhombic. $\text{Fe}_2\text{O}_3, 6\text{SeO}_2 + 2\text{H}_2\text{O}$, clinorhombic. $\text{Al}_2\text{O}_3, 4\text{SeO}_2 + 3\text{H}_2\text{O}$, orthorhombic. $\text{Al}_2\text{O}_3, 6\text{SeO}_2 + 2\text{H}_2\text{O}$, clinorhombic. $2(\text{U}_2\text{O}_3), 3\text{SeO}_2 + 7\text{H}_2\text{O}$, clinorhombic.

AMMONIACAL SELENITES.— $\text{ZnO}, \text{SeO}_2, \text{NH}_3$, orthorhombic. $\text{CdO}, \text{SeO}_2, \text{NH}_3$, orthorhombic. $\text{CuO}, \text{SeO}_2, \text{NH}_3 + \text{H}_2\text{O}$, triclinic. $\text{Ag}_2\text{O}, \text{SeO}_2, \text{NH}_3$, triclinic.

With a few exceptions, the compounds given in the above list have not hitherto been prepared.

The most successful methods for preparing the salts and obtaining them in well-defined crystals were found to be (1) heating the amorphous or crystalline compounds in sealed tubes at $150\text{--}270^\circ$ with water, or with a solution of selenious anhydride, or adding selenious anhydride to a solution of a salt already prepared and heating the mixture in sealed tubes; and (2) dissolving metallic carbonates in selenious acid and evaporating the solution.

The ammoniacal selenites were prepared by dissolving the selenites in ammonia and evaporating the solutions at the ordinary temperature or at 100° .

In estimating the selenium in the salts, except in the case of the salts of the sesquioxides, the best method was found to be the reduction of the selenious acid with sodium hydrogen sulphite in hydrochloric acid solution; the results are very satisfactory when care is taken to prevent the volatilisation of the selenious anhydride, and to ensure complete reduction. In the case of the selenites of the sesquioxides, attempts were made to determine the selenium by Rose's method, but as the results were not satisfactory, the salts were first boiled with a concentrated solution of sodium carbonate, and the selenious acid in the filtered solution estimated by reduction with sodium hydrogen sulphite as before.

F. S. K.

Preparation of the Nitrogen Hydride N_2H_4 . By E. J. MAUMENÉ (*Bull. Soc. Chim.* [3], 4, 175—180; compare Abstr., 1889, 14).—By the dry distillation of ammonium platinochloride, the chloride

$N_2H_4Cl_2$ is obtained in six-sided, orthorhombic crystals which condense on the walls of the retort. T. G. N.

Hydrazine Hydrate and Haloid Salts (Halogen Diammonium Compounds). By T. CURTIUS and H. SCHULZ (*J. pr. Chem.* [2], 42, 321—549; compare Abstr., 1889, 340).—Hydrazine sulphate forms rhombic crystals, $a : b : c = 0.74532 : 1 : 0.82825$; observed faces $\infty P\infty$, $0P$, $P\infty$, $\bar{P}\infty$, $\infty \bar{P}2$, $2\bar{P}2$; crystals tabular across $\infty P\infty$, colourless and clear; cryoscopic determination of its molecular weight, in water, gave 69.16, 62.871, and 60.705 respectively.

Hydrazine hydrate is best prepared by distilling a mixture of hydrazine sulphate (100 grams), potassium hydroxide (100 grams), and water (25) grams in a silver retort provided with a silver condensing tube. The distillation is continued (5—6 hours) until the last drop has passed over, and the distillate (250 c.c.) is then fractionated, the fractions being best divided into below 101° , 101 — 104° , 104 — 117° , 117° —constant boiling point. After four fractionations, the hydrazine hydrate (36 grams) boils constantly at 119° .

Most of the properties of hydrazine hydrate have been already detailed (Abstr., 1889, 340); it is hygroscopic, and absorbs carbonic anhydride; it can be kept in closed vessels unchanged; it dissolves in water and alcohol, but not in ether, chloroform, or benzene; it solidifies in solid carbonic anhydride and ether, but melts again below -40° ; it boils (739.5 mm.) at 118.5° ; its sp. gr. at 21° is 1.0305; in its reactions with indicators it resembles ammonia. Determination of the vapour density of hydrazine hydrate, made by Hofmann's method at 100° , show that its molecule, under these conditions, is $N_2H_4 \cdot H_2O$; those made by Victor Meyer's method at 170° , and at atmospheric pressure, show that the molecule is dissociated under these conditions into N_2H_4 and H_2O ; cryoscopic determinations show that the molecular weight of hydrazine hydrate in water is 68, agreeing with the formula $N_2H_4 \cdot 2H_2O$.

Hydrazine hydrate which has been redistilled over barium oxide fumes in the air more strongly than the pure liquid, showing that it contains free hydrazine dissolved in it. When the hydrate is heated in a sealed tube with barium oxide at 170° , and the tube is subsequently opened, hydrazine (dianide) escapes as a white fume; experiments in this direction are still in progress.

The hydrazine haloid salts are prepared either by mixing aqueous solutions of hydrazine hydrate and the halogen acid and evaporating, or by adding the acid to an alcoholic solution of the hydrazine hydrate, and subsequently adding ether, whereby the salt is precipitated. When hydrofluoric and hydrochloric acids are used, the salts $N_2H_4 \cdot 2HR$ are obtained by both methods; with hydrobromic acid, the first method yields the salt $N_2H_4 \cdot 2HBr$, and the second method the salt $N_2H_4 \cdot HBr$; with hydriodic acid, both methods yield the salt $N_2H_4 \cdot HI$.

The salts $N_2H_4 \cdot 2HR$ crystallise in the regular system, and are isotropic in polarised light; they dissolve easily in water, but are nearly insoluble in alcohol. The salts $N_2H_4 \cdot HR$ are easily soluble in water and in warm alcohol, from which they crystallise well. Both classes are insoluble in ether, benzene, &c.

Hydrazine dihydrofluoride (diammonium difluoride), $N_2H_4 \cdot 2HF$, melts at 105° , and sublimes undecomposed in presence of excess of the salt. Hydrazine dihydrochloride has been already described (Abstr., 1887, 715); it can also be obtained by passing chlorine into hydrazine hydrate. *Hydrazine dihydrobromide*, $N_2H_4 \cdot 2HBr$, melts at 195° : it can also be obtained by decomposing benzalazine (Abstr., 1889, 393) with hydrobromic acid. *Hydrazine dihydriodide*, $N_2H_4 \cdot 2HI$, can only be obtained by decomposing benzalazine with fuming hydriodic acid; it is very hygroscopic, becomes brown on exposure to light, and melts at 220° .

Hydrazine monhydrochloride has already been described (Abstr., 1889, 340). *Hydrazine monhydrobromide*, $N_2H_4 \cdot HBr$, is prepared by adding bromine to hydrazine hydrate suspended in chloroform; it forms large, anisotropic, columnar crystals and melts at 80° . *Hydrazine monhydriodide*, $N_2H_4 \cdot HI$, may be obtained by adding iodine to an alcoholic solution of hydrazine hydrate; it melts at 127° and then explodes.

Trihydrazine dihydriodide, $N_6H_{12} \cdot 2HI$, is obtained when iodine is added to a solution of hydrazine hydrate in a little alcohol until white crystals separate; it dissolves easily in water, and crystallises from alcohol in large, white needles which melt at 90° and are optically biaxial; when its aqueous solution is evaporated with hydriodic acid, it yields hydrazine monhydriodide.

Cryoscopic determinations of the molecular weights of the above salts show that in aqueous solution:—(1) the salts $N_2H_4 \cdot HR$ have molecular weights which are half those expressed by their formulæ; (2) trihydrazine dihydriodide has a molecular weight which is one-fifth of that expressed by its formula; (3) the salts $N_2H_4 \cdot 2HR$ have molecular weights which are one-fourth of those expressed by their formulæ (except that of $N_2H_4 \cdot 2HF$, which is one-half that expressed by the formula). With regard to hydrazine sulphate, see above. These phenomena are to be explained by the dissociation of the salts in cases (1) and (2) into free molecules of N_2H_4 and HR , and in case (3) into molecules of NH_3 and R .

The author concludes with some speculations as to the constitution of hydrazine hydrate and trihydrazine dihydriodide. A. G. B.

Phosphorus Trifluoride. By H. MOISSAN (*Ann. Chim. Phys.* [6], 19, 286—288; compare Abstr., 1885, 15 and 482).—Phosphorus trifluoride can be prepared by gradually adding phosphorus tribromide to zinc fluoride which is gently heated; the gas is washed with water, dried with pumice moistened with a little sulphuric acid, and collected over mercury. F. S. K.

Preparation of Phosphorus Oxyfluoride. By H. MOISSAN (*Bull. Soc. Chim.* [3], 4, 260—262; compare Trans., 1889, 759).—Zinc carbonate is dissolved in excess of hydrofluoric acid, the solution is evaporated, and the zinc fluoride dried at 300° and placed in a brass tube, to which a bromine burette, containing slight excess of the calculated quantity of phosphorus oxychloride, and a loaded delivery

tube are adapted by a paraffined cork. The leaden tube is connected to a brass tube cooled by a freezing mixture to -20° , and this leads to another tube containing zinc fluoride, which removes any traces of escaping oxychloride from the oxyfluoride. The phosphorus oxychloride is dropped slowly on to the zinc fluoride, the ensuing reaction being assisted by warming carefully at $40-50^{\circ}$, and the evolved gas is collected over mercury in glass vessels. The author determined the phosphorus contained in the gas in three instances as 29.2, 29.4, and 29.95 per cent., theory requiring 29.8 per cent., and the vapour density as 3.68, 3.69, and 3.71, theory requiring 3.63. T. G. N.

Arsenic Fluoride. By H. MOISSAN (*Ann. Chim. Phys.* [6], 19, 280—286; compare Abstr., 1885, 121).—Arsenic trifluoride is formed when arsenious anhydride is treated with anhydrous hydrogen fluoride, and when arsenic chloride is warmed with lead or silver fluoride, but it is best prepared by heating a mixture of arsenious anhydride and calcium fluoride with excess of sulphuric acid, as described by Dumas (*Ann. Chim. Phys.* [2], 31, 433).

Arsenic fluoride boils at 63° (750 mm.), and its density is 2.73 (compare MacIvor, *Chem. News*, 30, 169, and 32, 232). It solidifies at -8.5° to a mass of crystals. When exposed to a dull red heat in a glass vessel free from air, it is decomposed, yielding arsenious anhydride and silicon tetrafluoride. F. S. K.

Action of Hydrogen Sulphide on the Ortharsenates of the Alkali Metals. By W. McCAY (*Amer. Chem. J.*, 12, 547—553; compare Brauner and Tomášek, *Trans.*, 1888, 53, 145).—The author finds that arsenic pentasulphide may be prepared by the decomposition of a strong solution of an alkali arsenate with hydrogen sulphide, and subsequent precipitation by the addition of a mineral acid, according to the method proposed by Beizelius; but that the operation is successful only under the following definite conditions:—In the case of dihydrogen alkali arsenates, the solution must be properly diluted and kept hot, and the hydrogen sulphide passed in excess and for a long time. In the case of the di- and tri-alkali arsenates, the hydrogen sulphide must be kept present in such large excess and passed for such length of time that there is no chance of the potassium thioxyarsenate, which is always formed in passing, in the wet way, from arsenic acid to thioarsenic acid, to split up into potassium arsenite and sulphur, or to escape subsequent conversion into the thio-salt. G. T. M.

Certain Forms of Carbon. By P. SCHÜTZENBERGER and L. SCHÜTZENBERGER (*Compt. rend.* 111, 774—778).—When pure and dry cyanogen is passed through a porcelain tube at a cherry-red heat, it is only partially decomposed, and even at a bright-red heat the decomposition is very limited, the interior of the tube being covered with a thin, brilliant, blackish-grey coating, with a sub-metallic lustre resembling that of polished graphite. If, however, there is placed in the hot part of the tube some gas carbon with powdered cryolite sprinkled over the surface, the cyanogen decomposes completely into carbon and nitrogen, even at a cherry-red heat. The carbon separates

in a bulky mass of very slender filaments, and, after a time, stops up the tube. Those portions in contact with the walls of the tube are more compact and somewhat elastic. It is friable, and leaves on paper a mark resembling that made by graphite, but not so bright. When a piece of aluminium was placed amongst the gas carbon, the carbon separated round it in non-elastic filaments, which could be compressed between the fingers into a mass resembling graphite.

The carbon deposited at a cherry-red heat was treated with nitric acid and potassium chlorate at 20–25° for 24 hours. The insoluble residue, after being washed and dried, forms a deep maroon-brown powder, which decomposes suddenly when heated, becoming incandescent and evolving carbonic anhydride and water. The properties of this product are not materially affected by a second treatment with acid and chlorate in the cold, but if the mixture is heated at 50–60° for several hours, a somewhat pale brownish-yellow powder is obtained, which deflagrates energetically when heated. A portion of the product is soluble in water, and repeated treatment with the oxidising mixture converts the whole of it into yellow, soluble compounds. The pale brownish-yellow, insoluble product has the composition, C, 56.2; H, 2.5; O, 41.3 = 100; and its formula is $C_{11}H_4O_6$, that of Brodie's graphitic acid being $C_{11}H_4O_8$. The maroon-brown product obtained at 20–25° has the composition of graphitic acid. The carbon obtained in presence of aluminium yields similar products.

The filamentous carbon obtained by the decomposition of cyanogen is not identical with any of the established forms of graphite or carbon, and may be taken as a new modification.

Gas carbon, when treated two or three times in the cold with a mixture of potassium chlorate and nitric acid, yields a blackish powder which deflagrates on heating. At 45–50°, it yields products similar to those obtained from cyanogen carbon. It follows that the property of yielding hydroxides which deflagrate when heated is not peculiar to graphite, but is shared by some forms of amorphous carbon. The authors consider that the term *carbon hydroxide* is preferable to such terms as graphitic acid or graphitic oxide. C. H. B.

Allotropic Silver. By A. J. A. PRANGE (*Rec. Trav. Chim.*, 9, 121–133).—With the object of ascertaining the existence of argentous compounds, the author has examined the solutions of silver, and the silver dissolved therein, as described by Carey Lea (*Abstr.*, 1890, 210), and confirms this observer's results.

The red solution is obtained by treating with water the blue-black precipitate formed by the interaction of dilute solutions of ferrous sulphate, sodium citrate, and of silver nitrate. This solution deposits a black powder in a few days, but when more dilute, remains free from precipitate for many weeks. In either case, when freshly prepared, the solutions are perfectly transparent to both incident and reflected light, whilst an intense ray of light passed through the solution undergoes no polarisation, thus proving the absence of suspended matter. Exposure to diffused light or to solar light causes decolorisation and precipitation of a black substance, and

a similar effect is brought about by the addition to the solution of acids, alkalis, and neutral salts. As finely-powdered quartz or graphite also effects the precipitation, the author supposed a colloidal silver to be present, and on dialysis of the solution no silver passed the membrane, but a deposit was thrown down thereon.

Alternate freezing and thawing of the liquid causes decolorisation and formation of a precipitate. The solution has very great absorptive power; a layer 1 c.c. thick, containing 0.7 gram silver per litre, allows no light to pass through.

A solution containing 4.75 grams silver per litre was of a syrupy consistence, the colour of bromine, very unstable, and contained much iron salt associated with the dissolved silver. The heat of dissolution for 1 gram Ag in 2.179 litres of water = +250.8 cal., and for 1 gram Ag in 0.2258 litre of water = +126.73 cal.

From the solution, the silver was obtained by adding ammonium nitrate, and, after the blue-black precipitate thus obtained had been well washed with water, containing sufficient ammonium nitrate to prevent redissolution, until the traces of iron salts were removed as far as possible, it was treated with alcohol, to remove adhering ammonium nitrate, and dried over sulphuric acid for several days; all these operations must be carried out in darkness, or Carey Lea's golden modification (*loc. cit.*) is obtained, instead of a heavy, deep, blue-black substance, which, on compression, assumes a metallic lustre and is easily powdered. This is quite insoluble in water, but dilute mineral acids and acetic acid dissolve it readily. When spread in the moist condition on glass or paper and dried, a beautiful mirror is obtained.

Careful analysis proved it to be free from combined oxygen, but traces of iron are a constant impurity. The heat of transformation to ordinary silver was calculated as +60 cal. per gram.

T. G. N.

Ternary Alloys. By C. R. A. WRIGHT and C. THOMPSON (*Proc. Roy. Soc.*, 48, 25—45).—The authors in this paper give an account of their experiments with mixtures of lead, zinc, and tin at high temperatures, and with mixtures of lead, zinc, and silver. Their general conclusions are as follows:—

A mixture of three metals, A, B, and C, of which A and B are each miscible in all proportions with C, but not with each other, will in general, when allowed to remain molten for a sufficient length of time at constant temperature, divide into two ternary alloys of unequal density, if the proportion of C present falls below a certain amount; but if the quantity of C present is above this limit, no separation takes place, and a homogeneous alloy results.

Under ordinary circumstances, the different alloys thus formed are respectively a saturated solution of A in a mixture of B and C, and one of B in a mixture of A and C, the solubilities being such that the greater the proportion of C present, the more of A (or B) is dissolved. Certain metals, however, appear to be capable of forming compounds in atomic proportions (for example, AgZn_2 and Ag_2Zn_3), in which case the quantity of A (or B) dissolved does not always vary directly with the amount of C present. The effect of temperature on different mixtures

is very variable, but usually a rise of temperature increases the solubility of A in BC, and of B in AC, in some cases to a very considerable extent. The manner in which C divides itself between the two alloys depends on the nature and proportions of the metals present.

The numerical results are presented in numerous tables and curves.
J. W.

So-called Ammoniacal Mercury Compounds. By L. PENCÉ (*Gazzetta*, 20, 485—504; compare Abstr., 1889, 347; 1890, 1211).—Rammelsberg and Kane have shown that a number of the complex compounds of mercury and ammonia may be regarded as containing the radicle $(\text{Hg}_2\text{N})'$, *mercurammonium*. The author has also found (Abstr., 1890, 1211) that compounds containing this group are decomposed by the haloid ammonium salts, and has described a method of quantitatively determining the "mercurammoniacal" nitrogen in compounds containing the radicle. It consists in placing under a bell-jar a mixture of the compound with a saturated aqueous solution of ammonium bromide coloured by litmus, and a vessel containing a known quantity of normal oxalic acid. The whole is left until the bromide solution acquires a clear purple colour. One fourth of the nitrogen in the ammonia absorbed by the acid is derived from the mercurammonium group in the compound, the reaction proceeding according to one of the following equations:—

This method has been applied by the author to the elucidation of the constitution of the compound nitrates, sulphates, and iodides of mercury and ammonia, with the following results.

(1). *Nitrates*.—Six compounds are described by Gmelin, namely:—

a was prepared by Pagenstecher by supersaturating a solution of mercuric nitrate with ammonia, filtering, and allowing to evaporate; the author confirms Meyer's observation, that under these conditions the compound *e* only is formed. *b* was prepared by Kane and Soubeiron by precipitating a dilute solution of mercuric nitrate with a slight excess of ammonia, and washing the precipitate with boiling water. The author's analyses show that this compound is nothing but mercurammonium nitrate, $(\text{Hg}_2\text{N})\text{NO}_3$. *c*, prepared by precipitating a neutral solution of mercuric nitrate with the necessary quantity of dilute ammonia, has the composition

It evolves ammonia when heated with caustic potash (contrary to Kane's statement), and it is converted into mercurammonium nitrate by the action of boiling water. *d* was prepared by Hirzel, by digesting

yellow oxide of mercury with a moderately concentrated solution of ammonium nitrate. By following Hirzel's directions, the author was only able to obtain mercurammonium nitrate. *e*, obtained as described under *a*, has the constitution $(\text{Hg}_2\text{N})\text{NO}_3, \text{NH}_4\text{NO}_3, \text{H}_2\text{O}$. On treatment with boiling water, it loses ammonium nitrate and is converted into mercurammonium nitrate. *f*, prepared by Kane by dissolving *c* in a boiling 20 per cent. solution of ammonium nitrate and filtering, has the constitution $(\text{Hg}_2\text{N})\text{NO}_3, 2\text{NH}_4\text{NO}_3, 2\text{H}_2\text{O}$. It loses 1 mol. H_2O at $110-115^\circ$. It is decomposed by boiling water into mercurammonium nitrate and ammonium nitrate.

g. $(\text{Hg}_2\text{N})\text{NO}_3, 3\text{NH}_4\text{NO}_3$.—This is a new compound which is formed when a boiling 50 per cent. solution of ammonium nitrate is used in the preparation of the preceding compound. It may also be prepared by treating a concentrated solution of the basic nitrate, $\text{Hg}_2\text{O}(\text{NO}_3)_2$, with a 50 per cent. solution of ammonium nitrate. It crystallises in colourless, transparent needles which become almost opaque after exposure to the air for some time. Cold water abstracts ammonium nitrate from it, leaving the compound *c*; boiling water converts it into mercurammonium nitrate. It dissolves in ammonia, and on slowly evaporating the solution the compound *e* crystallises out in octahedra.

Sulphates.—Gmelin describes the compounds—

- | | |
|---|--|
| <i>h</i> . $2\text{NH}_3, 3\text{HgO}, \text{SO}_3$; | <i>i</i> . $2\text{NH}_3, 2\text{HgO}, \text{SO}_3$; |
| <i>j</i> . $2\text{NH}_3, \text{HgO}, \text{SO}_3$; | <i>k</i> . $2\text{NH}_3, \text{HgO}, \text{SO}_3, \text{H}_2\text{O}$; |
| <i>l</i> . $3[(\text{NH}_3, \text{Hg}_2\text{O})_2\text{SO}_4], \text{NH}_3, \text{HgSO}_4$; | <i>m</i> . $\text{NH}_3(\text{Hg}_2\text{O}_2), \text{NH}_3, \text{Hg}_2\text{O}, \text{SO}_4$. |

h, *i*, and *j* were prepared by Millon by saturating 100, 70, and 40 c.c. respectively of concentrated ammonia with mercuric sulphate, allowing the solution to evaporate over quicklime in an atmosphere of gaseous ammonia, and collecting the first crop of crystals in the first two cases, but evaporating to dryness to obtain the compound *j*. The author finds that whether 100 or 70 c.c. of ammonia are used, the first crop of crystals consist of octahedra having the composition $(\text{Hg}_2\text{N})_2\text{SO}_4, 2\text{H}_2\text{O}$; the crystals subsequently deposited have no constant composition. The product *j* is obtained in the manner described, but it is doubtful whether it is not a mixture of several substances. *k*, prepared by Schmieder by saturating a cold 20 per cent. solution of ammonium sulphate with yellow oxide of mercury and evaporating, has the composition $(\text{Hg}_2\text{N})_2\text{SO}_4, 3(\text{NH}_4)_2\text{SO}_4, 4\text{H}_2\text{O}$. It is converted by cold water into the compound *l*, and by boiling water ultimately into mercurammonium sulphate. *l* is obtained by treating the preceding compound with cold water. It has the composition $7(\text{Hg}_2\text{N})_2\text{SO}_4, (\text{NH}_4)_2\text{SO}_4, 12\text{H}_2\text{O}$. It loses the whole of its water at 115° . *m* was obtained by Schmieder by dissolving *k* in dilute sulphuric acid and precipitating the solution with potash, but under these conditions the author could only obtain mercurammonium sulphate.

n. $5(\text{Hg}_2\text{N})_2\text{SO}_4, 14(\text{NH}_4)_2\text{SO}_4, 16\text{H}_2\text{O}$.—This compound is formed when a mixture of a saturated solution of mercuric sulphate in ammonia (sp. gr. = 0.906) with an equal volume of a solution of ammonia saturated at 0° is allowed to remain for 24 hours. It crystallises in rectangular prisms which become opaque on drying in

the air. It is converted by cold water into the compound *l*. It is readily soluble in ammonia, and the solution, when exposed to the air in presence of sulphuric acid, deposits crystals of mercurammonium sulphate.

Iodides.—Besides the compound $\text{NH}_2(\text{Hg}_2\text{O})\text{I}$, shown by Rammelsberg to be the hydrate of mercurammonium iodide, namely, $\text{Hg}_2\text{NI}, \text{H}_2\text{O}$, Gmelin describes the compounds *o*, NH_2HgI_2 , and *p*, $2\text{NH}_2\text{HgI}_2$. The former is considered by Rammelsberg to have the composition $\text{Hg}(\text{NH}_2\text{I})_2 + \text{HgI}_2$, but the author's results lead to the formula $3\text{Hg}_2\text{NI}, 4\text{HgI}_2, 8\text{NH}_4\text{I}$; *p* is regarded by Rammelsberg as $\text{Hg}(\text{NH}_2\text{I})_2$; the author finds, however, that it is formed when ammonia is added to a solution of mercuric iodide in ammonium iodide, and this renders it probable that its composition may be represented by the formula $\text{Hg}_2\text{NI}, 3\text{NH}_4\text{I}$, since ammonia precipitates "fusible white precipitate," $\text{Hg}_2\text{NCl}, 3\text{NH}_4\text{Cl}$, from solutions of mercuric chloride in ammonium chloride, and the compound $\text{Hg}_2\text{NBr}, 3\text{NH}_4\text{Br}$ from solutions of mercuric bromide in ammonium bromide (Abstr., 1890, 1211).

S. B. A. A.

Manganese Oxides. By A. GORGEU (*Bull. Soc. Chim.* [3], 4, 16—30; compare Abstr., 1889, 829; 1890, 260).—The author has prepared and examined specimens of hydrated manganese dioxide by all the known methods, and gives analytical data respecting the several products. The best yield is obtained by the action of dilute solutions of manganese nitrate and potassium permanganate on each other in presence of some free nitric acid.

As crystals of manganese nitrate when heated melt in their water of crystallisation, and then decompose at 125 — 145° to form manganese manganites, and at 150 — 165° to form manganese dioxide, the following method may be used for the production of anhydrous manganese dioxide:—600 to 800 grams of manganese nitrate crystals are warmed in a flask until red fumes appear, when the flask is to be removed from the flame, and the clear liquid decanted from the manganese manganites, and maintained at 150 — 160° for 40—60 hours, when a black, crystalline precipitate containing 99—100 per cent. of manganese dioxide is obtained, which is identical with polianite.

The several hydrated manganese dioxides differ in the amount of water of hydration they contain, according to the reactions by which they are formed, and to the experimental conditions, and it appears impossible to prepare a hydrated oxide by the wet method which shall correspond with an oxide of the formula MnO_2 , on account of the tendency existing in this substance to combine with manganous oxide at the moment of liberation.

The hydrated oxides prepared below 105° redden litmus, neutralise definite quantities of solutions of the alkaline hydroxides, and give a brown solution in water which is transparent to direct light, whereas those prepared above 120° , together with the anhydrous dioxides and the minerals pyrolusite and polianite, do not; but even the last mentioned combine with hydrated manganous oxides to form manganese manganites, when left in contact under water for some days, and the reaction is accelerated by heat.

The hydrated oxides combine more readily with manganous oxide, the rate of action varying directly with their amount of water of hydration.

Both hydrated and anhydrous manganese dioxides evolve oxygen at 400° .

When hydrated manganese dioxide, prepared as above described, is left for some time in contact with very dilute solutions of metallic salts, corresponding manganites are formed, the cobalt and copper manganites corresponding with lanpadite and asbolite respectively.

Potassium permanganate is rapidly reduced to manganate by boiling a solution of the salt containing 20 per cent. of potassium hydroxide with an equivalent quantity of potassium manganite, produced by the action of carbonic anhydride on an alkaline solution of potassium permanganate.

T. G. N.

Violet Chromium Fluoride. By G. FABRIS (*Gazzetta*, 20, 582—584).—When violet chromium sulphate is heated with an excess of normal ammonium fluoride, the green, crystalline precipitate formed has the composition $\text{CrF}_3 \cdot 3\text{NH}_4\text{F}$. When the reaction is allowed to proceed in the cold, the hydrated fluoride, $\text{CrF}_3 + 9\text{H}_2\text{O}$, is obtained. This compound is best prepared by adding the ammonium fluoride gradually to a cold solution of the chromium sulphate. It is insoluble in alcohol and in ammonium fluoride, and only very sparingly soluble in water; it dissolves in hydrochloric acid and in potash, forming violet and green solutions respectively. When heated in the air it loses its water, turns green, and is ultimately converted into chromium sesquioxide.

S. B. A. A.

Artificial Production of a Chromium Blue. By J. GARNIER (*Compt. rend.*, 111, 791).—Potassium chromate, 48.62 parts, calcium fluoride, 65 parts, and silica, 157 parts, are fused in a brasqued crucible. A blue glass is obtained, surrounded by a pellicle of metallic chromium.

C. H. B.

Action of Ammonia on Solutions of Normal Ammonium Titanofluoride. By A. PICCINI (*Chems. Centr.*, 1890, ii, 544; *Rend. Acad. Lincei*, 6, i, 568—571).—If an excess of ammonia is added to a solution of ammonium titanofluoride, $\text{TiF}_4 \cdot 2\text{NH}_4\text{F}$, the whole of the titanic acid is precipitated. If, however, ammonia is added drop by drop to the warm solution of the fluoride, the white precipitate which first forms redissolves later, until at a certain point the liquid has merely an opalescent appearance: if now allowed to remain, a white, crystalline precipitate settles out. It is completely soluble in a solution of ammonium titanofluoride, but is decomposed by water, titanic acid being precipitated. The author ascribes to it the formula $3(\text{TiF}_4 \cdot 2\text{NH}_4\text{F}) \cdot 2\text{TiO}_3 \cdot 3\text{NH}_4\text{F}$.

J. W. L.

Atomic Weight of Bismuth. By R. SCHNEIDER (*J. pr. Chem.* [2], 42, 553—565).—In this paper, the author criticises Classen's memoir on this subject (*Abstr.*, 1890, 706). He complains that the consideration of Marignac's work is dismissed too summarily by

Classen, and that the criticisms thereon are not valid. The accusation against the bismuth which the author and Marignac used, of containing lead, is trivial; for even if it contained as much as 0.25 per cent. of lead, which is practically impossible, the atomic weight would only be raised 0.17, an amount which is well within the limits of variation in the determinations. The author criticises Classen's apparatus and concludes that his atomic weight, 208.9 ($O = 16$), is less likely to be correct than 208.07. A. G. B.

Action of Hydrogen Sulphide on certain Metallamines. By E. F. SMITH and H. F. KELLER (*Ber.*, 23, 3373—3375).—On passing pure hydrogen sulphide over palladio-ammonium chloride at 70° — 80° , the salt becomes black, and at higher temperatures ammonium chloride volatilises; the residue is insoluble in any one acid, but dissolves sparingly in aqua regia, and probably has the formula PdS . Purpureocobalt chloride, rosecobalt sulphate, and luteocobalt chloride react in a similar manner with hydrogen sulphide at ordinary temperatures, whilst purpureochromium chloride requires to be heated almost to the dissociation temperature of hydrogen sulphide before any change occurs. J. B. T.

Mineralogical Chemistry.

Celestine containing Free Sulphur. By H. J. JOHNSTON-LAVIS (*Min. Mag.*, 8, 28—29).—The author describes some crystals of celestine from Girgenti, Sicily, containing as much as 13.69 per cent. of sulphur. The sp. gr. of the crystals was 3.739, the included sulphur lowering the sp. gr. of its host. It would appear that part of the sulphur crystals and celestine formed simultaneously, and the latter was compelled to include the sulphur grains as its crystals grew in size. B. H. B.

Elaterite from Ross-shire. By W. MORRISON (*Min. Mag.*, 8, 133—134).—This mineral tar is an intensely black, lustrous, sticky substance found in fissures in the conglomerate above the old red sandstone at the Craig Well, near Dingwall. On dry distillation, it yields an inflammable oil, gas, and water. It melts at 140° , leaving on ignition a slight ash containing ferric oxide and lime. B. H. B.

Analyses of various Minerals. By I. MACADAM (*Min. Mag.*, 8, 135—137).—The author gives the results of analyses of diatomite from Mull, of bornite and malachite from the limestone of Kishorn, Ross-shire, of galena and zinc-blende from Tyndrum, Perthshire, of fichtelite from Handforth, Cheshire, and from Shielding, in Ross-

shire, and lastly of elaterite from Dingwall. The last, described in the preceding abstract, gave the following results:—

C.	H.	O. &c.	N.	S.	Total.
81.19	13.37	4.45	0.13	0.86	100.00

B. H. B.

Identity of Bruiachite and Fluorspar. By M. F. HADDLE (*Min. Mag.*, 8, 274—277).—The mineral from Loch Bhrnithaich, in Inverness-shire, described in 1887, under the name of *bruiachite* (*Min. Mag.*, 7, 42), is found by the author to be fluorspar, the analysis giving the following results:—

Ca.	F.	BaSO ₄ .	Total.
51.12	48.56	0.23	99.91

B. H. B.

Pyrargyrite and Proustite. By H. A. MIERS (*Min. Mag.*, 8, 37—102).—This is an exhaustive monograph on the red silver ores. The literature is collated, and the crystalline forms previously observed are tabulated. Excluding a number of doubtful forms, the author has determined 23 new forms on pyrargyrite crystals, and four new forms on proustite crystals. The results are given of 15 analyses of specimens in the British Museum. The variations in the rhombohedron angle among the whole series of pyrargyrite analysed fall within the irregular variations in individual specimens, and cannot be ascribed to the presence of varying quantities of arsenic. The same is true of proustite containing antimony. (Compare Abstr., 1888, 657.)

B. H. B.

Crystals of Copper Pyrites. By S. L. PENFIELD (*Amer. J. Sci.*, 40, 207—211).—The author gives a crystallographical description of some very unusual and interesting crystals of copper pyrites from the French Creek iron mines, Chester Co., Pennsylvania, the locality from which some curiously developed crystals of iron pyrites have been obtained. It is very remarkable that at this one locality crystals of iron pyrites are found imitating tetragonal and orthorhombic symmetry, and crystals of copper pyrites imitating isometric and hexagonal rhombohedral symmetry.

B. H. B.

Metacinnabarite from California. By W. H. MELVILLE (*Amer. J. Sci.*, 40, 291—295).—An excellent specimen of metacinnabarite found in the quicksilver mine of New Almaden, California, gave on analysis the following results:—

S.	Hg.	Fe.	Zn.	Mn.	CaCO ₃ .	Quartz.	Org. matter.
13.68	78.01	0.61	0.90	0.15	0.71	4.57	0.63

The mineral occurs in finely developed and brilliant crystals belonging to the rhombohedral system. The sp. gr. is 7.118. The crystals exhibit a high metallic lustre and black colour. They are brittle with a hardness of 2. (Compare Penfield on metacinnabarite crystals from California, Abstr., 1886, 314.)

B. H. B.

Mangano-magnesian Magnetite. By A. H. CHESTER (*Min. Mag.*, 8, 125—126).—A mineral from New Zealand was analysed with the following results:—

Fe ₂ O ₃ .	FeO.	Mn ₂ O ₄ .	MgO.	CaO.	SiO ₂ .	Total.
66.71	19.62	4.63	7.15	trace	2.38	100.49

From these figures, it is seen to be a magnetite, in which part of the ferric oxide is replaced by manganic oxide, and part of the ferrous oxide by manganous oxide and magnesium oxide. It may, therefore, be called a mangano-magnesian magnetite, a variety not noticed hitherto.

B. H. B.

Dufrenite from Cornwall. By E. KINCH (*Min. Mag.*, 8, 112—115).—The mean of a number of analyses of botryoidal dufrenite from Wheal Phoenix gave the following results:—

H ₂ O.	SiO ₂ .	P ₂ O ₅ .	FeO.	Fe ₂ O ₃ .	Al ₂ O ₃ .	CaO.	MgO.	Total.
11.47	0.43	31.10	6.80	47.03	0.87	1.68	0.17	99.53

From these results, there seems no reason to doubt that pure specimens of dufrenite contain a higher ratio of acid to base than that indicated by the formula usually ascribed to the species,

The formula suggested by the author is $3\text{Fe}_2\text{O}_3, \text{FeO}, 2\text{P}_2\text{O}_5, 6\text{H}_2\text{O}$.

B. H. B.

Ferric Sulphates from Chili. By F. A. GENTH and S. L. PENFIELD (*Amer. J. Sci.*, 40, 199—207).—The authors describe some excellent specimens of the ferric sulphates from the Mina de la Compania, near Sierra Gorda, in the Province of Tocapilla.

1. *Amaranillite* (Abstr., 1888, 923).—The crystallisation is triclinic; colour brownish-red; hardness 2.5; sp. gr. 2.286. Analysis (No. I) gave the formula $\text{Fe}_2\text{S}_2\text{O}_9 + 7\text{H}_2\text{O}$. [Compare analyses by Freuzel, Abstr., 1888, 923; Mackintosh, Abstr., 1890, 454; and Darapsky, Abstr., 1890, 456.]

2. *Sideronatrite*.—Optical properties indicate orthorhombic symmetry. Hardness 1.5; sp. gr. 2.355. Analysis (No. II) gives the formula $2\text{Na}_2\text{SO}_4, \text{Fe}_2\text{S}_2\text{O}_9 + 7\text{H}_2\text{O}$.

3. *Ferronatrite* (Abstr., 1890, 455).—No distinct crystals were observed, but the cleavage and the optical properties show that the crystallisation must be hexagonal. Hardness 2.5; sp. gr. 2.547. Analysis (No. III) gave results agreeing with the formula

	H ₂ O.	SO ₃ .	Fe ₂ O ₃ .	CaO.	Na ₂ O.	K ₂ O.
I.	28.29	35.46	37.46	trace	0.59	0.11
II.	17.07	44.22	21.77	—	16.39	—
III.	11.89	51.30	17.30	0.22	19.95	0.16

4. *Utahite*.—Minute, brownish-white scales from the Mimbres mine,

Georgetown, New Mexico, gave, on analysis, results corresponding with the formula Fe_2SO_4 .

5. The authors have also examined some perfect crystals of *atacamite*, brought with the ferric sulphates from the Sierra Gorda. The analysis gave results agreeing with the formula $\text{CuCl}_2 \cdot 3\text{Cu}(\text{OH})_2$.
B. H. B.

Contributions to Mineralogy. By F. A. GUNTHER (*Amer. J. Sci.*, 40, 204—207).—*Picropharmacolite*, from Joplin, Missouri, occurring in incrustations of dolomite, appears to be a mixture of several varieties of the same mineral. Analysis gave the following results:—

	H_2O .	CaO .	MgO .	MnO_2 .	As_2O_5 .
I.	23·11	22·42	6·64	0·26	47·60
II.	24·58	19·64	8·41	0·9	47·74
III.	20·35	17·09	11·54	0·31	50·56

I. Botryoidal crusts, made up of radiating fibres, sp. gr. 2·583. Formula $(\text{H}_2\text{CaMg})_3\text{As}_2\text{O}_5 + 6\text{H}_2\text{O}$. II. Crusts mixed with globular aggregations. III. Radiating silky groups, after the powder had been placed over sulphuric acid for a month.

Pitticite, from the Clarissa mine, Tintic District, Utah, occurring in cryptocrystalline masses, gave results corresponding with the formula $4(\text{Fe}_3\text{As}_2\text{O}_8)_2\text{Fe}_2(\text{OH})_8 + 20\text{H}_2\text{O}$.

The so-called *gibbsite* from Chester Co., Pennsylvania, is found by the author to be a hydrous aluminium phosphate of unknown constitution.
B. H. B.

Dudgeonite, Hydroplumbite, and Plumbonacrite. By M. F. HEDDLER (*Min. Mag.*, 8, 200—203).—*Dudgeonite* is the name given by the author, after its discoverer, to a mineral found in the Pibble mine, Kirkcudbrightshire. It occurs in cavities in copper-nickel. It is a greyish-white solid, having a hardness of 3 to 3·5, and giving, on analysis, the following results:—

NiO .	CoO .	CaO .	As_2O_5 .	H_2O .	Total.
25·01	0·76	9·32	39·33	25·01	99·43

Its formula is $(\frac{2}{3}\text{NiO} + \frac{1}{3}\text{CaO})_3\text{As}_2\text{O}_5 + 8\text{H}_2\text{O}$, that of annabergite with one-third of the nickel oxide replaced by lime.

A mineral partially described by the author is thought to have come from Leadhills, and to have the formula $3\text{PbO} \cdot \text{H}_2\text{O}$. The crystals are white, and probably hexagonal. The name proposed is *hydroplumbite*.

A mineral from Leadhills, which appeared to be hydroplumbite, gave, on analysis, results corresponding with the formula $\text{PbCO}_3 \cdot 3\text{PbO} \cdot \text{H}_2\text{O}$. Not being a hydrated cerussite, it may be called *plumbonacrite*.
B. H. B.

Silicate containing Copper and Silver. By E. JACQUEMIN (*Bull. Soc. Chim.* [3], 4, 255).—A mineral, called "pierre verte," obtained from a lode near Bussang, contained silver, corresponding with 210—225 grams per tonne, and copper equal to 35—45 kilos. per tonne,

and appears to be a copper hydrosilicate accompanied by a cupro-argentic silicate and cupric ferric silicate in a siliceous matrix.

T. G. N.

Minerals from the Lizard. By J. J. H. TRALL (*Min. Mag.*, 8, 116—120).—The author gives the following analytical results:—

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	Cr ₂ O ₃	FeO	MnO	CaO	MgO	Na ₂ O	K ₂ O	Ignition.
I.	49.9	6.2	1.7	0.6	3.9	0.4	26.4	16.1	—	—	0.9
II.	49.4	29.8	1.2	—	—	—	12.6	1.7	3.3	0.4	1.7
III.	48.8	10.6	1.7	trace	4.7	—	12.2	18.6	—	—	1.8
IV.	52.8	2.8	1.8	—	—	—	25.2	16.1	—	—	0.5
V.	50.8	3.6	3.7	trace	6.8	—	1.2	26.1	0.2	—	5.8

I. *Chrome-diopside*, found as a constituent of gabbro at Coverak, Cornwall. The mineral has a sp. gr. of 3.2. II. *Labradorite*, associated with the chrome-diopside and olivine in the gabbro mentioned above. III. *Hornblende*, a very pale-coloured variety, occurring in a gabbro schist at Pen Voose. IV. *Malacolite*, occurring with labradorite, sphene, and an unknown mineral as constituents of an extremely hard and finely crystalline rock at Karaklews. Much of the so-called saussurite of the Lizard is similar to this rock in composition. V. *Anthophyllite*, occurring in a zone surrounding the altered olivine in some varieties of the Lizard gabbros. It is evidently a secondary mineral resulting from the alteration of olivine.

B. H. B.

Mordenite. By L. V. PIRSSON (*Amer. J. Sci.*, 40, 232—237).—Under the name of mordenite, How published (*Trans.*, 1864, 100) a description of a new zeolite occurring at Morden Point, Nova Scotia. To this species he assigned the formula $\text{RO}, \text{R}_2\text{O}_3(\text{SiO}_2)_6, 6\text{H}_2\text{O}$. The accuracy of this formula has been questioned, but the author announces the re-discovery of this interesting mineral from the Hoodoo Mountain, in Western Wyoming, and proves the accuracy of How's work. The analytical results obtained were as follows:—

SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	CaO	MgO	K ₂ O	Na ₂ O	H ₂ O	Total.
66.40	11.17	0.57	1.94	0.17	3.58	2.27	13.31	99.41

These results are closely in accord with How's formula. Under the name of pitulolite, Cross and Eakins (*Abstr.*, 1886, 990) described a new zeolite with a formula strikingly similar to that of mordenite. In the crystal form and optical properties, however, the two zeolites are entirely unlike.

B. H. B.

Large Porphyritic Crystals of Felspar. By T. H. HOLLAND (*Min. Mag.*, 8, 154—157).—In consequence of the striking analogies which have been shown to exist between the basalts of Iceland and those of Mull, the author has undertaken an examination of the porphyritic felspars occurring in the lavas of Mull. The crystals examined are an inch or more across, yellowish-green in colour, and have a sp. gr. of 2.72. On analysis, they yielded—

SiO ₂ .	Al ₂ O ₃ + Fe ₂ O ₃ .	CaO.	Na ₂ O.	Ignition.	Total.
50.80	31.54	12.83	3.96	0.52	99.65

These results are in close agreement with those obtained by other observers with the Icelandic feldspars. B. H. B.

Conversion of a Feldspar into a Scapolite. By J. W. Judd (*Min. Mag.*, 8, 186—198).—At Bamle, in Norway, observations prove that a pyroxene-feldspar rock has been converted into a hornblende-scapolite rock. A microscopic study of this rock, described in great detail by the author, proves that the scapolite has been produced by a plagioclase feldspar, and that in most cases the change is incomplete. After the feldspar crystals had become charged along their solution planes with cavities containing sodium chloride, the effect of internal stresses in the rock-mass was to bring about those chemical reactions by which the feldspar molecules were broken up, and their material became united with the sodium chloride to form scapolite.

B. H. B.

Occurrence of Silver in Volcanic Dust. By J. W. Mallet (*Proc. Roy. Soc.*, 47, 277—281).—The author had already detected silver in the volcanic ash from Cotopaxi (*Abstr.*, 1877, 454). He has now found a trace of the same metal in the dust obtained during the eruption of Tunguragua (Ecuador) on the 11th January, 1886. The mountain had been quiescent for over a century. Besides the chief constituents, silica and alumina, the ash contains considerable quantities of the oxides of iron, calcium, and sodium, together with smaller quantities of the carbonates of calcium and magnesium. The silver amounts to one part in 107,200, and is probably present as chloride; for, though easily dissolved by solution of potassium cyanide or thio-sulphate, it is not extracted by nitric acid. The Cotopaxi ash contained one part of silver in 83,600. J. W.

Two New Iron Meteorites. By E. E. Howell (*Amer. J. Sci.*, 40, 223—226).—1. *Meteorite from Hamilton Co., Texas.*—This was discovered in 1887. It weighed 179 lbs., the two greater dimensions being 17½ and 13 inches. The Widmanstätten figures are brought out with remarkable rapidity on the application of very dilute acid. The amount of troilite found in cutting the iron is not great, and seems to be distributed in thin, narrow plates, no nodules having been met with. On analysis, the iron yielded the following results:—

Fe.	Ni.	Co.	Cu.	P.	S.	C.	Total.
86.54	12.77	0.63	0.02	0.16	0.03	0.11	100.26

Its sp. gr. is 7.95.

2. *Meteorite from Puquios, Chili.*—This is said to have been found in 1884. It weighed 14 lbs. 7½ ozs., the two largest diameters being 10 and 5½ inches. The surface of the iron is unusually smooth, only a few shallow pittings being visible. The etched sections show that the mass has been subjected to fracture and dislocation, result-

ing in an undoubted faulting of the Widmanstätten figures and of the troilite. In all probability these are the first faults observed in an iron meteorite. They are clearly not produced by the impact of the fall upon the earth, but are a part of the meteorite's earlier history. On analysis, the iron yielded the following results:—

Fe.	Ni.	Co.	Cu.	P.	S.	C.	Total.
88.67	9.83	0.71	0.04	0.17	0.09	0.04	99.55

Its sp. gr. is 7.93.

B. H. B.

Five New American Meteorites. By G. F. KUNZ (*Amer. J. Sci.*, 40, 312—323).—1. *Meteorites from Brenham Township, Kiowa Co., Kansas.*—20 meteorites, weighing altogether 2000 lbs., were found in this district in 1886. The following is an analysis of these meteorites:—

Fe.	Ni.	Co.	Cu.	P.	S.	C.	Si.
88.49	10.35	0.57	0.03	0.14	0.08	trace	trace

The olivine (I) and the dark outer zone of olivine (II) gave the following results:—

	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO.	NiO.	CoO.	MnO.	MgO.	S.
I. 40.70	trace	0.18	10.79	0.02	—	0.14	48.02	—	—
II. 34.14	—	—	23.20	trace	0.03	0.09	40.19	5.42	—

The sp. gr. of the iron freed from olivine was 7.93, whilst that of the olivine was 3.376. The iron is brilliant white, enclosing the troilite, and surrounding the olivine crystals. The outer zone of dark-brown olivine is in reality composed of an intimate mixture of troilite and olivine. This group of meteorites is of special interest, because of the probable connection with the meteoric iron found in 1883 in the Turner mounds in Ohio.

2. *Meteorite from Winnebago Co., Iowa.*—This meteorite was observed to fall on May 2nd, 1890. It is a typical chondrite, with a sp. gr. of 3.638, and is composed approximately of 19.40 per cent. of nickeliferous iron, 6.19 per cent. of troilite, 36.04 per cent. of silicates soluble in hydrochloric acid, and 38.37 per cent. of silicates insoluble in hydrochloric acid. The nickeliferous iron on analysis gave the following results:—

Fe.	Ni.	Co.	P.	Total.
92.65	6.11	0.65	trace	99.41

3. *Meteorite Stone from Ferguson, Haywood Co., North Carolina.*—This fell on July 18, 1889. Its weight was about 8 ozs., and it very closely resembled the meteoric stone from Mocs, Transylvania.

4. *Meteorite Iron from Bridgewater, Burke Co., North Carolina.*—This weighs 30 lbs., and measures 22½ by 15 by 10 cm. It belongs to the caillite group, and resembles the Cabin Creek and Glorieta Mountain meteorites in structure. Analysis gave the following results:—

Fe.	Ni.	Co.	P.	Cl.	Total.
88.90	9.94	0.76	0.35	0.02	109.97

Its sp. gr. was 6.617.

5. *Meteoric Iron from Summit, Blount Co., Alabama.*—This meteorite weighs 2.2 lbs., and measures 5 by 2 by 3 inches. It contains a large quantity of free iron chloride, and showed only a slight trace of the original crust, being almost completely oxidised. On etching with nitric acid, no Widmanstätten figures were developed, but merely a fine marking similar to that of the Linnville meteorite. Analysis gave the following results:—

Fe.	Ni.	Co.	P.	Total.
93.39	5.62	0.58	0.31	99.90

The sp. gr. was found to be 6.949.

B. H. B.

Australian Meteorites. By A. LIVERSIDGE (*Chem. News*, 62, 267).—The *Thunula meteorite*, found near Windorah, in the Diamantina District, Queensland, weighed 137 lbs., had a sp. gr. 7.78, and a well-marked crystalline structure; it was also remarkable for numerous nodules of iron sulphide, which in crystallising seem to have given rise to the numerous fissures that proceed from them. It consists essentially of nickeliferous iron containing a trace of cobalt and a small quantity of sulphur, phosphorus, and carbon.

Various earthy meteorites have been found in New South Wales. Of the three *Barratta meteorites*, the first, which has already been described, has a sp. gr. 3.429; the second weighs 31 lbs., sp. gr. 3.706; the third weighs 48 lbs., sp. gr. 3.429; the *Gilgoin meteorite* weighs 67½ lbs., sp. gr. 3.857; the *Eli Elwah*, 33½ lbs., with a sp. gr. of 3.537. These consist essentially of magnesium silicates (as enstatite), with more or less nickeliferous iron and some other substances in small quantities; they resemble one another in character, showing some variation in being more or less cracked or granular.

D. A. L.

Mineral Water of Penon de los Banos, Mexico. By L. L'HÔTE (*J. Pharm.* [5], 22, 427—430).—The spring occurs on the side of a hill of gravel about 4 kilom. north-east of Mexico. The water is perfectly limpid and inodorous. Its taste is first slightly acid, then alkaline; its temperature 44.5°. L. Rio de la Loza found the atmosphere at the spring to contain:—Air (?), 6.2; carbonic anhydride, 63.3; nitrogen, 28.8; water, 1.7 per cent. by volume. Sp. gr. of the water at 15° when received by the author, 1.00174. Total solid residue, 2.216 grams per litre. Arsenic, iodine, and bromine could not be detected. The solid residue contained:—

Sodium carbonate	0.1834	grams	per litre.
Pota-sium carbonate	0.2945	"	"
Calcium carbonate	0.4039	"	"
Magnesium carbonate.....	0.4286	"	"
Sodium sulphate.....	0.0074	"	"
" phosphate.....	0.0013	"	"
" borate	traces	"	"
" chloride.....	0.7366	"	"
Lithium chloride.....	0.0060	"	"
Silica	0.1532	"	"
Alumina	0.0012	"	"
Iron oxide	0.0009	"	"
Organic matter	traces	"	"

2.2160

The water is closely analogous to those of Royat and Mont-Dore (Auvergne). J. T.

Hot Spring Waters. By A. LIVERSIDGE (*Chem. News*, 62, 264—266).—Four samples of water from hot springs on Ferguson Island were examined. The surface rocks of this island are principally slatey, but the immediate neighbourhood of the hot springs has all the usual characters of such localities—incrustations, sulphur hillocks emitting sulphurous fumes and steam, seething mud pools, &c. Each of the four samples of water had a sediment consisting mostly of sulphur; in one sample (1) it was blue, and contained a few diatom frustules and small crystals of selenite, in another (4) it was brown, whilst in the others (2 and 3) it was yellow. Sample 1 reacted acid, had a strong odour of sulphurous anhydride, deposited sulphur on exposure to the air, and, on evaporation, left a pale-brownish, hygroscopic residue, which, on ignition, intumesced and gave off sulphuric fumes, leaving a mass, yellow when hot and brown when cold, consisting of soluble and insoluble silica, iron (originally ferrous), magnesia, lime, and sodium chloride in abundance. The other samples were very similar: sample 2 contained a good deal of free sulphuric acid and lithium, whilst samples 3 and 4 contained both sulphurous acid and hydrogen sulphide, and also lithium. These samples gave, in parts per 1000, the numbers under 1, 2, 3, 4 in the following table:—

	1.	2.	3.	4.	5.
Total solids	14.10	4.90	3.10	7.58	0.76
Loss on ignition	9.63	1.27	0.63	2.11	0.34
Chlorine	—	1.24	0.73	1.39	—

Sample 5 is a water from a hot spring on Savo Island; it had a black deposit consisting of particles of iron sulphide, of quartz, and other transparent minerals with a few diatom frustules. The water was clear, slightly acid, highly charged with hydrogen sulphide, and on exposure deposited sulphur. The residue from its evaporation was whitish, sulphurous, and silky-looking, and on ignition gave off

much steam, and blackened; the carbonaceous matter burnt away slowly. Hydrochloric and sulphuric acids, hydrogen sulphide, silica, iron, aluminium, calcium, magnesium, and sodium were detected.

A sample of water from a fresh water lake on the raised atoll known as Santa Anna was of the density of fresh water, tasted flat and fresh, rapidly decolorised permanganate, and contained, besides plenty of chlorides, some lime and ammonia. The lake is cut off from the sea by a swampy tract one-third of a mile across.

Some samples from the trachytic island of Simbo were examined. This island at the southern portions has indications of dying volcanic activity. At an elevation of 300 feet, there are fumeroles emitting steam, temperature 208—210° F., hydrogen sulphide, and sulphurous acid, and depositing sulphur, alum, sodium chloride, milky opal, iron stains, &c.; the water from them shows sulphurous acid and hydrogen sulphide, but no hydrochloric or carbonic acid. A fumerole at an elevation of 1100 feet above the sea discharged principally aqueous vapour at a temperature of 175—180° F., very slightly acid, but containing neither hydrogen sulphide nor hydrochloric acid, nor sulphurous or carbonic anhydride, and forming no deposit round the orifice.

D. A. L.

Organic Chemistry.

Active Amyl Derivatives. By P. A. GUYE (*Compt. rend.*, 111, 745—747).—If the views previously explained (*Abstr.*, 1890, 722) are correct, any substitution in the group CH_2Cl in active amyl chloride that keeps the mass of this group higher than that of the unaltered H, Me, and Et groups will yield derivatives with a rotatory power of the same sign as that of the amyl chloride. Examination of forty amyl derivatives, which may be regarded as derived from the active chloride in the way indicated, proved that this deduction is correct.

C. H. B.

Hydrolysis of Halogen Carbon Compounds. By C. CHABRIÉ (*Compt. rend.*, 111, 747—748).—Ethylene fluoride is obtained as a colourless gas by heating ethylene bromide at 200° with silver fluoride. It is absorbed by lime water, with formation of glycol and calcium fluoride. The author is endeavouring to obtain erythrol in a similar manner. He has also investigated the action of halogen derivatives on boric anhydride at a high temperature. Ethylene bromide and glycerol tribromhydrin yield a considerable quantity of boron bromide at 250°. Carbon tetrachloride yields boron chloride in large quantity; tetrachlorethylene reacts with less energy and hexachlorobenzene yields no boron chloride. Carbon tetrachloride, silver fluoride, and amorphous boron yield gases containing fluorine,

chlorine, carbon, and boron, with some deposition of carbon and boron, and a small quantity of silver. C. H. B.

β -Dipropylene. By F. COUTURIER (*Bull. Soc. Chim.* [3], 4, 30—31).—If pinacone, after treatment with sulphuric acid, is submitted to distillation, it yields, in addition to pinacolone, a liquid boiling at 60—70°, which on fractionation affords an impure substance boiling at 65°; this, when heated with calcium chloride in sealed tubes, and subsequently fractionated over sodium yields β -dipropylene, C_6H_{10} , which boils at 69.5°. It neither forms a compound with cuprous chloride nor with silver nitrate in ammoniacal solution, but yields a tetrabromide, $C_6H_8Br_4$, which is soluble in alcohol and in ether; it must, therefore, differ in constitution from the isomeric hydrocarbon, boiling at 39°, prepared by Favorsky (Abstr., 1888, 798) by the action of alcoholic potash on pinacolone dichloride, and probably has the constitution $CH_3 \cdot CMe \cdot CMe \cdot CH_3$. By the action of acetic anhydride on pinacone at 80—90° for several days, a crystalline diacetyl derivative of pinacone and a small quantity of β -dipropylene are obtained; the yield of the diacetyl derivative is further enhanced if the action is maintained in the cold during several weeks, when it may be extracted by dissolving the excess of pinacone in water, and recrystallising the residual crystals from ether. T. G. N.

Constitution of Fulminic Acid. By R. SCHOLL (*Ber.*, 23, 3503—3519).—Although the author's researches on this subject are not yet complete, he has thought it necessary, in view of the recent paper of Holleman (this vol., p. 64), to publish the results obtained up to the present time. From results obtained in his researches on the alkylated glyoxime peroxides, it appeared not impossible that fulminic acid might be glyoxime peroxide itself, $\begin{matrix} HC \cdot N \cdot O \\ | \\ HC \cdot N \cdot O \end{matrix}$.

Against this supposition, however, is the fact that phenylglyoxime peroxide does not yield salts (see this vol., p. 316), and that ethereal salts cannot be prepared from mercuric fulminate. The author also finds that it cannot be converted into acid derivatives of phenylglyoxime peroxide, but that by the action of acetic chloride the chief product obtained is *acetylisocyanic acid*, $CONAc$. To carry out the last-named reaction, mercuric fulminate is mixed with light petroleum, and an excess of acetic chloride added. Hydrocyanic acid and a small quantity of isocyanic acid are evolved, and acetylisocyanic acid passes into solution. The latter has not yet been isolated, but that it has really the constitution assigned to it is shown by the facts that it unites with alcohol forming ethyl acetylcarbamate, $NHAc \cdot COOEt$, with ammonia to form monacetylcarbamide, $H_2N \cdot CO \cdot NHAc$, and with acetamide to form symmetrical diacetylcarbamide, $CO(NHAc)_2$. Further, it is resolved by water into carbonic anhydride and acetamide. The residue which remains after separating the light petroleum solution consists chiefly of mercuric chloride, but contains also small quantities of acetylcarbamide, and symmetrical diacetylcarbamide. The formation of the latter can be readily explained, as part of the acetylisocyanic acid is decomposed by traces of moisture with

formation of acetamide, which then combines with unaltered acetylisocyanic acid, forming symmetrical diacetylcarbamide. The properties of this substance agree fully with the description of Schmidt (Abstr., 1872, 718), who does not, however, give its melting point, which the author finds to be 152—153°.

Attempts were made to isolate acetylisocyanic acid, by using nitrobenzene as diluent in the above reaction, and carefully fractionating the product under diminished pressure. A liquid was obtained boiling at 78—80°, which is not, however, pure acetylisocyanic acid, but appears to contain about 14 per cent. of acetonitrile. Somewhat similar results were obtained by Schützenberger (*Compt. rend.*, 54, 154) in attempting to prepare this compound from acetic chloride and silver isocyanate.

The yield of acetylisocyanic acid actually obtained amounted to more than 50 per cent. of the theoretical, and it would therefore appear that this is the only primary reaction, and that the other products are all formed by secondary reactions. The formula which most readily explains this is Steiner's (Abstr., 1883, 1074), namely, $\text{HO}\cdot\text{N}\cdot\text{C}\cdot\text{C}\cdot\text{N}\cdot\text{OH}$, but it is difficult to understand how a compound of this constitution, containing two carbon atoms united by double linkage, should be formed by the oxidation of alcohol.

H. G. C.

Action of certain Inorganic Salts on the Specific Rotatory Power of Cane-sugar. By K. FARNSTEINER (*Ber.*, 23, 3570—3578).—In this paper, an account is given of the action of the chlorides of the metals of the alkalis and of the alkaline earths on the specific rotatory power of cane-sugar. The author finds that with a constant relation of sugar to water, the chlorides of strontium, barium, and magnesium cause a decrease in the rotation, which continues to diminish as the quantity of salt added is increased. The first action of chloride of calcium is to cause a decrease in the rotation, which, however, on the addition of a certain quantity of the salt, reaches a maximum, further addition causing an increase in the rotation, which eventually exceeds that of the pure sugar solution.

If the relation of sugar to the salt be kept constant, and the quantity of water varied, it is found that the addition of water causes in all cases an increase in the specific rotatory power, that is, the action of the salts is lessened. The specific rotatory power is almost unaffected by varying the quantity of sugar with a constant relation between salt and water. The chlorides of lithium, sodium, and potassium behave in a similar manner.

An examination of the action of the same quantities of different salts shows that in the case of strontium, calcium, and magnesium the depression varies inversely with the molecular weight, and that the product of the two quantities is approximately a constant. Barium chloride does not act in the same manner, but the chlorides of the alkalis show a similar relation. The relation, however, only holds within each group of chlorides, and not for two salts belonging to different groups.

H. G. C.

Starch. By C. SCHEIBLER and H. MITTELMETTER (*Ber.*, 23, 3473).—A reply to the recent communication of Zulkowsky (this vol., p. 165) on the same subject.

Gummy Exudation from the Sugar Beet. By E. O. v. LIPP-MANN (*Ber.*, 23, 3564—3566).—A number of large, unripe beet-roots, which had been allowed to remain for some weeks in paper, were found at the end of that time to show a very remarkable appearance. Without any particular bruising being visible, a number of resinous drops had separated out in the furrows which commonly occur in the root, and had flowed together forming a hard, brittle, tasteless, and odourless mass, which could be readily and completely separated from the roots. In appearance it resembled the ordinary plant gums; it was insoluble in cold water and alcohol, and on burning evolved the characteristic odour of the carbohydrates, leaving only a trace of ash. It slowly dissolved in boiling alkalis, and was precipitated from the neutralised solution by alcohol. When freshly precipitated, it dissolved in water, forming a neutral, dextrorotatory solution. On boiling with dilute sulphuric acid, furfuraldehyde distilled over, and arabinose and galactose were found in the residue; when oxidised with nitric acid, it yielded mucic acid. From these results, it would appear possible that the compound is an anhydride of arabinose and galactose, $C_5H_{10}O_5 + C_6H_{12}O_5 - H_2O = C_{11}H_{20}O_{11}$. The analysis of the crude compound agrees fairly closely with this formula, as also does the quantity of furfuramide and of mucic acid obtained in the foregoing reaction. The lack of material has, however, put an end to further investigation, as no other case of the formation of the gum-like compound has been observed, even when the roots have been specially bruised.

H. G. C.

Diisobutylamine Ethyl Oxalate. By H. MALBOR (*Bull. Soc. Chim.* [3], 4, 253).—When an alcoholic solution of oxalic acid is added to diisobutylamine, a white precipitate is formed, which consists of diisobutylamine hydrogen oxalate and of diisobutylamine ethyl oxalate, resulting from the action of the former substance on the alcohol; the mixture is crystallised from boiling alcohol, when the diisobutylamine hydrogen oxalate first separates as brilliant scales, and the mother liquor on evaporation yields acicular crystals of the ethyl salt, $COOEt \cdot COO \cdot NH_2(C_4H_9)_2$; these are dried over sulphuric acid, and are recrystallised from boiling ether. When the substance is heated with water in a reflux apparatus for several days, diisobutylamine hydrogen oxalate is produced. The author is continuing the study of the compound.

T. G. N.

Action of Propaldehyde on Alcohols. By S. B. NEWBURY and M. W. BARNUM (*Amer. Chem. J.*, 12, 519—520; compare Genther, *Annalen*, 126, 63).—*Propylidene diethyl ether*, $CH_3Me \cdot CH(OEt)_2$, is obtained by heating for 12 hours in a closed flask at 100° a mixture of propaldehyde (1 vol.), ethyl alcohol (2 vols.), and glacial acetic acid ($\frac{1}{2}$ vol.). The product is shaken with a strong solution of calcium chloride to remove unchanged alcohol, dried, and submitted

to fractional distillation. The pure ether boils at 122.8° under a pressure of 744 mm., and has a specific gravity of 0.8825 at 0° .

Propylidene dimethyl ether, obtained in a similar way, boils at $86-88^{\circ}$, and has a specific gravity of 0.8657 at 0° . G. T. M.

Action of Alcohol on Acraldehyde. By S. B. NEWBURY and E. M. CHAMOT (*Amer. Chem. J.*, 12, 521—523).—The yield of isotriethylin, prepared according to the instructions given by Alsberg (*Jahrsber.*, 1864, 495), is very unsatisfactory and uncertain. The compound is best prepared by heating a mixture of acraldehyde (1 vol.) and absolute alcohol (3 vols.) at a temperature of 50° for five days. On shaking the product with a strong solution of calcium chloride, nearly the whole of it separates as an oily layer, which is dried and distilled in a vacuum. The purified product is a colourless liquid having a fruity odour, boiling at 85° under a pressure of 11 mm., and with decomposition at $180-185^{\circ}$ under ordinary pressure, and having a specific gravity of 0.8959 at 0° . That it is isocriethylin or triethoxypropane is shown by its behaviour towards bromine and by analysis, but its properties are different from those ascribed to that compound by Alsberg. The position of the third ethoxy-group is not established, although the facts, that it readily decomposes on boiling, and that the difference between the boiling point of this substance and that of propylidene diethyl ether (compare preceding abstract) is nearly the same as that between the boiling points of acetal and ethoxyacetal, point to the third group as occupying the α -position, and to the constitution of the compound being $\text{OEt}\cdot\text{CHMe}\cdot\text{CH}(\text{OEt})_2$. G. T. M.

Action of Crotonaldehyde on Alcohol. By S. B. NEWBURY and W. S. CALKIN (*Amer. Chem. J.*, 12, 523—525).—When mixtures of crotonaldehyde and alcohol are heated for a considerable time at temperatures up to 100° , the substances remain unchanged; combination, however, readily takes place when 60 grams of the former and 120 grams of the latter are heated, in a closed bottle for six days at 50° , with 30 grams of dry zinc chloride. The product, *triethoxybutane*, probably having the constitution

is a colourless liquid of pleasant, fruity odour, boiling at $88-90^{\circ}$, under a reduced pressure of 150 mm., and with slight decomposition at 190° under ordinary pressures. The specific gravity of the liquid at 0° is 0.8825. G. T. M.

The Indian Grass Oils. By F. D. DODGE (*Amer. Chem. J.*, 12, 553—564; compare Abstr., 1890, 231).—*Citronellic aldehyde* has a density of 0.8560 at 20° , and a rotatory power expressed by $[\alpha]_D = +4.50'$. Its molecular refraction, $R_a = 47.60$, does not correspond with that calculated for an aldehyde having a hexatomic nucleus like the menthol series, but agrees with that calculated for the open chain formula $\text{C}_4\text{H}_9\cdot\text{CH}\cdot\text{CH}\cdot\text{C}_2\text{H}_5\cdot\text{COH}$, or a similar one; hence, citronellic aldehyde must be regarded as a homologue of

acetaldehyde. On distilling the bromine additive product obtained from 100 grams of the aldehyde, 13 grams of cymene were obtained. This compound, however, was not formed when the aldehyde was treated with iodine and the product distilled, but a hydrocarbon boiling near 160° was obtained.

Citronellal-phosphoric acid is prepared as follows:—Phosphoric anhydride (5 grams) is covered with dry benzene (20 c.c.) and treated with water (0.55 gram) dissolved in ether (30 c.c.). A cake of metaphosphoric acid forms, and the greater part of the liquid is then poured off. To the residue, citronellal anhydride (10 grams) or citronella oil (20 grams) is added, and the containing vessel kept at a temperature of 70° for several hours. A concentrated solution of sodium carbonate is added until the solution becomes alkaline, the excess of oil separated, and the aqueous solution extracted with ether. Should the aqueous liquid remain coloured, a few drops of hydrochloric acid are added and the treatment with ether continued; this part of the process is repeated until the solution becomes colourless. Excess of concentrated hydrochloric acid is now added, the solution cooled and filtered, and the precipitated acid crystallised from warm dilute alcohol. It is sparingly soluble in water, from which it crystallises in prisms or long, flat needles, but dissolves readily in alcohol, from which, on slow evaporation of the solvent, it crystallises in square plates melting at 203° . It is a monobasic acid; the potassium salt crystallises in long needles and is very soluble in water; the sodium salt crystallises in forms resembling those of the free acid; the aniline salt and the quinoline salt both crystallise in white needles, the former melting at 165° . The acid is dextro-rotatory, and most probably has the constitution

although the author has not succeeded in forming similarly constituted compounds from other aldehydes.

Lemon Grass Oil.—This substance is of uncertain botanical origin. It resembles citronella oil, inasmuch as its chief constituent is an aldehyde, which may be isolated by treating the oil with sodium hydrogen sulphite. When 1000 grams of the dry sulphite are dissolved in 5 litres of hot water, 1 litre of the oil added whilst the solution is still warm, and the mixture vigorously stirred, a pasty mass of the hydrogen sulphite compound separates. On remaining for two or three hours, this precipitate dissolves, leaving a heavy, aqueous solution, containing the aldehyde, and a layer of residual oil (300 c.c.) above. In 24 hours, the solution is perfectly clear and may be siphoned off, filtered, and made strongly alkaline with sodium hydroxide. The supernatant layer of aldehyde is separated, filtered, and dried, when it forms a yellow oil (yield 65–68 per cent. of the grass oil taken) of pleasant, citrene odour, and is slightly volatile in a current of steam. It boils with gradual decomposition at 225° , has $n_D^{20} = 0.8968$ at 15.5° , is probably inactive, behaves with silver nitrate, phenylhydrazine, aniline, and paratoluidine like citronellal aldehyde; gives paramethylpropylbenzene on distillation with phosphoric anhydride, and cymene on distilling with steam the red oil

obtained by the action of concentrated hydrochloric acid; on treatment with zinc-dust and acetic acid, it gives a product, which is probably the corresponding alcohol. Analysis of the aldehyde shows that it is isomeric with camphor, $C_{10}H_{16}O$. The above-mentioned aqueous liquid, containing the aldehyde, appears to be not merely a solution of the hydrogen sulphite compound in excess of sulphite, for a crystalline substance, having approximately the formula

can be separated from it, and further additions of the aldehyde to the solution do not cause the whole to precipitate as the sodium hydrogen sulphite compound. That portion of the lemon grass oil which does not combine with sodium hydrogen sulphite appears to contain a terpene as well as cymene.

Indian Geranium Oil—Samples of this oil differed greatly in behaviour when distilled (compare Semmler, *Abstr.*, 1890, 951).

G. T. M.

Action of Dilute Nitric Acid on Acetone. By S. B. NEWBURY and W. R. ORNDORFF (*Amer. Chem. J.*, 12, 517—519; compare Debus, *Annalen*, 100, 1, and Lubavin, *J. Russ. Chem. Soc.*, 1881, 329 and 495).—Acetone (1 kilo.) was added to nitric acid of sp. gr. 1.42 (1 kilo.), the mixture placed in tall glass cylinders, and a few drops of fuming nitric acid introduced at the bottom of each by means of a long pipette. In a few hours, bubbles of carbonic anhydride commenced to form, and the evolution of gas continued steadily for several weeks. At the end of two months, the liquid, which had a marked odour of hydrocyanic and acetic acids, was poured into a large dish and allowed to evaporate spontaneously. After several months, crystals of ammonium tetroxalate and free oxalic acid were found in the syrupy residue, which, on further concentration and cooling with ice, yielded a large quantity of crystals, the chief product of the reaction. These crystals agreed in every respect with hydroxyisobutyric acid, $OH \cdot CMe_2 \cdot COOH$, and the original syrup furnished zinc hydroxyisobutyrate when boiled with zinc oxide. The mother liquor contained the zinc salt of another acid, but in quantity too small to admit of its identification. Neither pyruvic acid nor any other products of simple oxidation, without a breaking up of the acetone molecule, were formed in perceptible amounts. The production of hydrocyanic acid by the oxidation of organic substances has been explained by Hantzsch (*Annalen*, 222, 65), and the formation of hydroxyisobutyric acid from acetone, hydrocyanic and hydrochloric acids, by Staedeler (*ibid.*, 111, 320).

G. T. M.

Action of Hydroxylamine on Isonitrosoketones. By R. SCHOLL (*Ber.*, 23, 3578—3581).—When concentrated boiling aqueous solutions of hydroxylamine hydrochloride and isonitrosoacetone are mixed, the heat developed in the reaction causes the boiling to continue for some time. On neutralising with aqueous soda, a yellowish powder crystallises out, from which ether extracts methylglyoxime. The residue is practically insoluble in the common solvents, but dissolves in small quantity in boiling alcohol or water, separating from

the latter in white, matted needles. It becomes brown at 180—200°, and explodes at 238—247°; it dissolves readily in mineral acids and solutions of sodium hydroxide and carbonate, and is reprecipitated on neutralisation. Its composition, as found from analysis and the determination of the molecular weight by Raoult's method, is $C_6H_5N_3O_4$. Its *hydrochloride*, $C_6H_5N_3O_4 \cdot HCl$, is formed by passing hydrogen chloride into the dry substance suspended in ether, and forms a hard, crystalline cake, which dissolves fairly readily in absolute alcohol, melts at 112—113°, and explodes at a higher temperature.

Isonitrosoacetophenone reacts with hydroxylamine in a similar manner, forming phenylglyoxime and a substance insoluble in ether and in all common organic solvents. It dissolves in soda with a yellow colour, and is reprecipitated by acids in white flakes having the composition $C_{10}H_{13}N_3O_4$. It also dissolves in hot hydrochloric acid, but separates out unaltered on cooling, and is probably identical with the compound obtained by Müller and Pechmann by the action of hydroxylamine on phenylglyoxal (Abstr., 1890, 51).

H. G. C.

Formation of Zinc Propionate by the Action of Carbonic Anhydride on Zinc Ethide. By R. SCHMITT (*J. pr. Chem.* [2], 42, 568—569).—Wanklyn (*Annalen*, 107, 125) obtained sodium propionate by acting on zinc sodium ethide with carbonic anhydride. The author has succeeded in synthesising zinc propionate by acting on zinc ethide with liquid carbonic anhydride in an autoclave at 150—160°. At the same time there is a secondary reaction, by which some of the zinc propionate is decomposed into diethyl ketone and zinc carbonate.

A. G. B.

Preparation of Cerotic Acid. By T. MARIE (*J. Pharm.* [5], 22, 343—344).—125 grams of bees'-wax is heated with 3 litres of 93° alcohol for two hours. After cooling, the alcoholic jelly is poured off and the treatment with alcohol is repeated two or three times, and each time for a longer period, until the whole of the cerotic acid is removed. The alcoholic portions are united, filtered, and distilled with a little potash, to retain the volatile acids which have been removed from the wax, and the distillate serves to dissolve the impure acid upon the filter. This solution being heated to boiling, the myricin contained forms minute droplets, which are deposited on cooling quietly, and adhere closely to the flask. The supernatant jelly is poured on to a filter and washed with a small quantity of alcohol. After three such treatments and two crystallisations from alcohol, the acid is colourless, and melts at 76—77°; it is then almost pure. If converted into the lead salt, according to Brodie's method, ether extracts but an insignificant amount of matter, and the regenerated acid melts at 78°.

J. T.

Formation of Ethereal Salts by Means of Ethyl Chlorocarbonate. By R. OTTO and W. OTTO (*Arch. Pharm.*, 228, 500—516).—When ethyl chlorocarbonate is gradually added to sodium formate covered with about twice its volume of alcohol, carbonic anhydride is at once evolved; after remaining some time at the ordinary tempera-

ture, the liquid contains, besides sodium chloride and ethyl carbonate, ethyl formate and free formic acid. with perhaps some free hydrochloric acid. To separate the ethyl formate, the solution is supersaturated with sodium carbonate, water added, if necessary, and sodium chloride to reduce the solubility of the formate, which is then siphoned off, placed over ignited potash, and purified by fractional distillation. An intermediate carboxy-compound is supposed to be formed during the reaction, thus:— $\text{H}\cdot\text{COONa} + \text{ClCOOEt} = \text{NaCl} + \text{HCO}\cdot\text{O}\cdot\text{COOEt}$; this ethylic carboformate is partly decomposed directly, thus:— $\text{HCO}\cdot\text{O}\cdot\text{COOEt} = \text{CO}_2 + \text{HCOOEt}$ (I), and the remaining part under the action of water from the alcohol gives $\text{HCO}\cdot\text{O}\cdot\text{COOEt} + \text{H}_2\text{O} = \text{CO}_2 + \text{EtHO} + \text{HCOOH}$ (II). If alcohol and water be excluded, equation (I) still holds good, but the remaining part of the carboformate is decomposed as follows:— $2\text{HCO}\cdot\text{O}\cdot\text{COOEt} = \text{Et}_2\text{CO}_3 + \text{CO}_2 + (\text{HCO})_2\text{O}$ (III), the latter immediately decomposing into formic acid and carbon monoxide. Sodium acetate treated with alcohol and ethyl chlorocarbonate similarly yields acetic anhydride and also ethyl carbonate, showing that a reaction analogous to (III) holds good here, thus:— $2\text{MeCO}\cdot\text{O}\cdot\text{COOEt} = (\text{MeCO})_2\text{O} + \text{Et}_2\text{CO}_3 + \text{CO}_2$. Calcium propionate, sodium isovalerate, and sodium stearate yielded analogous ethyl compounds. Three monobasic acids of the aromatic series were next examined. Sodium benzoate when acted on by ethyl chlorocarbonate in presence of alcohol formed essentially ethyl benzoate and benzoic anhydride, whilst when water is excluded ethyl carbonate is also formed. Here also an intermediate carboxy-compound, $\text{C}_6\text{H}_5\text{CO}\cdot\text{O}\cdot\text{COOEt}$, is supposed to enter into the reaction, analogous to the compound formed with formates. Potassium metatoluate yielded ethyl metatoluate and a larger amount of metatoluic anhydride. Next, the sodium salt of an isomeride of the last acid, phenylacetic acid, was treated. This yielded ethyl phenylacetate, but no anhydride, and in this respect resembles the fatty series. Of bibasic acids, the potassium salt of oxalic acid yielded scarcely any ethyl oxalate in presence of alcohol, owing to the precipitation of the salt from its aqueous solution by this alcohol. In the absence of alcohol, a small quantity of ethyl oxalate was formed after some days. With potassium succinate, the reaction was very energetic. Ethyl potassium succinate was produced, and a little ethyl carbonate. In the bibasic aromatic series, potassium phthalate was employed. Ethyl phthalate was formed, but much phthalic acid was re-formed. Finally, sodium salicylate yielded a little ethyl salicylate and carbonate, and again much of the salicylic acid was regenerated.

J. T.

Pimelic Acids. By C. A. BISCHOFF and K. JAUNSNICKER (*Ber.*, 23, 3399—3409).—Symmetrical dimethylglutaric acid (m. p. 105°), from methyl iodide and ethyl isobutenyltricarboxylate, is identical with the "trimethylsuccinic acid" from ethyl methylmalonate and ethyl bromisobutyrate, and also with the acid from ethyl methylmalonate and methyl iodide, as well as with Zelinsky's acid (compare *Abstr.*, 1890, 132). On heating with hydrochloric acid in a sealed tube for 24 hours at $230\text{--}250^\circ$, the para-acid is formed (*loc. cit.*).

After the separation of dimethylglutaric acid from the product of the action of methyl iodide on ethyl isobutenyltricarboxylate, the lower fraction, boiling at 200—245°, yields a compound which has the formula $C_6H_{10}O_4$; two preparations showed the melting points 88—92° and 103—113°, whilst the electrolytic conductivities, $[\kappa]_{\infty} = 353$, are $\kappa = 0.0114$ and 0.0112 respectively. This acid appears to occupy a position in the series intermediate between methylsuccinic acid and antidimethylsuccinic acid; the formula points to its being an isomeric dimethylsuccinic or ethylsuccinic acid. The paper concludes with a systematic comparison of the acids obtained: (I) by the oxidation of castor oil; (II) from amylene bromide (trimethylsuccinic acid); (III) from methylene iodide and ethyl methylmalonate (dimethylglutaric acid); (IV) from methyl iodide and ethyl isobutenyltricarboxylate.

J. B. T.

Ethyldimethylsuccinic Acid. By C. A. BISCHOFF and N. MINZ (*Ber.*, 23, 3410—3413).—*Ethyldimethylsuccinic acid*,

is prepared by heating ethyl orthobromisobutyrate with ethyl sodium ethylmalonate in xylene solution at 180—190° for 21 hours, under a pressure of 3 atmospheres the product appears to consist of a mixture of two ethereal salts; it is hydrolysed with potash, and, after purification, the pure acid crystallises from benzene or water in long, concentric prisms, melts at 139° (uncorr.), and is insoluble in light petroleum, carbon bisulphide, and xylene, but readily dissolves in ether, acetone, chloroform, or glacial acetic acid. The electrolytic conductivity is $\kappa = 0.0582$ $[\mu_{\infty} = 351]$. The barium and silver salts have been prepared; the latter is crystalline, and insoluble in water.

J. B. T.

Tetramethylsuccinic Acid. By K. AUWERS and J. A. GARDNER (*Ber.*, 23, 3622—3625).—*Tetramethylsuccinimide*, $C_6H_{12} \begin{smallmatrix} CO \\ > \\ CO \end{smallmatrix} NH$,

is prepared by dissolving tetramethylsuccinic acid in aqueous ammonia; the solution is evaporated, and the residue heated at 230° for several hours in a sealed tube; the compound crystallises from a mixture of benzene and light petroleum in flat needles, melts at 187°, and may be distilled without decomposition; it may also be prepared by heating the anhydride with aqueous ammonia at 100°. The *phenylimide*, $C_6H_5 \begin{smallmatrix} CO \\ > \\ CO \end{smallmatrix} NPh$, is obtained by the action of aniline on the acid or anhydride, and crystallises from dilute alcohol, or a mixture of benzene and light petroleum, in needles, melts at 88°, and is insoluble in cold water.

By treating the acid with phenylhydrazine, only one compound is obtained, which crystallises in flat, lustrous needles melting at 124°; it may be volatilised without decomposition, and has the formula $\begin{smallmatrix} CMe_2 \cdot CO \cdot NH \\ | \\ CMe_2 \cdot CO \cdot NPh \end{smallmatrix} >$ or $\begin{smallmatrix} CMe_2 \cdot CO \\ | \\ CMe_2 \cdot CO \end{smallmatrix} > N \cdot NPh$. The anhydride is the sole product formed by the action of phosphorus pentachloride

on tetramethylsuccinic acid or its salts. With resorcinol, the acid yields a fluorescein derivative, which dissolves in acids with a red coloration, and a green fluorescence. J. B. T.

Homologues of Maleic Acid. By C. A. BISCHOFF (*Ber.*, 23, 3414—3423).—A reply to Anschütz's paper (this vol., p. 176). The affinity of sodium for oxygen is greater than that of hydrogen, consequently, in hydrogen sodium carbonate the oxygen of the group ONa is at a greater distance from the carbon atom than that of the group OH; in carbonic acid, however, the oxygen atoms of both hydroxyl groups are equally distant from the carbon atom; hence collisions readily occur, and the compound decomposes into water and carbonic anhydride. The same principle is illustrated by reference to acetaldehyde and chloral hydrate. A comparison is then instituted, by means of models, between succinic and maleic acids, on the one hand, and symmetrical dimethylsuccinic and pyrocinchonic acids on the other; it is shown that the hydroxyl groups approach as closely as in the case of carbonic acid. As regards the influence of the other atoms or groups in the molecule, the elimination of two hydrogen atoms from succinic acid, or their displacement by two methyl groups, facilitates the formation of anhydrides. It is proposed to determine what influence the ethyl and methyl groups have on the elimination of water from maleic acid.

By the action of bromine on propenyltricarboxylic acid, carbonic anhydride and hydrogen bromide are evolved, and the resulting succinic acid derivative, $\text{COOH}\cdot\text{CHMe}\cdot\text{CHBr}\cdot\text{COOH}$, yields citraconic acid on distillation, whilst by the action of hydrochloric acid at 160° , mesaconic acid is formed. Ethylmaleic and ethylfumaric acids are prepared in a similar manner from butenyltricarboxylic acid. Disubstituted maleic acids may be obtained from the corresponding succinic anhydrides (compare Bischoff and Voit, *Abstr.*, 1890, 743).

Ethylmethylethylmaleic anhydride is a colourless oil which boils at 237° , is soluble in potash, and is reprecipitated unchanged by hydrochloric acid. Xeronic anhydride is formed in the same way from diethylsuccinic anhydride. J. B. T.

Combination of Malic Acid with Potassium Sodium Molybdate and with Acid Sodium Molybdate. By D. GARNERZ (*Compt. rend.*, 111, 792—794).—The salts were added gradually to a solution of a definite quantity of malic acid, the total volume of liquid being kept constant, and the rotatory power was determined in the manner previously described. With potassium sodium molybdate,

the levorotatory power at first increases in proportion to the quantity of salt added, and attains a maximum when three equivalents of acid are present for each equivalent of salt. Subsequent variations in rotatory power indicate the formation of compounds containing respectively 3 equivalents of acid and 2 of the salt, 3 equivalents of the acid and 3.5 of the salt, and 3 of the acid and 6.5 of the salt.

With malic acid and the acid sodium molybdate, $3\text{Na}_2\text{O}, 7\text{MoO}_3$, the

variations in rotation indicate the formation of a compound of 3 equivalents of acid and 1 of the salt, and a compound of equal equivalents of the acid and the salt, the phenomena being analogous to those observed with ammonium molybdate, although the rotatory powers are somewhat larger. C. H. B.

Ethyl Isobutenyltricarboxylate. By C. A. BISCHOFF (*Ber.*, 23, 3395—3399).—Auwers and Jackson have shown (*Abstr.*, 1890, 1098) that the compound obtained by the action of ethyl methylmalonate on ethyl bromisobutyrate has the formula

and, when hydrolysed, yields dimethylglutaric acid with elimination of carbonic anhydride. The author had, however, previously prepared, in a similar manner, an identical compound from ethyl isobutenyltricarboxylate and methyl iodide, which he considered to be trimethylsuccinic acid. Further investigation has shown that "ethyl isobutenyltricarboxylate" consists of two compounds of the formulæ $\text{COOEt}\cdot\text{CMe}_2\text{CH}(\text{COOEt})_2$ and $\text{COOEt}\cdot\text{CHMe}\cdot\text{CH}_2\text{CH}(\text{COOEt})_2$, respectively, and that, on hydrolysis and elimination of carbonic anhydride, it yields a mixture of α -methylglutaric acid and dimethylsuccinic acid, which may be separated by fractional distillation. No trimethylsuccinic acid could be isolated from the methyl iodide and ethyl isobutenyltricarboxylate product, which, therefore, consists only of dimethylglutaric acid. Trimethylsuccinic acid has, however, previously been prepared, and is known by the name isopimelic acid (compare this vol. p. 289). J. B. T.

Action of Nitrous Acid on Amido-derivatives. By E. A. KLOBBE (*Rec. Trav. Chim.*, 9, 134—154).—The action of nitrous acid on the following compounds has been investigated by the author in order to determine the influence on the action of the accumulation of negative groups in the amido-derivative.

Nitrous acid acts on methyl amidoformate to form methyl alcohol, with evolution of nitrogen and carbonic anhydride. With the same reagent, ethyl methylamidoformate yields a nitroso-derivative, $\text{NO}\cdot\text{NMe}\cdot\text{COOEt}$, which is a red liquid of sp. gr. 1.133 at 15°, boiling at 70° under a pressure of 27 mm. Methyl methylamidoformate also forms a nitroso-compound, $\text{NO}\cdot\text{NMe}\cdot\text{COOMe}$, having similar properties to the last-named compound. Methyl ethylamidoformate, in aqueous solution, is acted on by a current of nitrogen trioxide, and forms a nitroso-derivative, $\text{NO}\cdot\text{NEt}\cdot\text{COOMe}$, which is a dark-orange liquid of sp. gr. 1.143 at 15°.

Methyl acetylamidiformate, which is obtained by the action of ethyl methylcarbamate on acetic chloride at a moderate heat, is a crystalline substance which melts at 93°, and is very soluble in water, alcohol, ether, chloroform, and crystallises easily from benzene. On treating an aqueous solution of this substance with nitrogen trioxide, decomposition occurs according to the equation $\text{CH}_3\text{CO}\cdot\text{NH}\cdot\text{COOMe} + \text{HNO}_2 = \text{CH}_3\text{COOH} + \text{N}_2 + \text{CO}_2 + \text{MeOH}$.

Methyl imidodiformate, $\text{NH}(\text{COOMe})_2$, is prepared by mixing methyl chloroformate (1 mol.) and methyl amidoformate (1 mol.) with 4 parts of toluene, and acting on the mixture with sodium (1 mol.). After filtration of the product, the unattacked sodium is removed from the residue, and the mass is treated with dilute sulphuric acid, which yields up to toluene a crystalline substance melting at 134° ; this is very soluble in water, alcohol, acetone, and chloroform, slightly soluble in ether, and almost insoluble in light petroleum. Nitrous acid has no action whatever on this substance, neither has it any action on ethyl dimethylamidoformate or on the corresponding methyl derivative.

Ethyl methylacetylamidoformate cannot be made by acting on ethyl nitrosomethylamidoformate with acetic anhydride or on ethyl methylcarbamate with the same reagent; but in presence of zinc chloride, the reaction occurs in the latter case. Ethyl methylcarbamate (60 grams), acetic anhydride (30 grams), and zinc chloride (4 grams) are heated for some minutes at the boiling point of the mixture until a yellow coloration is produced; the liquid is extracted with ether, and yields, on distillation, a liquid which boils at 189° (corr.) and has a sp. gr. 1.083 at 15° , its melting point being $8-9^\circ$. Nitrous acid does not act on this substance.

Ethyl nitrosomethylamidoformate, $\text{NO} \cdot \text{NMe} \cdot \text{COOEt}$. This red liquid is dissolved in all proportions by alcohol, ether, and benzene, and is but slightly soluble in water although distillable with steam. The analogy in the composition of this substance to that of ethyl nitromethylcarbamate led the author to treat it with ammonia, which does not react except in the presence of water, when it forms ethyl carbamate and methyl alcohol with evolution of nitrogen, pointing to the formation of a compound $\text{NHMe} \cdot \text{NO}$, which immediately decomposes. Aqueous solutions of mono- and of di-methylamine react similarly to form the compounds $\text{NHMe} \cdot \text{COOEt}$ and $\text{NMe}_2 \cdot \text{COOEt}$, boiling at 165° and 147° (corr.) respectively. Ethyl ethylcarbamate reacts on the substance with formation of nitrogen, carbonic anhydride, and ethyl methylamidoformate. In contradistinction to the nitro-derivative, $\text{NO}_2 \cdot \text{NMe} \cdot \text{COOEt}$, which yields with ammonia an acid nitramine, $\text{NHMe} \cdot \text{NO}_2$, the nitroso-derivative furnishes only decomposition products of a corresponding nitrosamine, $\text{NHMe} \cdot \text{NO}$; the author endeavoured to isolate its potassium and barium salts, but was unsuccessful. Mineral acids decompose ethyl nitrosomethylamidoformate with substitution of hydrogen for the group NO ; oxidation is effected by an acid solution of potassium permanganate, but the nitroso-compound is not converted into the nitro-compound.

By reduction of ethyl nitrosomethylamidoformate with zinc-dust and acetic acid, a colourless solution is formed, having strong reducing properties, and probably containing the hydrazine, $\text{NH}_2 \cdot \text{NMe} \cdot \text{COOEt}$; but this the author was unable to isolate, or to obtain a condensation product of, with aldehydes. At the same time, a small quantity of a white powder, which melts at $127-128^\circ$ and sublimes at 180° , is obtained; this appears to be ethyl dimethyltetrazonedicarboxylate, $\text{N}_2(\text{NMe} \cdot \text{COOEt})_2$. This substance is also formed when the liquid resulting from the reduction of a solution of the nitroso-compound

is oxidised by potassium permanganate, ferric chloride, or bromine water, the last reagent affording the better yield. It is soluble in alcohol, benzene, acetone, or acetic acid, but is insoluble in water, ether, light petroleum, or solutions of the aqueous hydroxides or the mineral acids.

By similar reactions, methyl nitrosoamidoformate yields the tetrazone, $N_4(NMe\cdot COOMe)_2$, which melts at 184° ; and methyl nitroso-methylamidoformate, the corresponding derivative, $N_4(NEt\cdot COOMe)_2$, melting at $88-89^\circ$. The author concludes with theoretical speculations as to the rationale of the reactions. T. G. N.

Reduction of Glycuronic Acid by Sodium Amalgam. By H. THIERFFELDER (*Zeit. physiol. Chem.*, 15, 71-76; compare Abstr., 1887, 717; 1889, 337).—Pure sodium glycuronate was dissolved in five times its weight of water in a loosely-stoppered flask, and a little 2.5 per cent. sodium amalgam added, when hydrogen was evolved; the liquid was then neutralised by sulphuric acid, and more amalgam added; after some weeks, all the glycuronic acid had disappeared. The liquid was filtered, acidified with sulphuric acid, and excess of alcohol added; the sodium sulphate thus precipitated was filtered off, and the filtrate evaporated to dryness on the water-bath, with the addition of barium carbonate. The residue was taken up with water, filtered, concentrated, acidified with sulphuric acid, and extracted with a mixture of alcohol and ether. The extract was evaporated to a syrup, when, after a short time, small, colourless crystals were deposited; on recrystallisation from water, rhombic crystals, 1 cm. long, were obtained. Details are given relating to the measurement of the crystals. The substance has a slightly sweet taste, is readily soluble in water, but only sparingly in alcohol. It melts at $178-180^\circ$, and has the composition $C_6H_{12}O_7$. Its barium, calcium, and potassium salts were examined. Examination of the solubilities and circular polarisation (the free acid is optically inactive) excluded gluconic and galactonic acids. It does not reduce Fehling's solution, so it cannot be mannitic acid. Similar considerations lead to the conclusion that it is not either of the three mannonic acids: so it is not the same as any known acid with the formula $C_6H_{12}O_8$; the nature of the new acid must therefore be the subject of renewed investigation.

W. D. H.

Action of Methyl Iodide on Furfurylamine. By M. ZENONI (*Gazzetta*, 20, 513-517).—Furfurylamine may be readily prepared in considerable quantities by reducing furfuraldoxime with alcohol and sodium. The yield is 20 per cent. When a solution of furfurylamine (1 part), in twice its volume of methyl alcohol, is heated with methyl iodide (5 parts), the product, after purification, is a white, crystalline powder which melts at $118-120^\circ$, and has the composition $C_6H_{14}ON$. This substance has the general properties of the iodides of the organic bases. It is soluble in water and alcohol, and is reprecipitated from the aqueous solution on addition of potash.

Its constitution is probably $CH \begin{smallmatrix} \nearrow CH\cdot C\cdot CH_2\cdot NMe_3I \\ \searrow CH\cdot O \end{smallmatrix}$. The correspond-

ing *hydroxide* is formed by the action of moist silver oxide on the iodide, and may be obtained as a deliquescent, crystalline mass which absorbs carbonic anhydride from the air. The *chloride* is obtained by treating the iodide with fresh moist silver chloride. It is a deliquescent crystalline compound. The *aurochloride*, $C_6H_4ONCl, AuCl$, *platinochloride*, and *picrate* are yellow, crystalline compounds; the latter melts with decomposition at about 180° .

On distilling the hydroxide, an alkaline liquid having an odour resembling that of trimethylamine and an oily product, which is resinified by hydrochloric acid, pass over. S. B. A. A.

Action of Acid Chlorides on Bases in presence of Alkalis. By C. SCHOTTEN (*Ber.*, 23, 3430—3431).—Polemical remarks on Marckwald's paper (this vol., p. 181).

Pyromucic and Dehydromucic Acids. By M. ZENONI (*Gazzetta*, 20, 517—520).—The author further confirms the results obtained by Oliveri and Peratoner (*Abstr.*, 1890, 1242); both the solid product of the distillation of mucic acid and the mother liquor, after sufficient purification, yielding ordinary pyromucic acid melting at 132 — 133° . In the course of the experiments, a considerable quantity of a reddish-yellow residue, consisting of dehydromucic acid, was obtained. This compound would appear to be more particularly formed when mucic acid is distilled at a low temperature. The *methyl* salt of this acid, $C_6H_2O_5Me_2$, crystallises from water in large, white needles, and melts at 112° . It is not affected by treatment with bromine or nitric acid.

The *hydrazone*, $C_6OH_3CO \cdot N_2H_2Ph$, obtained by heating the theoretical quantities of pyromucic acid and phenylhydrazine, crystallises in white needles, and melts at 142 — 143° ; its solution in concentrated sulphuric acid is coloured deep violet on the addition of ferric chloride. S. B. A. A.

Bromobenzonitriles. By M. SCHÖPFF (*Ber.*, 23, 3435—3440).—The best method of preparing these nitriles is to distil the corresponding bromobenzoic acids with lead thiocyanate. The yield of nitrile appears to be better the lower the melting point of the acid.

Orthobromobenzonitrile is formed by distilling orthobromobenzoic acid (20 grams) with lead thiocyanate (36 grams) and purifying the product by steam-distillation. It crystallises in white needles, melts at 51° , and boils at 251 — 253° (uncor.) under 754 mm. pressure. It is easily soluble in hot water and alcohol, and has a characteristic odour resembling that of benzaldehyde and benzonitrile. The yield amounts to 45 per cent. of the theoretical. Orthobromobenzonitrile can also be obtained by distilling orthobromobenzamide with phosphoric anhydride.

Orthobromobenzoic chloride, prepared by the action of equal weights of phosphorus pentachloride and orthobromobenzoic acid, is a colourless liquid which boils at 241 — 243° (uncor.) under 757 mm. pressure, and gradually solidifies after a time. It has an odour resembling that of benzoic chloride, but less pungent. It is slowly decomposed by cold water, more quickly by hot water, and reacts very energetically.

with ammonia. *Orthobromobenzamide*, prepared by treating the chloride with finely powdered ammonium carbonate at the temperature of the water-bath, crystallises from hot water or alcohol in long, hard needles, melts at 156° when heated rapidly, and sublimes above 100° .

Metabromobenzonitrile is obtained by distilling metabromobenzoic acid with lead thiocyanate, and is extracted from the distillate with ether, after the unaltered acid has been neutralised with dilute ammonia. It crystallises in needles, melts at 38° , and boils at 225° .

Parabromobenzonitrile is best prepared from parabromobenzamide by distillation with phosphoric anhydride and purification of the product by steam-distillation. Owing to the high melting point of parabromobenzoic acid, only 33 per cent. of the theoretical yield is obtained on distilling it with lead thiocyanate. It crystallises from hot water or alcohol in slender, white needles, melts at 113° , is somewhat less volatile with steam than the ortho-compound, sublimes in white needles, and boils at $235\text{--}237^{\circ}$ (uncorr.).

When orthobromobenzonitrile is nitrated and the product hydrolysed, it is converted into orthobromometanitrobenzoic acid melting at $179\text{--}180^{\circ}$. Parabromobenzonitrile, when treated in the same way, yields parabromometanitrobenzoic acid melting at 193° . The nitration is best effected by means of a mixture of potassium nitrate and sulphuric acid. By employing fuming nitric acid, the nitrile remains unaltered.

Orthobromometanitrobenzonitrile crystallises from water in needles, melts at 117° , and is volatile with steam.

Parabromometanitrobenzonitrile crystallises in white needles, melts at 120° , is not so volatile with steam as the ortho-compound, dissolves easily in hot water, alcohol, and acetone, less easily in chloroform and benzene, and is insoluble in light petroleum. The amide is alone formed if the parabromometanitrobenzonitrile is allowed to remain in the nitric acid mixture for a short time. The amide forms colourless needles, melts at 156° , and is not volatile with steam.

E. C. R.

Action of Methylchloroform on Phenol in presence of Potassium and Sodium Hydroxides. By P. BIGINELLI (*Chem. Cent.*, 1890, ii, 620; from *Ann. Chem. Farm.*, 12, 65—68).—With the object of generalising the reaction between chloroform and phenol in presence of potash, by which hydroxyaldehydes are produced, the author substituted methylchloroform for chloroform, when, if the reaction were similar, hydroxybenzyl methyl ketone, should be produced. Instead of this, a substance of the formula $C_{14}H_{12}O_2$ is formed, which the author regards as diphenylethylidene ether, $CH_2:C(OPh)_2$. It is very soluble in ether, and melts at $95\text{--}96^{\circ}$. It does not dissolve in potash, neither does it react with phenylhydrazine. With bromine water, a compound of the formula $C_{14}H_{12}Br_2O_2$ is formed without any hydrogen bromide being produced. It crystallises in plates which melt at 125° .

A second substance is formed in the above reaction, a liquid, which distils with steam; after drying over sulphuric acid, the analysis gave the formula $C_8H_8O_2$, which agrees with that of orthohydroxy-

acetophenone. It does not, however, appear to combine with phenylhydrazine, or with hydroxylamine. By treating it in methyl alcohol solution with sodium amalgam, a crystalline substance smelling strongly of oil of roses was obtained. J. W. L.

Tetrachlorophenol. By L. HUGOUNENQ (*Bull. Soc. Chim.* [3], 4, 8—9; compare Abstr., 1890, 241).—Tetrachloranisoil is heated with hydriodic acid of sp. gr. 1.5 (4 parts) in sealed tubes at 145—148° for 20 hours, and from the solution of the product in aqueous soda tetrachlorophenol is precipitated on the addition of hydrochloric acid, and after washing and drying, is crystallised from light petroleum. Thus prepared, it forms white needles, melts at 152°, is sublimable, and boils at 278° with decomposition. Tetrachlorophenol is insoluble in water, but dissolves in organic solvents; the alcoholic solution decomposes carbonates and seems not to be poisonous. A mixture of nitric and sulphuric acids decomposes the substance with formation of chloronitroquinones. The author has prepared the acetyl derivative, C_6HCl_4Ac , and the ammonium, silver, lead, and copper salts.

T. G. N.

Constitution of Thymoquinone and β -Hydroxythymoquinone Derivatives. (By G. MAZZARA, *Gazzetta*, 20, 481—485).—In a previous paper (see Abstr., 1890, 965), the preparation of β -hydroxythymoquinone from carvacrol [$Me:O_2:Pr:OH = 1:3:6:4:5$] was described. To characterise this compound more fully, the anilide and toluidide [$NHPh$ or $NH \cdot C_6H_4Me = 2$] were prepared by boiling the alcoholic solution of the quinone with aniline, or toluidine, respectively. The *anilide* crystallises from alcohol in minute, deep-blue scales, dissolves in alkaline hydroxides forming a violet solution, and melts at 185—187°, whilst the isomeride derived from α -hydroxythymoquinone melts at 135°. The *toluidide* also crystallises in blue scales which melt, however, at 196—197°; whereas the corresponding isomeride melts at 165°.

It is noticeable that in compounds derived from thymol, the melting point is lowered in passing from the nitro- to the dinitro-derivatives, and from the hydroxythymoquinone to either the anilide or toluidide, whilst the reverse occurs in the corresponding compounds from carvacrol.

The author regards it as finally established that the β -bromo- and β -bromohydro-thymoquinone are really α -derivatives [$Br = 2$].

S. B. A. A.

Thymoquinone Dioxime. By F. KEHREMANN and J. MESSINGER (*Ber.*, 23, 3557—3564).—As already shortly mentioned (Abstr., 1890, 1403), thymoquinone dioxime, $C_9H_7Pr^2Me(NO_2)_2$, may be obtained by the action of hydroxylamine on thymoquinone monoxime (nitrosothymol). In order to prepare it, a hot saturated alcoholic solution of the latter is boiled with double the theoretical quantity of hydroxylamine hydrochloride, the acid set free being nearly neutralised from time to time. The resulting crystalline powder is dissolved in warm soda, precipitated by acetic acid, and recrystallised from boiling alcohol. It forms yellowish-white granules, which are

insoluble in water and ammonia, sparingly soluble in cold alcohol and acetic acid, and readily in solutions of the caustic alkalis, forming salts which are decomposed by carbonic anhydride. It becomes brown at 200° and decomposes with evolution of gas at 235°. Its solution in soda has the colour of an alkaline solution of potassium ferricyanide, and on the addition of very concentrated alkali, the sodium salt separates out in golden-yellow, prismatic crystals which are very soluble in water. The dioxime is not identical with the polythymoquinone dioxime described by Liebermann and Ilinski (Abstr., 1886, 239).

When an alkaline solution of potassium ferricyanide is added to a similar solution of thymoquinone dioxime, a green, flocculent precipitate of *dinitrosoecumene* separates. It has an odour resembling that of iodine and of thymoquinone, and is volatile with steam, undergoing considerable decomposition at the same time. It is soluble in alcohol, ether, and acetic acid with an intense green colour, the solutions also rapidly undergoing decomposition. In the dry state, it is fairly stable, and melts at 72° to a greenish-yellow liquid which then solidifies and again melts at 130° with decomposition. The authors regard it as most probable that the compound has the formula

When boiled with nitric acid of sp. gr. 1.35, it is converted into *paradinitroecumene*, $\text{C}_6\text{H}_2\text{MePr}^\alpha(\text{NO}_2)_2$, which crystallises from hot dilute alcohol in large, colourless, thick prisms, melts at 77–78°, and is readily soluble in alcohol, ether, acetic acid, and benzene. When reduced with tin and hydrochloric acid, it yields *paradiamidocumene*, which may be more readily obtained from thymoquinone dioxime by suspending it in alcohol, warming with an excess of stannous chloride and hydrochloric acid, evaporating the alcohol, diluting with water, and adding aqueous soda. The base is extracted with ether, and the solution agitated with concentrated hydrochloric acid as long as separation of the hydrochloride takes place. The latter is dissolved in the least possible quantity of hot water, and concentrated hydrochloric acid added; it then separates in well-developed, colourless, four-sided plates, which are quite stable in the air, whereas the free base readily undergoes oxidation. The diamidocumene hydrochloride obtained by Liebermann and Ilinski (*loc. cit.*) is identical with the foregoing, but the latter investigators do not appear to have obtained it quite pure.

On boiling *paradiamidocumene* hydrochloride with acetic anhydride and anhydrous sodium acetate, it yields the *diacetyl* compound, $\text{C}_{14}\text{H}_{20}\text{N}_2\text{O}_4$, crystallising in slender, white, silky needles and melting at 260°.

H. G. C.

Cholesterol. By K. OBERMÜLLER (*Zeit. physiol. Chem.*, 15, 37–48).—Two formulae, $\text{C}_{26}\text{H}_{44}\text{O}$ and $\text{C}_{27}\text{H}_{46}\text{O}$ (Reinitzer, Abstr., 1888, 1076), have been ascribed to cholesterol (cholesterin). The chief object of the present research was, by the analysis of certain cholesterol compounds, to determine which is the correct one. The general result of the

analyses is that Reinitzer's formula is correct. The following compounds were prepared :—

Potassium cholest-eroxide, $C_{27}H_{45}OK$, was prepared by placing potassium in an ethereal solution of cholesterol. It agrees in all its properties with Reinitzer's sodium cholesteroxide.

Cholesteryl propionate, $C_{27}H_{45}\cdot C_3H_5O_2$, was prepared by heating a mixture of cholesterol with propionic anhydride on the water-bath for half-an-hour; on cooling, it sets to a fatty mass; this is extracted with ether, and the propionate precipitated from the extract by alcohol in the form of rhombic plates; melting point 98° . It is easily soluble in ether, benzene, and carbon bisulphide, sparingly soluble in alcohol. After fusion, there is, on cooling, a play of colours observed, blue, green, orange, and red, in the order named, by reflected light; the complementary colours are seen by transmitted light. In order to use this reaction as a test for cholesterol, the latter must first be obtained in a pure condition; it may be most readily freed from the fats with which it is usually mixed by the method of saponification before described (Abstr., 1890, 1474).

Cholesteryl benzoate, $C_{27}H_{45}\cdot C_7H_5O_2$.—This is best prepared by the action of benzoic chloride on cholesterol; and this preparation may be used for the quantitative estimation of cholesterol. The crystals are plates which show two melting points, namely, 145° and 178° . A compound with similar properties was prepared from ischolesterol.

Cholesteryl phthalate, $C_6H_4(COO\cdot C_{27}H_{45})_2$, was prepared by heating phthalic anhydride and cholesterol at 180° , and crystals obtained by the addition of alcohol to a hot ethereal solution. It is sparingly soluble in cold ether; melting point $182\cdot5^\circ$.

Cholesteryl benzyl ether, $C_{27}H_{45}\cdot O\cdot C_7H_7$, prepared by heating sodium cholesteroxide and benzyl chloride at 100° , was crystallised from an alcoholic-etheral solution in thin plates melting at 78° .

Cholesteryl propionate dibromide, $C_{27}H_{45}Br_2\cdot C_3H_5O_2$.—This additive product is similar to that prepared previously by Wislicenus and Moldenbauer, $C_{27}H_{45}Br_2O$ (*Annalen*, 146, 178), by the action of broxine dissolved in carbon bisulphide on pure cholesterol, and to that prepared by Reinitzer (*Wiener Monatsh.*, 1888, Heft 5), by the action of bromine on cholesteryl acetate. This substance is important, as the relation between carbon and bromine gives a key to the formula of cholesterol. *Cholesteryl bromobenzoate*, $C_7H_4BrO_2\cdot C_{27}H_{45}$, was also prepared and analysed.

W. D. H.

Derivatives of Diphenylamine. By O. ERNST (*Ber.*, 23, 3423—3430).—*Amidochlorodiphenylamine*,

is prepared by the reduction of the nitro-compound with stannous chloride, tin, and hydrochloric acid in alcoholic solution; it crystallises from alcohol in long, colourless needles, melts at 99° , and is readily soluble in ether, benzene, and chloroform. The *picrate* crystallises in yellowish-brown plates. The *acetyl derivative*,

is formed by the action of the calculated quantity of acetic anhydride at 100° , and crystallises from alcohol in silky, lustrous needles which melt at 150° .

Ethenylorthamidochlorodiphenylamine, $\text{CMe} \begin{smallmatrix} \text{NPh} \\ \text{N} \end{smallmatrix} \text{C}_6\text{H}_4\text{Cl}$, is obtained on boiling the amido-compound with excess of acetic anhydride; it crystallises with difficulty in small, colourless needles. The *platinochloride* crystallises from alcohol in long, brown needles.

Phenylazimidochlorobenzene, $\text{N} \begin{smallmatrix} \text{NPh} \\ \text{N} \end{smallmatrix} \text{C}_6\text{H}_4\text{Cl}$, is prepared by the action of nitrous acid on orthamidochlorodiphenylamine; it crystallises from alcohol in colourless, lustrous needles, and melts at 128° .

By the oxidation of an acid solution of amidochlorodiphenylamine with ferric chloride, a violet-red dye is produced, the *hydrochloride* of which crystallises in yellowish-green, metallic, lustrous needles; the *picrate* is deposited in dark-green needles; the *sulphate* resembles the hydrochloride. The free *base* is obtained by the action of ammonia on the salts, as a brownish-red, crystalline precipitate.

On heating orthamidochlorodiphenylamine with an equal molecular proportion of aniline hydrochloride at 200° , a deep-blue colouring matter is formed; dilute solutions exhibit a copper-red fluorescence. The addition of ammonia changes the colour to reddish-violet with yellow-red fluorescence. A similar substance is formed by heating orthamidochlorodiphenylamine hydrochloride alone. This compound probably belongs to the fluorindine group, but its constitution, like that of the previous dye, is unknown.

Dinitrophenylamidotoluyllamine, $\text{C}_6\text{H}_3(\text{NO}_2)_2\text{NH}\cdot\text{C}_6\text{H}_4\text{Me}\cdot\text{NH}_2$,

is prepared by the action of dinitrochlorobenzene on orthotoluylenediamine; it crystallises from alcohol in brownish-yellow needles, melts at 147° , and is insoluble in water, but readily dissolves in benzene or chloroform. The compound is soluble in acids, with a pale-yellow colour.

Dinitrophenylazimidotoluene, $\text{N} \begin{smallmatrix} \text{C}_6\text{H}_4\text{Me} \\ \text{N} \end{smallmatrix} \text{N}\cdot\text{C}_6\text{H}_3(\text{NO}_2)_2$, is prepared by the action of nitrous acid on the previous compound; it crystallises from alcohol in small, pale, brownish-yellow needles, melts at 186° , and is insoluble in ether, but readily dissolves in benzene, chloroform, or glacial acetic acid.

Dinitrophenyl- β -naphthylamine, $\text{C}_{10}\text{H}_7\text{NH}\cdot\text{C}_6\text{H}_3(\text{NO}_2)_2$ [$\text{NH} : (\text{NO}_2)_2 = 1 : 2 : 4$], is prepared from dinitrochlorobenzene and β -naphthylamine; it is somewhat sparingly soluble in alcohol, from which it is deposited in brick-red crystals, and melts at 179° .

Dinitrophenyl- β -naphthol, $\text{C}_{10}\text{H}_7\text{O}\cdot\text{C}_6\text{H}_3(\text{NO}_2)_2$ [$\text{O} : (\text{NO}_2)_2 = 1 : 2 : 4$], is obtained from β -naphthol as a pale-yellow, viscous liquid which solidifies after some time, and crystallises from alcohol in stellate groups of pale-yellow needles melting at 95° .

The corresponding diamido-derivatives are prepared by the reduction of these three nitro-compounds; *diamidophenylamidotoluyllamine*

and *diamidophenyl-β-naphthylamine* yield azo-derivatives on oxidation, but *diamidophenyl-β-naphthol* does not yield any colouring matter.

J. B. T.

Action of Phosphorus Pentachloride on Hydroxyazobenzene. By K. HEUMANN and R. PAGANINI (*Ber.*, 23, 3550—3554).—The action of phosphorus pentachloride on hydroxyazobenzene was first examined in 1870 by Kekulé and Hidegh (*Ber.*, 3, 235), who obtained a compound which they believed to be hydroxyazobenzene,

The reaction was also examined by Wallach and Belli, and Wallach and Kiepenheuer (*Abstr.*, 1880, 556; 1882, 393), who also found the formula $\text{C}_{12}\text{H}_{10}\text{N}_2\text{O}_2$, and showed that the substance is reconverted by sodium in alcoholic solution into hydroxyazobenzene, but that it does not yield an acetyl compound, and is insoluble in alkalis. The last two properties are not in favour of the above constitutional formula, and the authors have therefore reinvestigated the reaction. They find that when equal parts of hydroxyazobenzene and phosphorus pentachloride are warmed on the water-bath until evolution of hydrogen chloride ceases, and the product no longer dissolves in alkali with a deep-yellow colour, a mixture of two compounds is obtained which may be separated by the difference in their solubilities in alcohol. The one agrees in all its properties with the so-called hydroxyazoxybenzene, and crystallises from acetone in golden-yellow plates melting at 148° . It was, however, found to contain phosphorus, the empirical formula being $\text{C}_{30}\text{H}_{27}\text{N}_6\text{O}_4\text{P}$, which agrees equally well with the figures for carbon, hydrogen, and nitrogen given by the investigators named above. Its ready conversion into hydroxyazobenzene is due, not to a reducing action, but to the alkali present, as zinc-dust and alcohol are without action on it. It is therefore *benzeneazophenyl phosphate*, $\text{PO}(\text{O} \cdot \text{C}_6\text{H}_4 \cdot \text{N} \cdot \text{NPh})_2$, and may also be prepared by acting on the potassium salt of hydroxyazobenzene with phosphorus oxychloride.

The second product of the reaction crystallises in broad, orange-yellow needles, melts at 88° , and sublimes in golden plates. It is identical with the parachlorazobenzene prepared by Heumann and Mentha (*Abstr.*, 1886, 874) from paramidoazobenzene. H. G. C.

Thiophenylhydrazine. By J. RUHL (*Ber.*, 23, 3482—3483).—*Thiophenylhydrazine*, $\text{S}(\text{C}_6\text{H}_4 \cdot \text{NH} \cdot \text{NH}_2)_2$, may be readily obtained from thioaniline by diazotising, adding sodium hydrogen sulphite, and reducing with zinc-dust. On the addition of concentrated hydrochloric acid, the *hydrochloride* separates out as a sparingly soluble salt, which is collected, pressed, dissolved in water, and treated with alkali, which precipitates the free base in small plates. The latter, after washing with cold water, is recrystallised from the hot liquid, and separates in yellowish, lustrous plates which, on drying, form a mass resembling paper. It melts at 115° , decomposes at 130° , is sparingly soluble in cold, more readily in hot water, easily in alcohol and reduces Fehling's solution in the cold. Its *hydrochloride* and *sulphate* form white powders.

Thiophenylhydrazine readily combines with 2 mols. benzaldehyde, forming the crystalline hydrazone, $S(C_6H_4N_2H:CHPh)_2$; it also combines with phenylcarbamide.
H. G. C.

Diamylphenylhydrazone. By S. GRIMALDI (*Chem. Centr.*, 1890, ii, 553; from *L'Orosi*, 13, 190—193).—In manner similar to that used for the preparation of nonylmethylphenylhydrazone (Abstr., 1890, 1394), the author has now prepared its isomeride, *diamylphenylhydrazone*, from diamyl ketone, which was obtained by the dry distillation of calcium capronate. The ketone combines readily with phenylhydrazine, the elimination of water commencing at ordinary temperatures, and considerable development of heat occurring during the process. *Diamylphenylhydrazone*, $C(C_5H_{11})_2N:NHPh$, is an oily, slightly-red liquid, having a strong, agreeable odour, but burning taste. It is neutral, insoluble in water, soluble in ether, alcohol, chloroform, &c.; sp. gr. = 0.93896 at 0°. It remains fluid at -9.5°.

J. W. L.

Isomeric Forms of Orthonitrophenylglyoxylic Hydrazone. By A. KRAUSE (*Ber.*, 23, 3617—3622; compare Fehrlin, Abstr., 1890, 1117).—The hydrazone is converted into an isomeric form (m. p. 188—189°) by the action of aqueous potash in the cold; soda is, however, without action. Both compounds yield lead salts, from which, on treatment with sulphuric acid, the original substances are regenerated. Isatic hydrazone, together with a little aniline, is formed from each compound on reduction with stannous chloride.

By heating the hydrazone with sodium ethoxide and twice the molecular proportion of ethyl iodide in a sealed tube for three hours at 130—140°, the *ethyl salt* is obtained, crystallising from alcohol in yellow prisms melting at 126—128°. No diethyl derivative could be prepared.

When treated with hydrochloric acid, the hydrazone decomposes into ammonia, aniline, and resinous matters.

Metanitrophenylglyoxylic hydrazone is dissolved in alcohol and treated with aqueous potash; a sparingly soluble salt is formed which is allowed to remain for 24 hours; on the addition of hydrochloric acid, evolution of gas takes place, and a green, insoluble compound is obtained which melts at 284—285°.

The author considers that from these results the formulæ previously advanced for the two orthonitro-derivatives are no longer probable, and he suggests that the isomerism of the compounds may be of a stereometric nature, similar to that of many oximes, and explicable by the same hypotheses.

J. B. T.

Phenacyl Sulphide. By J. TAFEL and A. MAURITZ (*Ber.*, 23, 3474—3475).—In a paper recently published by Delisle (*Annalen*, 260, 250), the latter has described acetyl phenyl sulphide, and has announced his intention of preparing other ketonic sulphides. The authors have already obtained *phenacyl sulphide*, $S(CH_2COPh)_2$, and in view of the above paper of Delisle, now publish the results of their investigation.

Phenacyl sulphide is readily prepared by dissolving 100 parts of

bromacetophenone in 400 parts of alcohol, and adding a solution of 12 parts of sodium in 400 parts of alcohol saturated with hydrogen sulphide, cooling well during the addition, and subsequently heating for a short time on the water-bath. It crystallises from alcohol in compact, colourless prisms, melts at 77° , is very slightly soluble in hot water, readily in alcohol, acetic acid, chloroform, and benzene, and also dissolves in cold concentrated sulphuric acid with a yellow colour. It is coloured yellow by boiling alkalis, and reduces Fehling's solution without deposition of capric sulphide. On treatment with an alkaline solution of hydroxylamine, it yields the *dioxime*,

which is recrystallised from acetic acid. It melts at 151° , and is sparingly soluble in water, light petroleum, and benzene, readily in alcohol, ether, and acetic acid. The *dihydrazone*,

obtained by heating the sulphide with phenylhydrazine at 100° , crystallises from alcohol in slender, colourless needles which become yellow in the air; it melts at $146-147^{\circ}$. It is readily soluble in benzene and chloroform, almost insoluble in water and dilute acids, but dissolves in cold concentrated sulphuric acid with a yellowish-green colour.

When bromacetophenone is boiled with alcoholic soda, it yields a crystalline compound of as yet unascertained constitution, which seems to have the formula $C_{16}H_{13}O_2Br$.

H. G. C.

Metaparadiamidobenzoic Acid. By A. ZEHRA (*Ber.*, 23, 3625—3635).—[N : H : C = 1 : 2 : 4] *Difuranylquinoxalinemetacarboxylic acid*, $\begin{matrix} C(C_4H_3O):N \\ C(C_4H_3O):N \end{matrix} > C_6H_3 \cdot COOH$, is prepared by the action of

furile on metaparadiamidobenzoic acid in glacial acetic acid solution; it crystallises from alcohol in pale-yellow needles, softens at 235° , and melts at 245° . The compound is insoluble in benzene, but dissolves in dilute ammonia or alkaline carbonates; with hydrochloric acid, it yields a yellowish-red colour, whilst the sulphuric acid solution is cherry-red, and the original substance is precipitated unchanged on the addition of water. The *barium salt*, $(C_{17}H_9N_2O_4)_2Ba$, crystallises in pale-yellow needles.

Diphenylquinoxalinemetacarboxylic acid, $\begin{matrix} CPh:N \\ CPh:N \end{matrix} > C_6H_3 \cdot COOH$, prepared from diamidobenzoic acid and benzile, crystallises from glacial acetic acid or alcohol in yellowish plates or needles, softens at 280° , and melts at 285° . It is very sparingly soluble in organic media, but dissolves in alkaline carbonates and hydrochloric acid. The *barium salt*, $(C_{21}H_{11}N_2O_4)_2Ba + 3H_2O$, crystallises from dilute alcohol in small, white needles. The *ethyl salt* is deposited from alcohol in white needles, melts at 151° , and is insoluble in ammonia.

Dimethylquinoxalinemetacarboxylic acid, $\begin{matrix} CMe:N \\ CMe:N \end{matrix} > C_6H_3 \cdot COOH$, is

prepared from diamidobenzoic acid and diacetyl; it crystallises from alcohol in small, white needles, softens at 250° , and melts at $257-260^{\circ}$ with decomposition. It is readily soluble in alkaline carbonates and hydrochloric acid, but more sparingly in benzene or ether. The silver salt, $C_{11}H_9N_2O_4Ag$, is obtained in small, white, insoluble needles.

Methylhydroxyquinoxalinecarboxylic acid, $\begin{matrix} CMe=N \\ C(OH):N \end{matrix} > C_6H_3 \cdot COOH$,

prepared from diamidobenzoic acid and pyruvic acid, resembles the previous compound, and crystallises in white needles which blacken at 330° without melting. The barium salt, $(C_{10}H_7N_2O_3)_2Ba + 3H_2O$, is deposited in pale-yellow needles.

Methyl phenylenediacarboxymetaparadicarbamate,

is obtained from diamidobenzoic acid and methyl chloroformate; it crystallises in lustrous needles, softens at 300° and melts at 350° with gas evolution; it is insoluble in water, but dissolves in alkaline carbonates. The silver salt is gelatinous.

Carbamidometaphenylcarboxylic acid, $CO < \begin{matrix} NH \\ NH \end{matrix} > C_6H_3 \cdot COOH$, prepared from diamidobenzoic acid and carbonyl chloride, is deposited in small needles or plates which are scarcely altered at 360° ; it is very sparingly soluble except in alkaline carbonates.

Diacetylmeparadiamidobenzoic acid, $C_6H_3(NHAc)_2 \cdot COOH$, crystallises from alcohol in small, white needles, melts at 218° with evolution of gas, and is sparingly soluble in dilute hydrochloric acid.

Formylparamidobenzoic acid, $COOH \cdot C_6H_4 \cdot NH \cdot COH$ [$N : C = 1 : 4$], is prepared by dissolving paramidobenzoic acid in concentrated formic acid; it crystallises from alcohol in short, white needles and melts at 268° with decomposition. *Metanitroformylparamidobenzoic acid* is formed by the action of fuming nitric acid on the previous compound; it crystallises from alcohol in pale yellow needles, and melts at 221° with evolution of gas.

Methenylamidinophenylenemetacarboxylic acid,

is prepared by the reduction of the nitro-compound, and crystallises from dilute formic acid in white needles which decompose at 325° without melting. The hydrochloride, sulphate, and nitrate are crystalline.

J. B. T.

Substitution of the Anilido-group for Halogen Atoms in the Benzene Nucleus. By M. SCHOPFF (*Ber.*, 23, 3440—3445).—The behaviour of aniline towards parabromometanitrobenzoic acid has already been described (compare Abstr., 1890, 374). The author finds that a similar reaction takes place between aniline and ortho-bromometanitrobenzoic acid and the corresponding ortho- and para-nitriles and amides and the sodium salts of the acids.

Metanitro-orthanilidobenzoic acid, $NHPh \cdot C_6H_3(NO_2) \cdot COOH$, prepared by the action of aniline on orthobromometanitrobenzoic acid, is

obtained in small, straw-coloured needles, by precipitating its alcoholic solution with water; it melts at $247-248^{\circ}$. The anhydrous sodium salt is obtained as a brick-red compound by adding the theoretical quantity of sodium to a solution of the acid in absolute alcohol; it absorbs moisture from the air, and then crystallises in yellow needles containing 2 mols. H_2O , which are lost over sulphuric acid. The barium, calcium, lead, copper, silver, and mercury salts were also prepared. The *ethyl* salt of the above acid crystallises from alcohol in yellow plates, and melts at 121° .

Metanitroparanilidobenzonitrile, $NHPh \cdot C_6H_5(NO_2) \cdot CN$, is obtained by carefully heating the bromonitrile with aniline for a short time; it crystallises from alcohol in short, brick-red needles or plates and from hot water in needles, melts at 126° , and is easily soluble in alcohol, acetone, chloroform, and benzene, less soluble in light petroleum. Nitranilidobenzanilide and nitranilidobenzamide are formed in this reaction if the heating is prolonged, as the hydrogen bromide liberated in the formation of the anilidonitrile hydrolyses it to amide. These two compounds are easily separated, as the former is only slightly, the latter easily, soluble in hot alcohol. Metanitroparanilidobenzamide crystallises in yellow needles, melts at 187° , and by the further action of aniline is converted into metanitroparanilidobenzanilide.

Metanitro-orthanilidobenzonitrile, $NHPh \cdot C_6H_5(NO_2) \cdot CN$, is sparingly soluble in hot water, but easily soluble in alcohol; by precipitation with water, it is obtained in lemon-yellow needles which melt at 170° . Unlike the para-compound, it is not hydrolysed by prolonged heating with the hydrogen bromide formed in the reaction.

E. C. R.

Derivatives of Parabromometanitrobenzoic Acid. By A. GROHMANN (*Ber.*, 23, 3445—3450).—*Parabromometanitrobenzoic chloride*, $NO_2 \cdot C_6H_4 \cdot Br \cdot COCl$, obtained by the action of phosphorus pentachloride on parabromometanitrobenzoic acid, forms yellowish-white needles, melts at $51-53^{\circ}$, and is soluble in benzene, acetone, and chloroform, slightly soluble in light petroleum. When this compound is gently warmed with aniline, parabromometanitrobenzanilide is formed; at a higher temperature and in presence of excess of aniline, metanitroparanilidobenzanilide is formed. *Parabromometanitrobenzanilide* crystallises from alcohol in beautiful, orange-yellow crystals belonging to the monosymmetric system, and melts at 156° . It is soluble in alcohol, ether, benzene, carbon bisulphide, chloroform, and acetone, sparingly soluble in light petroleum, and insoluble in water. *Metanitroparanilidobenzanilide* forms leafy crystals, melts at 216° , and is soluble in alcohol, benzene, chloroform, acetone, and acetic acid, but insoluble in light petroleum.

Parabromometanitrobenzamide is best prepared by warming the chloride with ammonium carbonate. It crystallises from alcohol in colourless needles, melts at 156° (compare preceding abstract) and is soluble in alcohol, ether, and acetone, insoluble in water, light petroleum, chloroform, benzene, and carbon bisulphide. *Metanitroparanilidobenzanilide*, obtained by heating the bromamide with alcoholic

ammonia at 180°, crystallises in lemon-yellow needles, melts at 227°, and is soluble in acetone, acetic acid, sparingly in alcohol, and insoluble in water, benzene, light petroleum, and chloroform.

By the action of ammonia or aniline on ethyl parabromometanitrobenzoate, the halogen is displaced by the amido- or anilido-group; the ethoxy-group remains unaltered.

Ethyl metanitroparamidobenzoate melts at 145° and is soluble in alcohol, benzene, chloroform, acetone, ether, acetic acid, and aniline, insoluble in light petroleum. *Ethyl metanitroparanilidobenzoate* melts at 123° (compare Abstr., 1890, 374). E. C. R.

Toluidonitrobenzoic Acid and Naphthylamidonitrobenzoic Acid. By E. HEIDENBLEBEN (*Ber.*, 23, 3451—3458).—*Metanitropara-(ortho)toluidobenzoic acid*, $C_6H_4Me \cdot NH \cdot C_6H_3(NO_2) \cdot COOH$, is prepared by heating equal weights of orthotoluidine, bromonitrobenzoic acid, and glycerol in a reflux apparatus until the liquid, on cooling, solidifies to a brown mass. It crystallises from dilute alcohol in bright-brown needles, melts at 210—211°, and is easily soluble in alcohol, chloroform, benzene, acetic acid, and ether. The sodium salt, prepared by adding sodium to the alcoholic solution of the acid, crystallises in beautiful, dark-red needles. The *ethyl* salt forms bright-yellow plates, melts at 106°, and is easily soluble in alcohol, ether, chloroform and benzene.

Metamidopara(ortho)toluidobenzoic acid,

is prepared by heating the nitro-acid with alcoholic ammonium sulphide at 120°. It crystallises from dilute alcohol in white needles, melts at 167°, rapidly colours in the air, and dissolves in alcohol, acetone, and benzene. The *ethyl* salt is prepared by reducing the corresponding nitro-compound with alcoholic ammonium sulphide; it melts at 115°, and is easily soluble in alcohol, ether, and chloroform, slightly soluble in benzene.

Metanitropara(para)toluidobenzoic acid,

has already been described by M. Schöppf. The sodium salt forms beautiful, dark-red needles. The *ethyl* salt crystallises in beautiful dark-yellow shining plates, melts at 115°, and is easily soluble in alcohol, ether, and benzene.

Metamidopara(para)toluidobenzoic acid,

crystallises from dilute alcohol in bright yellow needles, melts at 155.5°, and is easily soluble in alcohol and acetone, insoluble in water. The *ethyl* salt crystallises in colourless needles, which turn blue on exposure to air, melts at 145°, and dissolves easily in alcohol, ether, and chloroform, sparingly in benzene.

Azimidopara(para)toluidobenzoic acid is obtained by acting on metamidopara(para)toluidobenzoic acid (2 grams) dissolved in absolute alcohol (20 c.c.), with amyl nitrite (4 c.c.), and a few drops of

concentrated hydrochloric acid. It crystallises from alcohol in beautiful, rose-red needles, and melts at 271° . The nitrazimido-compound is obtained by dissolving the azimido-compound in fuming nitric acid and precipitating with water. It forms a yellowish-white, non-crystalline powder, and melts at 253° .

Orthamidophenylpara(para)tolylamine, $C_6H_4Me \cdot NH \cdot C_6H_4 \cdot NH_2$, is obtained by distilling the amido-acid under diminished pressure, and may be purified by precipitation from its aqueous solution with ammonia. It crystallises from water in colourless plates which redden on exposure to air, melts at 74° , and is easily soluble in alcohol, ether, chloroform, and benzene. When dissolved in hydrochloric acid, oxidation takes place, and the solution becomes red.

Metanitropara- β -naphthylamidobenzoic acid,

is best prepared by heating a mixture of parabromometanitrobenzoic acid (1 part), β -naphthylamine (2 parts), and glycerol (3 parts) to boiling in a reflux apparatus. The compound, when pure, is brick-red, and is soluble in alcohol, acetone, and acetic acid, less soluble in benzene and chloroform, and insoluble in water. The sodium salt is a red, amorphous powder soluble in water. The *ethyl* salt crystallises from ether in beautiful, bright-yellow needles, melts at 127.5° , and is soluble in alcohol, acetone, acetic acid, and chloroform.

Metanitropara- α -naphthylamidobenzoic acid is prepared in the same way as the β -acid. It forms a red-brown, amorphous powder, and is easily soluble in dilute alcohol, &c., and somewhat soluble in hot water. The *sodium* salt forms a dark-red, amorphous powder. The *ethyl* salt crystallises in beautiful, red-brown plates, melts at 109° , and is easily soluble in alcohol, benzene, acetic acid, and chloroform.

Metamidopara- α -naphthylamidobenzoic acid,

prepared by reducing the nitro-acid with alcoholic ammonium sulphide, crystallises in white needles, which become red on exposure to air, decomposes at 90° , and is easily soluble in alcohol, benzene, ether, and chloroform, insoluble in water. E. C. R.

Nitration of Hydroxybenzoic Acids by Nitrous Acid. By A. DENINGER (*J. pr. Chem.* [2], 42, 550—553).—When salicylic acid is nitrated with nitric acid, the nitro-acid of m. p. 228° is the chief product, that of m. p. 144° being obtained in small quantity only. By the following methods, each can be obtained practically free from the other.

Asymmetrical metanitrosalicylic acid [m. p. 228° ; $COOH : OH : NO_2 = 1 : 2 : 5$] is obtained by mixing salicylic acid (100 grams) and sodium nitrite (130 grams) with water (150 grams), and slowly adding 1.2 litres of sulphuric acid (sp. gr. 1.52), so that the temperature may not rise above 15° , vigorous stirring being kept up during the process. After some four hours, the liquid is warmed to 50° ,

and after several hours more, the solid is filtered and recrystallised from water.

Consecutive metanitrosalicylic acid (m. p. 144°) is obtained by mixing salicylic acid (100 grams) and sodium nitrite (170 grams), with water (150 grams), and adding 1 litre of sulphuric acid (sp. gr. 1.52) at 60° all at once, so that the temperature may rise quickly, as otherwise much of the acid of m. p. 228° will be formed. The solution of the solid mass in water must be heated with animal charcoal for some time to eliminate orthonitrophenol.

Metanitroparahydroxybenzoic acid (m. p. 185°) is obtained by mixing parahydroxybenzoic acid (100 grams) and sodium nitrite (200 grams) with water (200 grams), adding 1 litre of sulphuric acid (sp. gr. 1.52) at 40° , and heating for a long time on the water-bath. When sodium nitrite and cold sulphuric acid are added to the parahydroxy-acid, no nitro-acid is formed; but, if the nitrite and sulphuric acid are mixed first, and the hydroxybenzoic acid then added, the yield of nitro-acid is abundant; this shows that the formation of nitro-ylsulphuric acid is necessary, a conclusion proved by substituting this acid for the mixed sodium nitrite and sulphuric acid with good results. Phenol cannot be nitrated like this. A. G. B.

Ortho- and Meta-cresotic Acid. By R. NIETZKI and F. RUPPERT (*Ber.*, 23, 3476—3480).—Orthocresotic acid unites with diazobenzene chloride in the usual manner, forming an azo-dye, which is readily converted by reduction with stannous chloride into *amid-orthocresotic acid*. On the addition of concentrated hydrochloric acid, the *hydrochloride* separates as a precipitate which is readily soluble in water, although but sparingly in hydrochloric acid, and may be readily purified by dissolving in water and precipitating with acid. On dissolving it in aqueous sodium carbonate and saturating with acetic acid, the free amido-acid is obtained in small, colourless plates, which are very sparingly soluble in the common solvents, and melt with decomposition above 300° . According to Jacobsen, orthocresotic acid has the constitution $[\text{OH} : \text{Me} : \text{COOH} = 1 : 2 : 6]$, and as the azo-group almost invariably replaces the hydrogen atom in the para-position to the hydroxyl group, it is probable that the amido-group in the above acid occupies the position 4.

When amidorthocresotic acid is treated with acetic anhydride and sodium acetate, it yields a *diacetyl* compound, which is very soluble and difficult to purify. On warming it with dilute alkali, the acetyl group in combination with the hydroxyl is eliminated, and on the addition of an acid, the *monacetyl* derivative is precipitated in small, colourless needles melting at 275° . On treating the amido-acid with nitrous acid, a very stable diazo-compound is formed, which may be recrystallised from hot water; on reduction, it yields a hydrazine derivative. On distilling the acid with quicklime or sodium carbonate, it yields paramidorthocresol, thus confirming the above assumption with regard to the position of the amido-group.

When acetylamidocresotic acid is nitrated in acetic acid solution, the carboxyl group is eliminated, and its place taken by the nitro-group. The *acetylamidonitrocresol* thus formed crystallises from

alcohol in thick, yellow needles which melt at 217° ; on boiling with dilute sulphuric acid, it yields the corresponding amidonitrocresol. This separates from alcoholic solution in long, brownish-red needles melting at 118° , and forms beautiful, red, crystalline salts with alkalis. On treatment with nitrous acid, it yields a diazo-compound, crystallising in yellow needles, which may be dried at $70-80^{\circ}$, but explode at a higher temperature. It is almost unaltered by boiling alcohol, but the diazo-group may be removed if a moderate quantity of alkali be added to the boiling solution. The nitrocresol thus formed is identical with the one obtained by Hofmann and v. Miller, which has the constitution $[\text{Me} : \text{OH} : \text{NO}_2 = 1 : 2 : 3]$, showing that the nitro-group has, in reality, taken the position previously occupied by the carboxyl.

Metacresotic acid was treated in exactly the same manner as the ortho-compound. The *amidometacresotic acid* obtained from it forms small, colourless plates which melt at 265° . From analogy, the most probable constitution is $[\text{OH} : \text{Me} : \text{COOH} = 1 : 3 : 4 : 6]$, and this is proved by the fact that, on distillation with sodium carbonate, it yields paramidometacresol, which is converted by oxidation into toluquinone. On treatment with nitrous acid, amidometacresotic acid yields a diazo-compound similar to that obtained from the ortho-compound; this also yields a hydrazine on reduction. The *diacetyl* and *monoacetyl* compounds are also obtained in a similar manner. The latter may also be nitrated with elimination of the carboxyl group, but in this case a dinitro-compound is obtained, which forms thick, yellow crystals melting at 225° , and has acid properties, forming a potassium salt which crystallises in beautiful, red needles. On warming with dilute sulphuric acid, it yields *amidodinitrocresol*, which crystallises from alcohol in ruby-red needles melting at 160° , and has both acid and basic properties. On heating with acetic anhydride, it yields a *diacetyl* derivative melting at 175° .

When amidodinitrocresol is treated with nitrous acid, it yields a very explosive diazo-compound, crystallising in yellow plates. The diazo-group may be removed by boiling with alcohol in weak alkaline solution; the dinitrocresol thus obtained crystallises in orange-red needles melting at 99° . The constitution of the latter can only be represented by one of the following formulæ, if it be assumed that one nitro-group takes the place of the carboxyl in the amido-acid,

- I. $[\text{OH} : \text{NO}_2 : \text{Me} : \text{NO}_2 = 1 : 2 : 3 : 6]$,
- II. $[\text{OH} : \text{Me} : (\text{NO}_2)_2 = 1 : 3 : 5 : 6]$.

Of these the former is the more probable, as compounds in which the nitro-groups occupy the adjacent position are usually unstable; moreover, on reduction, it yields a diamido-compound, which does not form an azine or quinoxaline on treatment with orthodiketones.

H. G. C.

Saligeninoxyacetic Acid. By P. BIGNELLI (*Chem. Centr.*, 1890, ii, 623—624; from *Ann. Chim. Farm.*, 12, 69—72).—*Saligeninoxyacetic acid*, $\text{OH} \cdot \text{CH}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{O} \cdot \text{CH}_2 \cdot \text{COOH}$, is prepared by warming saligenin with chloracetic acid in presence of sodium hydroxide. The mixture is first warmed on the water-bath, and finally over the flame directly. The mass is then dissolved in a little water, and the acid

liberated by the addition of sulphuric acid. The acid may be recrystallised from water, and is thus obtained in white, lustrous plates melting at 120° . The solutions of the sodium and potassium salts are precipitated by lead acetate, calcium chloride, and silver nitrate, but not by barium chloride. The lead and calcium salts are powdery; the silver salt has the formula $C_5H_5O_4Ag + 2H_2O$. It loses 1 mol. H_2O readily, but retains the second molecule somewhat persistently. By treating the silver salt with methyl iodide, an ethereal salt of the formula $C_{15}H_{25}O_7$ is obtained, which probably has the constitutional formula $OH \cdot CH_2 \cdot C_6H_4 \cdot O \cdot CH_2 \cdot COO \cdot CH_2 \cdot C_6H_4 \cdot O \cdot CH_2 \cdot COOMe$.

If saligeninoxycetic acid is heated in a current of dry air at $100-108^{\circ}$, it loses 1 mol. H_2O , and becomes converted into a caramel-like substance of the formula $C_6H_5O_3$, and melting at 140° . It is insoluble in all ordinary menstrua, and dissolves only in soda or potash.

J. W. L.

Thionylamines, a New Class of Compounds containing Sulphur. By A. MICHAELIS and R. HERZ (*Ber.*, 23, 3480—3482).—It has already been shown by Michaelis (*Abstr.*, 1890, 617) that thionyl chloride readily acts on primary and secondary asymmetrical hydrazines forming compounds in which the hydrogen atoms of the NH_2 group are displaced by the SO_2 group. The authors find that the same reaction takes place even more readily with the simple amido-compounds. The action of this reagent on aniline has also been examined by Schiff (*Annalen*, 102, 111) and Böttlinger (*Abstr.*, 1878, 863). The authors proceeded in a similar manner to the last-named, dissolving 20 grams of aniline in double its volume of dry benzene and adding 20 grams of thionyl chloride also diluted with benzene, when separation of a solid substance and development of heat takes place. The viscid mass is then heated in a reflux apparatus, when a further reaction takes place, and the contents of the flask become thin. After cooling, the precipitated aniline hydrochloride is filtered off, and the clear liquid distilled. As soon as the benzene has passed over, the thermometer rises to $198-200^{\circ}$ and a yellow liquid condenses, which after redistillation is quite pure, and as shown by its analysis, consists of *thionylaniline*, $SO \cdot NPh$. This boils at 200° , has an aromatic and somewhat pungent odour, and is slowly decomposed by water and dilute acids, and quickly by alkalis with formation of aniline and an alkaline sulphate.

Thionylparatoluidine, $C_7H_7N \cdot SO$, is prepared in a similar manner; it is a yellow liquid which has an aromatic odour, boils at 224° , and solidifies in a freezing mixture to well-developed, yellow crystals melting at 7° .

The reaction appears to be quite general, the thionyl group playing the same rôle with primary amines as the nitroso-group does with secondary amines.

H. G. C.

Metethoxyphenylsulphonic Acid. By A. DELINLE and G. LAGAI (*Ber.*, 23, 3392—3394).—*Potassium metethoxyphenylsulphonate*,

is deposited from water in hard, octahedral crystals, and from dilute alcohol in long, flat, lustrous needles. The *barium salt*, $C_6H_5SO_4Ba + 4H_2O$, crystallises in needles; the *calcium salt*, $(C_6H_5SO_4)_2Ca + 3H_2O$, is deposited in thin, colourless plates. The free *acid* crystallises with difficulty, and is readily soluble in water or alcohol. The *sulphochloride* crystallises from ether in hard, pale-yellow needles, and melts at 38° . The *sulphonamide* crystallises from water in long, white needles and melts at 131° . The *hydrosulphide*, $OEt \cdot C_6H_4 \cdot SH$, is prepared by the reduction of the sulphochloride, boils at $238-239^\circ$, and on warming with sulphuric acid gives a yellow coloration which changes successively to red, green, and blue. J. B. T.

Synthesis of Indigo and Allied Dyes. By K. HEUMANN (*Ber.*, 28, 3431—3435).—Phenylglycocineorthocarboxylic acid is prepared by heating anthranilic acid (63 parts) with chloracetic acid (47 parts) and water (500 parts) for two hours in a reflux apparatus. It crystallises from hot water as a yellowish, granular mass, and melts at about 200° with decomposition. It is only slightly soluble in cold water. The alcoholic solution shows a blue fluorescence. The preparation of indigotin from this compound is best carried out as follows:—Phenylglycocineorthocarboxylic acid (1 part) is fused with potash (3 parts) and water (1 part), with constant stirring, and the mixture heated at $180-200^\circ$ as long as it deepens in colour. The melt is treated with water, oxidised with a current of air or with ferric chloride and hydrochloric acid, and the precipitated indigo collected and washed. The temperature of the reaction is $60-80^\circ$ lower than is the case when phenylglycocine is employed (compare this vol., p. 75). E. C. R.

Synthesis of Indigo from Phenylglycocine. By L. LEDERER (*J. pr. Chem.* [2], 42, 565—567).—The author combats Heumann's claim for priority in this matter (this vol., pp. 75, 206). With regard to Heumann's criticism that the indigo cannot actually exist in the melt, the author points out that when indigotin is melted with sodium hydroxide in a test-tube, the melt first becomes yellow and then orange-red, subsequently again giving indigo-blue when treated with dilute sulphuric acid; this behaviour is exactly similar to that of phenylglycocine and sodium hydroxide when melted together.

A. G. B.

Action of Methyl Iodide on Hydro- α -methylindole. By C. ZATTI and A. FERRATINI (*Chem. Centr.*, 1890, ii, 554; from *Rend. Acad. Lincei*, 6, i, 463—466).—By boiling hydro- α -methylindole (1 part) with methyl iodide (3 parts) for 20 minutes in a reflux apparatus, an oil is formed which is insoluble in the excess of iodide. After distilling off the methyl iodide, the oily substance solidifies, and may be recrystallised from alcohol. It is of a slightly red colour, smells of indole, and melts at $200-202^\circ$. It is the iodide of an ammonium base, $C_8H_7 \langle \overset{CH_2}{\underset{NMe_2}{|}} \rangle CHMe$, and dissolves in water and alcohol. By the action of moist silver oxide, the *free base* may be obtained. The latter is crystalline, and absorbs moisture and carbonic anhydride

from the air. By agitating the iodide with freshly precipitated silver chloride, the *chloride* is formed, which is also hygroscopic. From it, the aurochloride and platinochloride may be prepared.

J. W. L.

Indazole Derivatives. By O. N. WITT, E. NÖLTING, and E. GRANDMOUGIN (*Ber.*, 23, 3635—3644).—The conversion of nitrotoluidine [$\text{Me} : \text{NH}_2 : \text{NO}_2 = 1 : 2 : 4$] into the corresponding phenol by means of the diazo-reaction is only complete under certain special conditions, for example, by the addition of sodium nitrite to the base dissolved in hot hydrochloric acid; in ordinary circumstances, more or less nitroindazole is formed, probably on account of the close proximity of the methyl and diazo-groups.

Nitroindazole, $\text{NO}_2 \cdot \text{C}_6\text{H}_3 \cdot \text{N} \begin{smallmatrix} \text{CH} \\ \diagup \diagdown \end{smallmatrix} \text{NH}$ [$\text{CH} : \text{NH} : \text{NO}_2 = 1 : 2 : 4$], is prepared by dissolving nitrotoluidine (30 grams) in 60 grams of concentrated sulphuric acid, diluted with 1 litre of water; the solution is cooled, mixed with 14 grams of sodium nitrite dissolved in 200 c.c. of water, and slowly warmed on the water-bath; it is finally boiled for a short time, and, on cooling, a mixture of nitroindazole and nitrocresol is deposited; this may be separated by repeated crystallisation from water or xylene; the pure product is obtained in white, lustrous needles which melt at 181° , and, in small quantities, may be volatilised without decomposition. The *sodium salt* crystallises in yellow needles. The *silver salt* is also yellow. The *methyl ether*, $\text{NO}_2 \cdot \text{C}_6\text{H}_3 \cdot \text{N} \begin{smallmatrix} \text{CH} \\ \diagup \diagdown \end{smallmatrix} \text{NMe}$, is obtained by the action of methyl iodide and alcoholic potash on nitroindazole or the mixture of this and the cresol; it crystallises from benzene in pale-yellow, flat needles, melts at 159° , is insoluble in light petroleum, and yields azoxy-derivatives on prolonged heating with alcoholic potash. The corresponding derivative of nitro-orthocresol crystallises from light petroleum in colourless needles melting at 74° . *Acetylnitroindazole* crystallises from alcohol in lustrous needles, melts at 139 — 140° , and sublimes without decomposition.

By the action of aqueous bromine on nitroindazole, a *monobromo-derivative* is formed, which is deposited from benzene in small, yellow prisms, and from alcohol in small needles, which melt at 229° . The *sodium salt* crystallises in red needles.

No satisfactory results were obtained by the oxidation of nitroindazole.

Nitroindazole may be reduced by the action of stannous chloride in acid solution; it is, however preferable to employ ammonium sulphide.

Amidoindazole, $\text{NH}_2 \cdot \text{C}_6\text{H}_3 \cdot \text{N} \begin{smallmatrix} \text{CH} \\ \diagup \diagdown \end{smallmatrix} \text{NH}$, crystallises from water in white plates or needles; the former contain water of crystallisation, whilst the latter are anhydrous and melt at 210° . The *hydrochloride* is deposited from alcoholic solution in white needles, decomposes at 230° without melting, and is readily soluble.

By the action of sodium nitrite on a salt of amidoindazole, *hydromy-*

indazole, $\text{OH} \cdot \text{C}_6\text{H}_3 < \begin{smallmatrix} \text{CH} \\ \text{N} \end{smallmatrix} > \text{NH}$, is obtained; it is deposited from water in colourless crystals, melts at $215\text{--}216^\circ$ (? $265\text{--}266^\circ$), and sublimes without decomposition. Indazole is produced by elimination of the amido-group from amidoindazole, and is found to be identical with a specimen prepared according to the method of E. Fischer and Kuzel. No indazole could be obtained from ortho-toluidine by the method described above.

J. B. T.

Derivatives of Benzidinemetasulphonic Acid. By A. ZEHRA (*Ber.*, 23, 3459—3464).—*Sodium diacetylbenzidinemetasulphonate*, $\text{NHAc} \cdot \text{C}_6\text{H}_4 \cdot \text{C}_6\text{H}_3(\text{NHAc}) \cdot \text{SO}_3\text{Na}$, is prepared by heating sodium benzidinesulphonate with somewhat more than an equal weight of acetic anhydride. Unlike most alkali salts of acetamidodisulphonic acids, it is sparingly soluble in cold water, but easily soluble in hot water, from which it crystallises in beautiful, long, colourless needles.

Metadinitrodiacetylbenzidinemetasulphonic acid,

obtained by treating a solution of the above compound in concentrated sulphuric acid, cooled to $+5^\circ$, with a mixture of concentrated nitric and sulphuric acids, has an orange-yellow colour, and is extremely soluble in water and alcohol. The *potassium* salt crystallises from hot water in yellow needles. By heating with dilute sulphuric acid (1 : 2), the acetyl groups are eliminated and *metadinitrobenzidinemetasulphonic acid*,

is obtained as a dark-red, granular mass, very slightly soluble in both hot and cold water, but somewhat soluble in dilute mineral acids. The *potassium* salt crystallises in bright-red needles, and is only slightly soluble in hot and cold water; the *ammonium* and *sodium* salts show the same behaviour. The tetrazo-compound yields with β -naphthol a blue-black dye of coppery lustre, which does not dye cotton, and dyes wool in an acetic acid bath a garnet-red; with β -naphtholdisulphonic acid R., it gives a beautiful reddish-violet, and with β -naphtholdisulphonic acid G., a violet-black dye.

Metadiamidobenzidinemetasulphonic acid,

is obtained by reducing the nitro-compound with tin and hydrochloric acid. The hydrochloride is extremely stable, and is easily soluble in hot water, slightly so in cold water. Sodium nitrate, when added to the acid solution, causes the precipitation of fine, yellow flocks, consisting probably of the azimide, but owing to the small quantity it could not be examined. Ferric chloride instantly darkens the solution, and precipitates a black compound. Platinic chloride does not form a double salt, but acts as an oxidising agent. The picrate crystallises in bright-yellow needles, and is sparingly soluble in

alcohol and water. When a hot acid solution of the diamine is treated with the potassium salt of croconic acid, the azine,

is formed; this when dry has a black colour and green metallic lustre, and is very slightly soluble in water, but more soluble in dilute alkali, from which the *potassium* salt is precipitated in black, micro-crystalline needles on the addition of concentrated potash. An aqueous solution of the azine is completely decolorised by barium chloride, and a heavy, black compound separates. E. C. R.

Fluorene Hydrides. By P. A. GUYE (*Bull. Soc. Chim.*, [3], 4, 266—268; compare Abstr., 1889, 720).—Fluorene (3.6 grams), phosphorus (3 grams), and hydriodic acid, sp. gr. 1.7 (9 grams), were heated in sealed tubes at 250—260° for 6—7 hours, and the liquid resulting from the extraction of the product with ether was fractionated over sodium. Two hydrides were obtained, a decahydride, $\text{C}_{13}\text{H}_{20}$, which boils at 254—256°, under a pressure of 727 mm., and which is still liquid at -15°, but crystallises above -73°, and is oxidised on contact with air, and an octohydride, $\text{C}_{13}\text{H}_{18}$, boiling at 272—275°, having properties similar to the former. Both these hydrides are soluble in ether and benzene, and have an odour like that of diphenylmethane. In addition to these hydrides, a sample of fluorene containing traces of phenanthrene yielded phenanthrene octohydride, boiling below 300°. T. G. N.

Oximes of Haloïd Benzophenones. By R. DEMUTH and M. DITTRICH (*Ber.*, 23, 3609—3617).—Parachlorobenzophenone, prepared from chlorobenzoic chloride and benzene, when acted on by hydroxylamine and excess of alkali in the cold, yields two oximes which may be separated by fractional crystallisation from alcohol; the one melts at 155—156° instead of 149°, as previously stated by Beckmann and Wegerhoff (Abstr., 1889, 1066), and is termed the α -oxime. The second, or β , and more soluble modification, is deposited from dilute alcohol in square prisms melting at 95°. No other oxime could be isolated. Both compounds dissolve completely, although with some difficulty, in aqueous alkalis. The β -oxime is converted into the α -modification by heating for about three hours on the water-bath, but no change occurs on boiling with alcohol. Both compounds yield chlorobenzophenone when heated with hydrochloric acid for eight hours at 100°.

α -Acetylparachlorobenzophenone crystallises from alcohol in rhombohedra, and melts at 147—148°. The β -acetyl derivative is readily soluble in alcohol, from which it is deposited in long, slender needles, and melts at 105—106°. The hydroximes are regenerated from both compounds by the action of alcoholic potash.

α -Parachlorobenzophenone benzyl ether is obtained by treating the hydroxime with benzyl chloride and sodium ethoxide, and crystallises

from alcohol in short prisms melting at 74—75°. The corresponding β -derivative is deposited from alcohol in long, flat needles, and melts at 98—99°. Both compounds yield benzyl iodide when heated with hydriodic acid.

Metadibromobenzophenone is best prepared by heating benzophenone with the calculated quantity of bromine, together with a little iodine and water, in a sealed tube for four hours at 150°; after purification, the product crystallises from alcohol in broad, lustrous needles, and melts at 141°; the yield is 40 per cent. On gently heating with solution of hydroxylamine hydrochloride, an *oxime* is obtained, which is sparingly soluble in alcohol, and crystallises in slender needles; the yield is quantitative. The ketone is regenerated by the action of hydrochloric acid. No other oxime could be separated, and only the one compound is formed on treating the ketone with hydroxylamine and excess of alkali in the cold. All attempts to transform the oxime into a second modification were fruitless. From these results, it would appear that the power of forming two oximes is dependent on the symmetry, or otherwise, of the molecule. J. B. T.

Action of Nitrogen Tetroxide on Aromatic Ketoximes and on Glyoximes. By R. SCHOLL (*Ber.*, 23, 3490—3505).—The author has previously shown (*Abstr.*, 1888, 443) that aliphatic ketoximes, when treated with nitrogen tetroxide in ethereal solution, are converted into pseudonitroles. The aromatic ketoximes behave in a somewhat similar manner, but the compounds obtained appear to correspond not with the fatty pseudonitroles, but with the dinitro-compounds obtained by the oxidation of the latter.

When benzophenonoxime (6 grams) is dissolved in ether (120 grams), and nitrogen tetroxide (3·5 grams) added, a brown solution is formed, which, after remaining for 10 minutes, is shaken with soda solution to remove nitric and nitrous acids, dried with calcium chloride, and allowed to evaporate in a vacuum. The product of the reaction is thus obtained in large, colourless, seemingly monosymmetric plates, which may be purified by the addition of water to the hot alcoholic solution. It has the composition $C_{13}H_{10}N_2O_4$, melts at 78—78·5°, decomposes with evolution of brown fumes at 98°, and is soluble in the common organic solvents. The simplest supposition is that it is *diphenyldinitromethane*, $CHPh_2(NO_2)_2$. That the nitro-groups have not entered the benzene ring is shown by the fact that on reduction it yields benzophenonoxime and benzyldihydramine, $CHPh_2NH_2$; the formation of the first-named compound is not, however, altogether in favour of the supposition that the above substance is a dinitro-compound, and it is not impossible that both this compound and also the corresponding fatty dinitro-compounds may have a constitution expressed by the general formula $X_2:C:N \begin{smallmatrix} O \\ \swarrow \\ O-NO_2 \end{smallmatrix}$, which agrees with the formula recently suggested by V. Meyer (*Abstr.*, 1888, 702) for the pseudonitroles, namely, $X_2:C:N \cdot O \cdot NO_2$. For the sake of simplicity, however, these substances may, for the present, be regarded as dinitro-compounds.

Acetophenonoxime is acted on by nitrogen tetroxide in the same

manner, but the oil obtained contains acetophenone, which could not be separated. On heating to 60° , the oil decomposes, with evolution of nitrous fumes.

Nitrogen tetroxide acts on aldioximes in quite a different manner; a simple oxidation taking place with formation of peroxides, thus, benzaldoxime yields *diphenylglyoxime peroxide*, $\text{Ph}\cdot\text{C}(\text{N}\cdot\text{O})\cdot\text{C}(\text{N}\cdot\text{O})\cdot\text{Ph}$, already described by Beckmann (Abstr., 1889, 980), under the name azodi-benzenyl peroxide. The reaction is also similar to the formation of diphenyldinitrosacyl (dibenzoylglyoxime peroxide) by the oxidation of nitrosoacetophenone with nitric acid (Holleman, Abstr., 1889, 49). As it appeared not impossible, from the author's experiments, that fulminic acid has the constitution $\text{HC}(\text{N}\cdot\text{O})\cdot\text{N}\cdot\text{O}$ (see this vol., p. 282),

the oxidation of the glyoximes has been more closely investigated.

Methylethylglyoxime is readily oxidised, both by alkaline potassium ferricyanide and by nitrogen tetroxide, the latter giving the best yield; the product of oxidation is a colourless, refractive, pleasant-smelling liquid, which boils at $115\text{--}116^{\circ}$ (uncorr.) under 16.5 mm. pressure, and is miscible with the ordinary organic solvents, but is only sparingly soluble in water, and insoluble in alkalis. Its analysis agrees with the formula $\text{C}_6\text{H}_8\text{N}_2\text{O}_8$, and on distillation at the ordinary pressures it is partly decomposed into isocyanates, and is therefore, in all probability, *methylethylglyoxime peroxide*, $\text{MeC}(\text{N}\cdot\text{O})\cdot\text{C}(\text{N}\cdot\text{O})\cdot\text{Et}$. The corresponding *dimethylglyoxime peroxide* is readily obtained by oxidising dimethylglyoxime with nitrogen tetroxide in ethereal solution. It closely resembles the foregoing, but boils practically without decomposition at $222\text{--}223^{\circ}$ under 726 mm. pressure.

The oxidation of monomethylglyoxime does not proceed as smoothly as in the two previous cases, an oil being obtained which is soluble in water, but very readily decomposes. It yields a yellow compound with soda, which also quickly becomes resinous. When the action of nitrogen tetroxide is allowed to continue for some time, a crystalline compound, of the formula $\text{C}_3\text{H}_5\text{N}_3\text{O}_8$, is also obtained, which has probably the constitution $\text{MeC}(\text{N}\cdot\text{O})\cdot\text{N}(\text{O})\cdot\text{C}(\text{N}\cdot\text{O})\cdot\text{Me}$.

More stable products are obtained from monophenylglyoxime. This is best prepared by the action of a boiling solution of hydroxylamine hydrochloride on the crude sodium salt of isonitrosoacetophenone obtained by Claisen and Manasse's method (Abstr., 1887, 944). The oxidation cannot be carried out in alkaline solution, as the peroxide is at once decomposed by alkalis, but nitrogen tetroxide in ethereal solution readily effects the change. The resulting solution, after washing with water, is evaporated, the residue extracted with chloroform, and purified by precipitating its chloroform solution with light petroleum, or its acetic acid solution with water. Analysis and determination of the molecular weight by Raoult's method showed its formula to be $\text{C}_8\text{H}_8\text{N}_2\text{O}_8$, which agrees with the expected constitu-

tional formula, $\begin{array}{c} \text{PhC:N}\cdot\text{O} \\ | \\ \text{HC:N}\cdot\text{O} \end{array}$. It has a bitter taste, melts with decomposition at 89—95°, is readily soluble in ether, acetone, chloroform, and acetic acid, more sparingly in alcohol, and insoluble in light petroleum. On recrystallising from alcohol, it is partially converted into benzaldehyde, and the odour of the latter and of phenylcarbamine is also observed on boiling it with water. With concentrated hydrochloric acid, it yields hydroxylamine. All attempts to displace the hydrogen atom by metals have been without success.

H. G. C.

Ethers of Benziloximes. By M. DITTRICH (*Ber.*, 23, 3589—3608).—Attempts to prepare the methyl ether of γ -benziledioxime according to the method of Japp and Klingemann resulted in the formation of products identical with those from β -benziledioxime, showing that the γ -oxime had become converted into the more stable β -modification by the action of the alkali. The hydrochloride of β -benziledioxime methyl ether softens at 130°, and melts at 140—143°, instead of 130° as previously given.

α -Benziloxime methyl ether is prepared by the same method, and crystallises from alcohol in lustrous plates; it melts at 62—63°, is readily soluble in ordinary media, and does not combine with hydrochloric acid. No isomeric compound could be detected.

γ -Benziloxime methyl ether is obtained as an oily liquid, which boils at 219—220° under a pressure of 40 mm.; the distillate solidifies on cooling and may be crystallised from alcohol, from which it is deposited in prisms melting at 64—65°; by distillation under ordinary pressure, it is decomposed, and it does not combine with hydrochloric acid. No isomeric ether could be isolated. The α -ether is unaltered by boiling with hydrochloric acid, but on heating with this reagent in a sealed tube for several hours at 100°, it is converted into the γ -modification; by treating the latter compound in the same manner at 120—130°, it decomposes into benzile and ammonium chloride. Determinations by Raoult's method, with benzene as solvent, show that the methyl ethers of benziledioxime have identical molecular weights.

By the action of α -methylhydroxylamine on benzile at ordinary temperatures, a compound is obtained which crystallises from dilute alcohol, melts at 64°, and closely resembles γ -benzilemonoxime methyl ether in appearance and behaviour.

β -Methylhydroxylamine, $\text{NHMe}\cdot\text{OH}$, is prepared by heating β -benziledioxime methyl ether with hydrochloric acid; the hydrochloride is deposited in long, prismatic crystals which melt at 85—90°, and readily reduce alkaline copper solution. Neither the free base nor the hydrochloride reacts with benzile at ordinary temperatures, whilst on warming and in presence of excess of alkali, the base is completely decomposed. On heating the dibenzyl ethers of α - and β -benziledioxime with hydriodic acid, benzyl iodide is eliminated, proving that the compound contains the group =NOH . By the action of α -benzylhydroxylamine on γ -benzilemonoxime benzyl ether at 130—150°, a dibenzyl ether of α -benziledioxime, melting at 153—154°, is formed.

The same compound is also prepared from α -benzylhydroxylamine and α -benzilmonoxime, proving that the α -dibenzyl ether contains two $\text{—NOC}_7\text{H}_7$ groups, and it is assumed that the methyl ethers have an analogous constitution.

Similar experiments with β -benzylhydroxylamine gave negative results.

Methyl iodide does not react with the non-basic methyl ether of α -benziledioxime, whilst by heating the second modification (α_2) with methyl iodide at 100° , it yields α -benziloxime methyl ether. On treating this same dimethyl ether (α_2) with hydriodic acid at 200° , methyl iodide and ammonia are formed.

These results show that the two α -benziledioxime methyl ethers are not geometrical isomerides, but are structurally different; it is suggested that whilst the non-basic modification (α_1) has the formula $\text{RO}\cdot\text{N}\cdot\text{CPh}\cdot\text{CPh}\cdot\text{NOR}$, the second (α_2) contains the groups —NOR and

; the above experiment with hydriodic acid tells, however, somewhat against this view. Benzile is formed by the action of amyl nitrite at ordinary temperatures on α - or γ -benziloxime; α -benziledioxime is converted, to a considerable extent, into the β -dioxime; the latter by similar treatment yields crystals of an oxidation product which melt at 114° and give phenyl cyanate on distillation.

J. B. T.

Diphenyltriketone. By R. DE NEUFVILLE and H. v. PECHMANN (*Ber.*, 23, 3375—3387).—Dibenzoylmethane is dissolved in chloroform and treated with bromine in molecular proportion, mixed with 3 parts of chloroform; during the addition of the bromine, a stream of dry air is drawn through the liquid in order to remove hydrogen bromide; the residue obtained, after evaporation of the chloroform, consists of *dibenzoylbromomethane*, CHBrBz_2 ; it crystallises from chloroform, on the addition of light petroleum, in lustrous needles, melts at 93° , and gives no coloration with ferric chloride. *Dibenzoylcarbinyl acetate*, $\text{CHBz}_2\cdot\text{OAc}$, is prepared by the action of anhydrous potassium acetate on the bromide; it crystallises from dilute alcohol in needles, melts at 94° , is insoluble in water or light petroleum, and gives a brown coloration with ferric chloride; the yield is 80 per cent. *Dibenzoylbromocarbinyl acetate*, $\text{CBz}_2\text{Br}\cdot\text{OAc}$, is obtained by the action of bromine on the previous compound; it is readily soluble in the ordinary media, and is deposited from chloroform, on the addition of light petroleum, in white crystals which melt at $101\text{—}102^\circ$; by heating the compound, either alone or in solution, acetic bromide is eliminated, and the triketone is formed.

Dibenzoyldibromomethane, CBr_2Bz_2 , is prepared by the action of dibenzoylmethane on twice the molecular proportion of bromine; it crystallises from alcohol, and melts at 95° . The compound is completely decomposed by the action of alkalis, whilst small quantities of triketone are formed on boiling an alcoholic solution with silver oxide, carbonate, or nitrate; an acetic acid solution of potassium acetate causes a similar reaction. *Nitrosodibenzoylmethane*, $\text{CBz}_2\cdot\text{N}\cdot\text{OH}$, is formed by treating dibenzoylmethane with amyl nitrite; it crystal-

lises from a mixture of chloroform and light petroleum, melts at 146° , and is soluble in alkalis with a yellow colour.

Diphenyltriketone or *dibenzoyl ketone*, $\text{CO}(\text{CO}\cdot\text{C}_6\text{H}_5)_2$, is prepared by heating dibenzoylcarbonyl acetate, or by the action of nitrous acid on nitrosodibenzoylmethane; it crystallises from anhydrous light petroleum in golden-yellow needles, melts at $69\text{--}70^{\circ}$, and boils at $247\text{--}248^{\circ}$ under a pressure of 60 mm., and at 289° under a pressure of 175 mm.; is very hygroscopic, and readily dissolves in all solvents except water.

"*Diphenyltriketone hydrate*," *dibenzomethylene glycol*, $\text{CBz}_2(\text{OH})_2$, is formed as a white, flocculent precipitate on dissolving the ketone in alcohol or glacial acetic acid and adding water; it melts at 90° , and is also formed by boiling dibenzoylbromocarbonyl acetate with glacial acetic acid, or by the action of potassium acetate on dibenzoyldibromomethane. Chemically, the hydrate resembles the ketone; both give a brilliant blue coloration on the addition of sulphuric acid to a benzene solution. The hydrate readily dissolves in alkalis with the formation of phenylbenzoylhydroxyacetic acid, $\text{OH}\cdot\text{CPhBz}\cdot\text{COOH}$, which has not yet been isolated. After the solution has remained for some time, this compound is decomposed by the further action of the alkali; part yields benzoic acid and phenylhydroxyacetic acid, whilst carbonic anhydride and benzoïn are produced from the remainder.

On treating the triketone with phenylhydrazine in molecular proportion at ordinary temperatures, a compound is deposited which crystallises from a mixture of chloroform and light petroleum in aggregates of almost colourless needles, melts at 135° , and acquires a red colour after remaining in contact with the air. The substance has the formula $\text{C}_{21}\text{H}_{18}\text{N}_2\text{O}_2$, but it is uncertain whether it is really a phenylhydrazone; it dissolves in concentrated sulphuric acid with a yellow colour, but the solution is not affected by ferric chloride or potassium dichromate (Bülow's reaction). By the action of excess of phenylhydrazine on the triketone, or on the previous compound, two substances are obtained and may be separated by treatment with benzene at ordinary temperatures; the one crystallises in yellow needles, melts at 223° , and has not yet been further investigated. The second compound is soluble in benzene, and consists of *benzenasotriphenylpyrazole*, $\left. \begin{array}{l} \text{N}=\text{CPh} \\ \text{NPh}\cdot\text{CPh} \end{array} \right\rangle \text{C}\cdot\text{N}_2\cdot\text{Ph}$; it crystallises from alcohol in orange-red prisms, and melts at $156\text{--}157^{\circ}$.

Diphenyltriketoneanilide, $\text{NPh}\cdot\text{CPh}\cdot\text{CBz}(\text{OH})_2$, is formed by treating the triketone with two parts of aniline at the ordinary temperature; it crystallises from benzene, on the addition of light petroleum, in yellow, concentric needles, melts at $99\text{--}100^{\circ}$, and gives a blue coloration with sulphuric acid and benzene. On boiling the triketone with alcoholic solution of aniline, the *dianilide*, $\text{C}(\text{OH})_2(\text{OPh}\cdot\text{NPh})_2$, is obtained, crystallising from benzene in yellow pyramids which melt at 148° .

Diphenyltrinitrosopropane, $\text{OH}\cdot\text{N}\cdot\text{C}(\text{CPh}\cdot\text{N}\cdot\text{OH})_2$, is obtained as a white, crystalline powder from nitrosodibenzylmethane and hydroxylamine; it is insoluble in water, but readily dissolves in alkalis and organic menstrua, and melts at $185\text{--}186^{\circ}$. A second compound is

formed in small quantity; this crystallises in plates, melts at 141° , is insoluble in alkalis, and has not yet been further investigated.

Attempts to prepare other triketones from acetophenone, benzoyl-acetone, acetylacetone, and ethyl acetoacetate have been unsuccessful.

J. B. T.

Cresoleinnamic and Metacresolglycollic Acids. By A. OGIALORO and O. FORTE (*Gazzetta*, 20, 505—513).—The cresoleinnamic acids were prepared by heating the corresponding sodium cresolglycollates with benzaldehyde and acetic anhydride.

Orthocresolcinnamic acid is obtained pure by decomposing its barium salt. It crystallises from a dilute alcoholic solution in small, white prisms, melts at 167 — 168° , and is very soluble in warm alcohol, moderately in ether, chloroform, and benzene. The *barium* salt, $(C_{10}H_{11}O_2)_2Ba + H_2O$, dissolves very sparingly in hot water, and may be obtained crystallised by evaporating the solution. The *silver* salt, $C_{10}H_{11}O_2Ag$, decomposes at 100° . The *methyl* salt, $C_{10}H_{13}O_2Me$, crystallises from dilute alcohol in colourless plates, melts at 61° , and dissolves very freely in alcohol and ether, and moderately in light petroleum and chloroform, but is insoluble in water; a brominated derivative, $C_{11}H_{13}BrO_2$, may be obtained by adding bromine to saturation to the methyl alcoholic solution of this compound, and heating the mixture for a few hours. It crystallises in brilliant, yellow scales, and melts at 231° .

Metucresolglycollic acid, $C_9H_{10}O_3$, is prepared by melting a mixture of metacresol and chloracetic acid in molecular proportion, and adding a quantity of aqueous soda (sp. gr. = 1.3) quadruple that of the cresol taken. It crystallises from boiling water in minute, white needles, and melts at 102° . The *barium* salt, $(C_9H_9O_3)_2Ba + 6H_2O$, crystallises from an aqueous solution in nodules consisting of very fine, white needles.

Metacresolcinnamic acid crystallises in white needles, melts at 155° , and dissolves freely in alcohol and ether. The *silver* salt is white and anhydrous, and is not altered by exposure to light. The *barium* and the *methyl* salts are uncrystallisable compounds; the latter is a viscid substance yielding a brominated derivative, $C_{11}H_{13}BrO_2$, which crystallises in colourless, rhombic tables, and melts at 109° .

Paracresolcinnamic acid crystallises in white needles, melts at 159 — 160° , and dissolves in alcohol, ether, and benzene. The acid cannot be completely purified, but a *silver* salt of the theoretical composition may be isolated. The *barium*, *magnesium*, and *methyl* salts are uncrystallisable; the last is a viscid product, and yields a brominated derivative, $C_{11}H_{13}BrO_2$, which crystallises from methyl alcohol in brilliant, colourless, rhombic tables melting at 124 — 125° .

S. B. A. A.

Sulphides of β -Naphthol. By S. ONUFROWICZ (*Ber.*, 23, 3355—3373).— β -Naphthol sulphide or β -hydroxynaphthyl sulphide, $S(C_{10}H_7OH)_2$, is prepared by the action of either sulphur dichloride or of sulphur and lead oxide on β -naphthol.

The *α -sodium* derivative, $S(C_{10}H_7ONa)_2 + 6H_2O$, is obtained by dissolving the sulphide in soda; it crystallises in colourless, concentric needles, is readily soluble in water or alcohol, and has an

alkaline reaction. The corresponding *calcium* and *barium* salts are colourless and crystalline, and, like the salts of the heavy metals, are very sparingly soluble in water. The *diethyl* derivative,

is prepared by the action of the calculated quantity of ethyl iodide and potash on the sulphide; it crystallises from benzene in long, slender, wax-like, lustrous needles, melts at 189° , and is not acted on by silver nitrate or mercuric oxide.

β -Naphthylamine and β -naphthol are formed by the action of ammonia on β -naphthol sulphide, whilst β -naphthol is the sole product when the sulphide is treated with cuprous chloride or silver chloride. By the action of silver nitrate or of mercuric oxide on the sulphide, a compound is obtained which crystallises from dilute alcohol in stellate groups of ruby-red plates, and melts at 164° ; the yield is 25–30 per cent. of the sulphide employed. This substance has the formula $C_{20}H_{11}SO_2$, and is not acted on when boiled with either soda or glacial acetic acid; when heated to 200° , it yields hydrogen sulphide and β -naphthol, whilst, by reduction with zinc-dust and glacial acetic acid, β -naphthol sulphide is regenerated. By the action of potassium dichromate and sulphuric acid, part of the sulphide is completely oxidised, and part remains unchanged; with dilute nitric acid, sp. gr. 1.18, phthalic acid is the sole product.

β -Naphthol sulphide is decomposed by concentrated nitric acid; but on dissolving the diethyl derivative in 10 parts of glacial acetic acid, adding 5 parts of fuming nitric acid, and cooling well with ice, *dinitronaphthyl ethyl ether*, $C_{10}H_7(NO_2)_2 \cdot OEt$ [$OEt : (NO_2)_2 = 2 : 1' : 4$], is obtained, and may be purified by treatment with benzene; it crystallises from dilute alcohol in long, slender, pale-yellow, silky needles, melts at 215° , and is not acted on by aqueous soda. The yield is 30 per cent. When heated with dilute nitric acid at 160 – 170° , dinitronaphthalenedicarboxylic acid [$(COOH)_2 : (NO_2)_2 = 1 : 2 : 3 : 6$] is produced.

Dinitronaphthalene [$NH_2 : (NO_2)_2 = 2 : 1' : 4$] is formed by heating the above ethyl derivative with concentrated alcoholic ammonia at 220 – 225° ; it is very sparingly soluble, and crystallises from toluene in slender, yellow needles which blacken at about 250° , but do not melt. When β -ethoxynaphthyl sulphide is treated with concentrated nitric acid at very low temperatures, the product, after washing with ice water, dissolved in benzene and the solution cooled, *ethoxydinitronaphthyl sulphide*, $S[C_{10}H_7(NO_2)_2 \cdot OEt]_2$, is deposited in slender, golden-yellow needles which melt at 235° . After some time, a further deposit is obtained from the mother liquor; this is dissolved in ether, and crystallises, on the addition of light petroleum, in slender, pale-yellow needles; it melts at 202° , and is readily soluble in alcohol or benzene, both at ordinary temperatures and on warming. This substance has the formula $C_{24}H_{20}N_2S_2O_6$, and is probably a dinitro-derivative.

β -Naphthol bisulphide or *β -hydroxynaphthyl bisulphide* is obtained by heating β -naphthol with sulphur at 175 – 180° for 24 hours; after purification, it crystallises from benzene in slender, yellow needles, melts at 169° , and is very sparingly soluble in ordinary menstrua. When

heated to 360° , it decomposes into hydrogen sulphide and β -naphthol; it is soluble in dilute, and gives a red colour with concentrated alkalis. The yield is 10 per cent. The same compound, together with a considerable quantity of the monosulphide, is also formed by the action of sulphur chloride at 0° on β -naphthol dissolved in benzene; the yield is about the same as before. The best results are obtained by heating a solution of the sulphide with half the molecular proportion of sulphur bromide for an hour on the water-bath; in this manner 10 grams of β -naphthol yielded 5 grams of pure bisulphide. β -Ethoxynaphthyl bisulphide, $S_2(C_{10}H_7OEt)_2$, is prepared in a similar manner to the corresponding monosulphide derivative; it crystallises from alcohol in greyish needles, and melts at 158.5° . The diacetate, $S_2(C_{10}H_7OAc)_2$, forms a yellow, hard, crystalline mass which melts at about 140° , and is soluble in ether, alcohol, benzene, and glacial acetic acid. The dibenzoate, $S_2(C_{10}H_7OBz)_2$, crystallises from benzene in greenish plates or prisms, and melts at 187° .

On heating the bisulphide with recently reduced copper at 230 – 240° , it yields β -dinaphthol, m. p. 212° ; the bisulphide is not altered by boiling with copper and xylene or cumene.

α -Naphthol trisulphide, $S_3(C_{10}H_7OH)_3$, is obtained by the action of sulphur chloride on α -naphthol, and is a pale yellow, amorphous substance which blackens at 220° , and is very readily soluble in dilute aqueous soda, but almost insoluble in organic media. The corresponding benzoate, $S_3(C_{10}H_7OBz)_3$, is a greyish powder melting at 194° .

When benzene is mixed with 0.5 part of sulphur chloride and 0.05 part of iodine, heated in a sealed tube for 100 hours at 115 – 125° , and the product boiled with benzene, toluene, carbon bisulphide, and xylene successively, a yellow, hard, amorphous mass remains which is slightly soluble in xylene, and has the formula S_6Ph_3 .

J. B. T.

Ethereal Oil of Asafostida. By F. W. SEMMLER (*Ber.*, 23, 3530–3533).—Up to the present, it has not been found possible to separate crude asafostida into its constituents by fractional distillation, but the author finds that this may be readily carried out under diminished pressure. Thus, under 9 mm., two specimens of crude oil of sp. gr. 0.843 at 22° and 0.9789 at 12° respectively, gave, on repeated fractionation, four chief fractions distilling below 65° , at 80 – 85° , 120 – 130° , 133 – 145° .

The fraction distilling below 65° , obtained from both specimens, had the same qualitative composition, but the constituents were present in different quantities, thus causing a difference in the specific gravity. On treatment with potassium in a vacuum until no more gas is evolved, and then distilling, a colourless, pleasant-smelling oil is obtained, which has the composition $C_{10}H_{16}$; it is a mixture of two different terpenes, one of which yields a liquid, and the other a solid dibromide. It is contained ready formed in the oil, and may also be obtained from the fraction distilling below 65° by adding mercuric chloride until no further precipitate is formed, and distilling in a current of steam. The first sample of oil was thus found to contain 6 per cent., and the second 8 per cent., of the mixture of terpenes.

The fraction 133—145° was treated with sodium in a vacuum, and on distillation under 9 mm. pressure, a colourless oil passed over at 123°, which had a pleasant, lavender-like odour, a sp. gr. of 0.9241 at 15°, and the composition $C_{15}H_{24}$. It belongs, therefore, to the group of sesquiterpenes, and forms a *hydrochloride*, $C_{15}H_{24} \cdot 2HCl$.

These two fractions consist chiefly of substances free from sulphur, the compounds containing the latter being found in the second and third fractions, which are, at present, being more closely investigated.

Indian Geranium Oil : Geranaldehyde and Geranic Acid. By F. W. SEMMLER (*Ber.*, 23, 3556—3557; see also *Abstr.*, 1890, 951).—In the previous paper, it was shown that geraniol, on treatment with chromic acid and distillation in a current of steam, yields an aldehyde, $C_{10}H_{16}O$, which may be termed *geranaldehyde*. If the residue, after removal of the aldehyde, is treated with phosphoric acid and again distilled in a current of steam, a small quantity of an oil is obtained which has an acid reaction. It may be prepared much more readily by making an emulsion of 6 grams of geranaldehyde in 500 grams of water, gradually adding a solution of 13.5 grams of silver oxide in dilute ammonia, acidifying with a slight excess of phosphoric acid, and distilling in a current of steam. The distillate is neutralised with soda, evaporated to dryness, the residue extracted with boiling absolute alcohol, and the latter expelled from the filtrate. The residue is taken up with water and precipitated by means of silver nitrate as the *silver salt*; this has the composition $C_{10}H_{18}O_2Ag$. *Geranic acid* is a thin oil.

The alcohol and aldehyde also occur in other oils, of which a more detailed account will be given later. (Compare also following abstract.)

H. G. C.

German and Turkish Rose Oil. By T. POLECK and C. F. KART (*Ber.*, 23, 3554—3555; see also Markovnikoff, this vol., p. 219).—The first product which passes over in the distillation of German rose oil is ethyl alcohol, about 5 per cent. of which is present. Terpenes could not be identified. After removing stearopteno, the German rose oil was distilled under diminished pressure, when it passed over almost entirely at 110—120° (1.4 mm.). Its boiling point at atmospheric pressure was found to be 215°. The Turkish oil behaves in a similar manner, both eleoptenes being levorotatory, the German variety having a sp. gr. of 0.8837 at 11°, and the Turkish, 0.8813 at 12°.

The analyses of the liquid portions of both oils indicated the formula $C_{10}H_{16}O$. This compound has the characteristics of a primary alcohol with two ethylene linkages, both with regard to the molecular refraction and its behaviour towards bromine. Its sodium derivative, chloride, iodide, and benzoate have been analysed. On oxidation, it yields, first, an aldehyde, $C_{10}H_{16}O$, and then an acid, $C_{10}H_{16}O_2$. Phosphoric anhydride and zinc chloride abstract the elements of water, forming a mixture of two different terpenes, $C_{10}H_{16}$, which differ considerably in their boiling point. If the action takes place below 0°, the higher boiling terpene is strongly dichroic. The only products of further oxidation found were carbonic anhydride, formic, acetic, and oxalic acids.

The properties of the liquid constituent of both the German and Turkish oils correspond exactly with those of geraniol, the chief constituent of Indian geranium oil (Semmler, *Abstr.*, 1890, 951, and preceding abstract), and a direct comparison of the aldehydes has shown their actual identity. The eleoptene of rose oil, therefore, also contains an open chain of carbon atoms, which, on elimination of water, unite to form a closed chain. H. G. C.

Phenolic Acid from Camphor. By P. CAZENEUVE (*Compt. rend.*, 111, 743—745).—Monochlorcamphor is treated with six times its weight of concentrated sulphuric acid at 50° for 30 hours and the product is poured into cold water. After some time, the liquid is filtered, heated, saturated with barium carbonate, and concentrated. Amethylcamphophenolsulphone (*Abstr.*, 1890, 1153) and the barium salt of the new acid crystallise together. They can be separated by crystallisation from alcohol of 70°, in which the barium salt remains dissolved, and it can afterwards be purified by crystallisation from water.

The barium salt crystallises in nacreous plates, and when treated with sulphuric acid it yields amethylcamphophenolsulphonic acid, $\text{OH}\cdot\text{C}_6\text{H}_{12}\text{O}\cdot\text{SO}_3\text{H}$, isomeric with the sulphone, a colourless, syrupy, uncrystallisable liquid, with a bitter, astringent, acid taste, and an odour recalling that of solutions of oak-bark. It is very soluble in water, alcohol, and ether, has no action on polarised light, and distils partially without decomposition under reduced pressure. Solutions of the barium salt gave a magnificent, blue coloration with ferric chloride. If the salt is boiled with acetic anhydride for 15 minutes, it yields an acetyl derivative, $\text{OAc}\cdot\text{C}_6\text{H}_{12}\text{O}\cdot\text{SO}_3\text{H}$, the barium salt of which has no action on ferric chloride. When treated with potassium hydroxide, the original phenolic acid is formed. C. H. B.

Action of Camphoric Anhydride on Benzene. By E. BURCKER (*Bull. Soc. Chim.* [3], 4, 112—113).—Under conditions similar to those by which benzoylpropionic acid is formed, camphoric anhydride and benzene react in presence of aluminium chloride to form a compound, $\text{C}_{18}\text{H}_{20}\text{O}_2$, which is separated from its sodium salt by treatment with hydrochloric acid as very light scales; it is soluble in alcohol, chloroform, ether, and acetic acid, but only sparingly in benzene, and almost insoluble in water. It melts at 125—126°, but if this temperature is passed it no longer solidifies on cooling, but remains as a syrup, and decomposes at a higher temperature without boiling. The compound behaves as a monobasic acid. Solutions of the alkaline hydroxides dissolve it, and the salts formed by it with cobalt, nickel, copper, and silver crystallise easily. With phenylhydrazine, it yields a yellow, crystalline derivative. Further work is being carried on to determine its constitution.

T. G. N.

Crystalline Principle from the Bark of *Diospyros virginiana*. By W. SCHLEIF (*J. Pharm.* [5], 22, 469—471; from *Amer. J. Pharm.*, 1890, 390).—The powdered root is extracted with light petroleum, by which a yellow solution is obtained, yielding a waxy residue on evaporation. The powder is then treated with ether and the solution

distilled, when a deep-red, crystalline residue is left; this is dissolved in hot alcohol and treated with an alcoholic solution of lead acetate, which removes the colouring matter only. After filtration, the liquid is treated with hydrogen sulphide, again filtered, and the still reddish, alcoholic solution is digested with animal charcoal on the water-bath, and concentrated by distilling off the alcohol; the crystals which separate are purified by repeated recrystallisation from alcohol until the dry product has a yellowish-grey colour. The crystalline mass thus obtained sometimes contains crystals 0.2 mm. long; these are soft, and waxy in appearance when moist. The dry substance is light brown in colour and granular in texture, with a peculiar odour, and a slightly astringent taste. It is soluble in alcohol, ether, and chloroform, very little soluble in water, and not at all in light petroleum. At 258° it takes a deeper tint, and at 262° it melts with apparent decomposition. The compound has a neutral reaction; it does not dissolve on boiling with dilute hydrochloric acid or in dilute potash solution; it burns on platinum foil without leaving any residue. Its alcoholic solution is not precipitated by alcoholic solution of lead acetate or of ammonia. It dissolves in glacial acetic acid. Its composition corresponds with the formula $C_{30}H_{27}O_{10}$. J. T.

β -Picoline. By A. LADENBURG (*Ber.*, 23, 3555—3556).—In reply to Stoehr's criticisms of the author's previous paper on this subject (*Abstr.*, 1890, 1432), Ladenburg states that the facts from which his conclusions were drawn were obtained in personal communications from Stoehr, and that, as there stated, the truth of those statements is now being experimentally investigated. H. G. C.

Derivatives of Toluquinoline and Metaxyloquinoline. By E. NOELTING and E. TRAUTMANN (*Ber.*, 23, 3654—3683).—Quinoline is dissolved in 10 parts of sulphuric acid (100 per cent.) and treated with the theoretical quantity of fuming nitric acid also dissolved in sulphuric acid; enough fuming sulphuric acid, containing 20—25 per cent. of sulphuric anhydride, is added to combine with the water contained in the nitric acid and also with that formed during the reaction; the mixture is either gently heated, or allowed to remain for several days at ordinary temperatures; in this manner only the two mononitro-derivatives are formed.

Nitroparatoluquinoline, $C_9H_7MeNO_2$ [$Me : NO_2 = 3 : 4$], is prepared by the action of nitric acid on paratoluquinoline in presence of sulphuric acid; it crystallises from alcohol in pale-yellow needles, melts at 116—117°, and is readily soluble in organic menstrua. The salts are crystalline, but readily undergo dissociation in presence of water. The proof of the above formula consists in the fact that the corresponding amido-derivative does not yield methylphenanthroline by the action of glycerol and picric acid. The *methiodide* crystallises from alcohol in long, yellow needles; on allowing these to remain in contact with the mother liquor, rhombohedra are formed; from water the compound is deposited in colourless rhombohedra, which become yellow at 100°; both forms melt at 189—190°.

Amidoparatoluquinoline is prepared by the reduction of the above nitro-derivative with iron and acetic acid; it crystallises from water

or dilute alcohol in yellow needles, and melts at 145° ; the yield is 90 per cent. of theory. The hydrogen salts are red, whilst the normal salts are almost colourless, but are red in aqueous solution. The *acetyl derivative* crystallises from water in white needles, melts at 160° , and yields colourless salts with acids.

Hydroxyparatoluquinoline, $C_9NH_4Me \cdot OH$, is prepared by the action of sodium nitrite on the amido-compound; it crystallises from alcohol in flat needles, melts at 230° , sublimes without decomposition, and is not volatile with steam. The same compound is also obtained by the action of fuming sulphuric acid at 90° on paratoluquinoline; the resulting sulphonic acid being then fused with potash. It forms well-characterised salts with acids and alkalis, and yields a *hydroxyazo-derivative* with diazobenzene chloride, which is deposited from alcohol in small, red needles melting at 176° .

Nitroso-hydroxyparatoluquinoline or *oxyparatoluquinoline oxime*, $C_9NH_4Me(NO \cdot H)O$, is obtained by the action of nitrous acid on the hydroxy-derivative at low temperatures; it crystallises from water in yellow needles and from alcohol in yellow plates, which decompose above 200° without melting. The *hydrochloride* is sparingly soluble in hydrochloric acid, and crystallises in yellow needles; the *sodium salt* is deposited in small, yellow plates. The nitroso-compound yields a stable green dye with iron mordanted cloth, this property is probably due to the presence of a salt-forming group in the peri-position [4 : 1'] to nitrogen; thus, whilst the three ortho-hydroxytoluquinolines (see below) and orthoquinone oximes give dyes with mordants, paraquinone oximes only do so if they contain the NOH group in the position 1.

Orthomethylhydroxyparatoluquinoline,

is prepared by the oxidation of the oxime with potassium ferricyanide, and crystallises from dilute acetic acid or alcohol in yellowish-brown plates, which decompose while melting.

Orthohydroxymetatoluquinoline, $C_9NH_4Me \cdot OH$ [$OH : Me = 1 : 2$], is prepared from amidorthocresol, [$OH : NH_2 : Me = 1 : 2 : 6$], glycerol, and picric acid; it crystallises from dilute alcohol in long needles, melts at $72-74^{\circ}$, is volatile with steam, and, in contact with copper oxide, colours the flame green; the yield is 80 per cent.

Nitroso-orthohydroxymetatoluquinoline, $C_9NH_4Me(NO \cdot H)O$ [$O : Me : NOH = 1 : 2 : 4$], is prepared by the action of sodium nitrite on the preceding compound, and it is deposited from alcohol or dilute acetic acid in yellow needles; it decomposes at about 200° without melting, and has no tinctorial properties. Soluble salts are formed with acids and bases. *Nitrorthohydroxymetatoluquinoline* is obtained from the preceding compound by oxidation with potassium ferricyanide in alkaline solution; it crystallises from alcohol in red needles and from benzene in yellow needles, melts at $192-193^{\circ}$, yields salts with acids and bases, and dyes mordanted cloth.

Orthohydroxymethylquinoline, $C_9NH_4Me \cdot OH$ [$OH : Me = 1 : 4$], is prepared from amidoparacresol, [$OH : NH_2 : Me = 1 : 2 : 4$]; it crystallises from dilute alcohol in long, colourless needles, melts at

122—124°, and gives a yellow dye with aluminium mordants; the yield is 65 per cent. of theory. *Nitroso-orthoxymethylquinoline*, $C_9H_7MeO:NOH$ [$O:NOH:Me = 1:3:4$], resembles the previously described isomerides, and dyes mordanted cloth; on oxidation, it yields the corresponding *nitro*-derivative, which crystallises from alcohol in slender, yellow needles melting at 205—206°; yellow colours are obtained with aluminium mordants.

Nitroparatoluquinoline, $C_9H_7Me:NO_2$ [$Me:NO_2 = 3:4$], is obtained from nitroparatoluidine, [$NH_2:NO_2:Me = 1:3:4$]; it crystallises from alcohol, and melts at 116—117°; the yield is 65 per cent. The corresponding *amido*-, *acetyl*-, and *hydroxy*-derivatives have been prepared and closely resemble the previously described isomerides. *Orthonitroparatoluquinoline*, $C_9H_7Me:NO_2$ [$NO_2:Me = 1:3$], is prepared from nitroparatoluidine [$NH_2:NO_2:Me = 1:2:4$], and crystallises from water in pale-yellow needles, melts at 122°, and does not combine with methyl iodide; the yield is 60 per cent. The salts crystallise readily, but dissociate with water. *Orthamidoparatoluquinoline* is prepared from the preceding compound by reduction with ammonium sulphide; it crystallises in slender needles, melts at 62—64°, sublimes without decomposition, and is volatile with steam. The *hydrochloride* forms orange needles. The *acetyl derivative* is obtained from water or dilute alcohol in large plates melting at 91—92°. It yields salts which readily crystallise. The *hydroxy*-derivative is prepared by means of the diazo-reaction, and is identical with the compound obtained from toluquinolinesulphonic acid [$SO_3H:Me = 1:3$] by fusion with potash. The *nitroso*-compound, $C_9H_7Me(NOHO)O$ [$O:Me:NOH = 1:3:4$], is very sparingly soluble, and crystallises in brown plates, which decompose at 200°, and do not dye. The *nitro*-derivative could not be obtained.

Orthamidochloroparatoluquinoline, $C_9H_7MeCl:NH_2$ [$NH_2:Me:Cl = 1:3:4$], is formed, together with amidotoluquinoline, by the reduction of the *nitro*-compound with tin and hydrochloric acid; it crystallises from alcohol in silky, lustrous needles, melts at 129—130°, and does not combine with diazo-compounds. The *monacid salts* are orange-yellow and readily undergo dissociation. The *hydrochloride* is sparingly soluble. The *acetyl derivative* is deposited from dilute alcohol in lustrous needles melting at 136—137°.

Nitrothotoluquinoline, $C_9H_7Me:NO_2$ [$Me:NO_2 = 1:2$], is prepared by the nitration of orthotoluquinoline, and crystallises in pale-yellow needles melting at 93°. It is volatile with steam, does not combine with methyl iodide, and on heating with alcoholic potash gives a violet colour, changing to red and finally to dirty brown on exposure to air. The yield is almost theoretical. The same compound is synthetically prepared from nitrotoluidine [$NH_2:Me:NO_2 = 1:2:5$]. The salts readily undergo dissociation.

Amidothotoluquinoline is obtained by reduction of the preceding compound with iron and acetic acid, and crystallises from water or dilute alcohol in long, yellow needles melting at 143°. The *hydrochloride* is red, the *dihydrochloride*, yellow.

Methylphenanthroline, C_9H_7Me $\begin{array}{c} N=CH \\ | \\ CH:CH \end{array}$ [$Me:CH:N = 1:3:4$],

is obtained by the action of glycerol and sulphuric acid on the amine, and is deposited from light petroleum in small crystals melting at 95–96°. It is identical with the compound obtained by synthesis from metatoluylenediamine. The *picrate* melts at 252–253°.

Acetamidorthotoluquinoline crystallises from water in silky, lustrous needles, and melts at 187°. *Hydroxyorthotoluquinoline*, from the amide, crystallises from dilute alcohol in colourless needles, and melts at 262–263° on rapidly heating. A compound identical with this has previously been prepared from orthotoluidinesulphonic acid [$\text{SO}_3\text{H} : \text{NH}_2 : \text{Me} = 1 : 3 : 4$]. With diazobenzene chloride, a *hydroxyazo*-derivative is formed, crystallising from alcohol in red needles melting at 138–139°, and soluble in aqueous alkalis. The *nitroso*-compound, $\text{C}_9\text{NH}_2\text{Me}(\text{NO})\text{O}$ [$\text{Me} : \text{NOH} : \text{O} = 1 : 3 : 4$], crystallises from alcohol in yellowish-brown plates, decomposes above 200° without melting, and gives “lakes” with the heavy metals. The *nitro*-derivative is formed on oxidation, and is deposited in orange needles which melt at 181–182°, and do not dye.

Asorthotoluquinoline, $\text{N}_2(\text{C}_9\text{NH}_2\text{Me})_2$ [$\text{Me} : \text{N} = 1 : 4$], is formed, together with amidotoluquinoline, by the reduction of nitroorthotoluquinoline with iron and hydrochloric acid; it crystallises from glacial acetic acid in orange needles, and melts at 260°. The *hydrochloride* is readily obtained in red crystals. On reduction with stannous chloride or alcoholic ammonium sulphide, a compound is formed which is insoluble in water, yields red salts, and has not yet been further investigated.

Azoxyorthotoluquinoline, $\text{ON}_2(\text{C}_9\text{NH}_2\text{Me})_2$, is formed, together with the *azo*-derivative, and may be separated by crystallisation from hydrochloric acid, in which it is tolerably soluble; it may be prepared directly by the incomplete reduction of nitrotoluquinoline, and crystallises from alcohol in slender, yellow needles melting at 201°. The *hydrochloride* is deposited in very slender, lemon-yellow needles; all the salts are readily dissociated. When heated with 10 parts of sulphuric acid at 110–115°, a compound is formed which is probably *hydroxyazotoluquinoline*, $\text{C}_9\text{NH}_2\text{Me} \cdot \text{N}_2 \cdot \text{C}_9\text{NH}_2\text{Me} \cdot \text{OH}$ [$\text{Me} : \text{OH} : \text{N} = 1 : 3 : 4$]; it is insoluble in alkalis, as is also the corresponding compound [$\text{Me} : \text{N} = 1 : 4$; $\text{Me} : \text{N} : \text{OH} = 1 : 3 : 4$] from amidotoluquinoline and hydroxytoluquinoline.

Nitrometaxyloquinoline, $\text{C}_9\text{NH}_2\text{Me}_2\text{NO}_2$ [$\text{Me} : \text{Me} : \text{NO}_2 = 1 : 3 : 4$], is obtained by nitrating metaxyloquinoline; it crystallises from alcohol in long, yellow needles, melts at 107–108°, is scarcely volatile with steam, and does not combine with methyl iodide. The salts are decomposed by water. The constitution of the compound is shown by its synthesis from nitroxyldine [$\text{NH}_2 : \text{Me} : \text{Me} : \text{NO}_2 = 1 : 2 : 4 : 5$]; it gives no coloration with alcoholic potash. *Amido-metaxyloquinoline* is formed by the reduction of the preceding compound with iron and acetic acid, or stannous chloride and hydrochloric acid; it crystallises from dilute alcohol in long, yellow needles, and melts at 91°. The *acetyl* derivative is deposited from water in colourless needles which melt at 201°. *Hydroxymetaxyloquinoline*, from the amido-compound and nitrous acid, crystallises from chloroform in white plates, and melts at 197–198°. On sublimation, it is obtained

in small needles, and salts are formed with acids and bases. The *hydrochloride* crystallises in yellow needles. J. B. T.

2-Methylquinaldine. By E. RIST (*Ber.*, 23, 3483—3487).—The author has already shown (*Abstr.*, 1890, 1324) that the so-called metamethylquinaldine obtained by Dobner and v. Miller from paraldehyde and metatoluidine (*Abstr.*, 1884, 183), and which might, therefore, have either the meta- or ana-constitution, is converted by oxidation into the quinaldinecarboxylic acid prepared by Döbner and v. Miller from metamidobenzoic acid and aldehyde. The *hydrochloride* of the latter acid forms small, characteristic tablets sparingly soluble in cold, readily in hot water, whilst the *platinochloride*, $4(C_{11}H_9NO_2.HCl).PtCl_4$, crystallises in reddish-yellow, monosymmetric prisms readily soluble in water. Its *silver* salt, $C_{11}H_9NO_2Ag$, crystallises from hot water in microscopic crystals soluble in ammonia and nitric acid.

To ascertain whether these compounds are really 2-derivatives, the author subjected Gerdeissen's 2-amidoquinaldine (*Abstr.*, 1889, 520) to Sandmeyer's reaction. The ordinary procedure cannot be adopted in this case, as the compound appears to form a stable nitrite. The mixture must be diazotised below 0° , allowed to remain, and then added to the freshly prepared cuprous cyanide on the water-bath in small quantities and with vigorous shaking. As soon as gas ceases to come off, the hot liquid is filtered, saturated with soda, and the precipitate recrystallised from water. The *nitrile* thus obtained forms silky needles melting at 82° , and crystallises with approximately 2 mols. H_2O , which are given off on drying over sulphuric acid, the melting point then becoming 104° . It is volatile in a current of steam, soluble in the ordinary solvents and in acids, and may be distinguished from the otherwise similar 2-amidoquinoline by the fact that it yields a colourless or pale-yellow solution with alkalis. On hydrolysis, it is converted into a quinaldinecarboxylic acid, which is identical with the acid already described. It follows, therefore, that both this acid and the methylquinaldine from which it was prepared have, in reality, the meta- and not the ana-constitution.

H. G. C.

Constitution of β -Quinaldinesulphonic Acid. By B. RICHARD (*Ber.*, 23, 3488—3490).—By the action of sulphuric acid on quinaldine, Döbner and v. Miller obtained a mixture of three sulphonic acids, two of which were shown to be ortho- and para-quinaldinesulphonic acids, whilst the constitution of the third, known as the β -acid, was not ascertained (*Abstr.*, 1884, 183). In order to determine its constitution, the author converted it by the usual reactions into the corresponding nitrile and carboxylic acid, both of which were found to be identical with the 2-cyanoquinaldine and quinaldine-2-carboxylic acid described by Rist (see preceding abstract). The acid from which they are prepared must, therefore, be quinaldine-2-sulphonic acid.

H. G. C.

Condensation of Metanitrobenzaldehyde with Quinaldine. By W. WARTANIAN (*Ber.*, 23, 3644—3653).—Metanitrobenzaldehyde

is heated for 3—4 hours on the water-bath with rather more than 1 part of quinaldine, zinc chloride being added from time to time in small portions; after purification and crystallisation from alcohol, a product is obtained which melts at 124—126°, and consists of a mixture of *metanitrobenzylidenequinaldine*,

and of the aldol compound, $\text{C}_6\text{NH}_5\cdot\text{CH}_2\cdot\text{CH}(\text{OH})\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$; the former substance may be separated by treatment with acetic anhydride at 135°; it is deposited from a mixture of benzene and light petroleum in yellow, nodular, crystalline aggregates, and melts at 139°. The *hydrochloride* forms long, rectangular crystals; the *nitrate* crystallises in pale-yellow, lustrous needles; the *picrate* is deposited in lemon-yellow, interlaced needles; the *platinochloride*, $(\text{C}_{17}\text{H}_{12}\text{N}_2\text{O}_3)_2\cdot\text{H}_2\text{PtCl}_6 + 1\frac{1}{2}\text{H}_2\text{O}$, is crystalline. When reduced with stannous chloride and hydrochloric acid, *metamidobenzylidenequinaldine*, $\text{C}_6\text{NH}_5\cdot\text{CH}:\text{CH}\cdot\text{C}_6\text{H}_4\cdot\text{NH}_2$, is produced, crystallising from a mixture of benzene and light petroleum in orange-red plates; it melts at 158—159°, and is insoluble in water, but readily dissolves in organic media, and is deposited from alcohol in pale-yellow needles. On heating the amido-compound with glycerol, sulphuric acid, and orthonitrophenol, *ethylenediquinoline*, $\text{C}_6\text{NH}_5\cdot\text{CH}:\text{CH}\cdot\text{C}_6\text{NH}_5$ [$\text{CH}:\text{CH} = 2':2$], is formed, but could not be obtained in crystals; it is readily soluble in alcohol, benzene, and chloroform. The *salts* and *platinochloride* are amorphous. The *methiodide* crystallises from methyl alcohol in golden-yellow needles, melts at 225—226°, and is insoluble in benzene, but readily dissolves in hot water.

No dimethyl iodide could be prepared. A bromo-additive compound is formed by the action of bromine on the methiodide in chloroform solution, and is deposited from methyl alcohol in slender crystals which commence to decompose at 180—190°, and melt at 210°.

Ethylenequinolinequinaldine, $\text{C}_6\text{NH}_5\cdot\text{CH}:\text{CH}\cdot\text{C}_6\text{NH}_5\text{Me}$ [$\text{CH} = 2'; \text{CH}:\text{Me} = 2:2'$], is prepared by the action of paraldehyde on amidobenzylidenequinaldine, and forms a yellow, plastic mass readily soluble in alcohol, benzene, or ether. The *nitrite* crystallises from water in stellate groups of reddish-yellow needles which commence to decompose at 125°, and melt at 135—136°. The *hydrochloride*, *nitrate*, *sulphate*, *picrate*, and *platinochloride* are all amorphous and readily soluble.

J. B. T.

β -Pyrazoledicarboxylic Acids. By MAQUENNE (*Compt. rend.*, 111, 740—743).—Dinitrotartaric acid not only acts on formaldehyde and acetaldehyde in presence of ammonia, but the reaction is general, and the author has prepared in this way a number of β -pyrazoledicarboxylic acids from the corresponding aldehydes. They are all only slightly soluble even in boiling water, and are almost insoluble in alcohol, but dissolve very readily in alkaline solutions, and yield mono-metallic salts which are neutral and crystallisable. Methyl-, ethyl-, and isopropyl-glyoxalinedicarboxylic acids crystallise with 1 mol. H_2O in brilliant, acicular prisms; the others form crystal-

line, anhydrous powders. Isobutylglyoxalinedicarboxylic acid and its alkaline salts have a sweet taste, but this property is wanting in the neighbouring homologues.

All the glyoxalinedicarboxylic acids decompose at about 300° , and yield carbonic anhydride and glyoxalines or β -pyrazoles, the decomposition being almost quantitative. This constitutes the best method for the preparation of glyoxalines. Many glyoxalines were prepared in this way, and the hexyl-glyoxaline was found to melt at $45-46^{\circ}$, and not at 84° as stated by Radziszewski.

2-Phenyl- β -pyrazole is solid, very slightly soluble in water or in warm benzene (from which it crystallises in lamellæ), but easily soluble in alcohol. It melts at 148° , and boils at about 340° (uncorr.), which distinguishes it from the isomeric 1-phenyl- α -pyrazole described by Knorr, which melts at 11° , and boils at 246.5° . The normal oxalate crystallises from aqueous solutions in anhydrous needles; the platinumchloride is anhydrous, and forms orange, microscopic crystals almost insoluble in cold water.

Difurfuramidodihydroxytartaric acid.—Furfuraldehyde does not act on dinitrotartaric acid in the same way as other aldehydes. When the aldehyde and acid in molecular proportion react in presence of excess of ammonia, a crystalline precipitate forms, and can be purified by solution in ammonia and reprecipitation with hydrochloric acid. It resembles the glyoxalinedicarboxylic acids in appearance, but has not their general properties, and yields no glyoxaline when distilled. The ammonium salt has the composition $C_{14}H_{10}N_2O_8(NH_4)_2 + 2H_2O$. The acid has the composition $C_{14}H_{12}N_2O_8$, is formed by the union of 2 molecules of furfuraldehyde with 1 molecule of tartaric acid, and probably has the constitution

C. H. B.

Caffeidine. By E. SCHMIDT and M. WERNECKE (*Arch. Pharm.*, 228, 516—543).—Caffeidine sulphate was prepared by boiling caffeine with barium hydroxide (Strecker's method) for half an hour only; white, needle-shaped crystals were finally obtained which are easily soluble in water, much less soluble in alcohol. By treating the sulphate with barium hydroxide, a little water, and chloroform, the free base is obtained as a solid, crystalline mass with a neutral reaction; it melts at about 94° . The free base readily decomposes with the formation of ammonia, methylamine, and cholestrophane. *Caffeidine hydriodide*, obtained by neutralising the free base with dilute hydriodic acid, forms white, tabular, anhydrous needles, easily soluble in hot water, somewhat less soluble in hot alcohol, insoluble in chloroform. *Caffeidine hydrochloride*, obtained by treating the hydriodide in aqueous solution with silver chloride, forms long, thin, somewhat hygroscopic needles. *Caffeidine nitrate*, prepared by precipitating the hydriodide solution with silver nitrate, forms large, white, strongly hygroscopic needles. Caffeidine sulphate, when treated with nitric acid, yields cholestrophane, ammonia, methylamine, and carbonic anhydride; but no ammonia is formed if the mixture is heated for a long time.

Oxidation of the sulphate with potassium dichromate and sulphuric acid yields the same products, and not diethyloxamide as found by Maly and Andreasch, excepting when the mixture is heated for some time. Oxidation with bromine gives the same compounds, as does also treatment with potassium chlorate and hydrochloric acid. Fuming hydrochloric acid completely decomposes caffeidine sulphate at 150° with the formation of carbonic anhydride, formic acid, ammonia, methylamine, and sarcosine (compare Abstr., 1888, 69). J. T.

Derivatives of Morphine. By W. DANCKWOERT (*Arch. Pharm.*, 228, 572—595).—Morphine, when heated with excess of acetic chloride, yields diacetylmorphine (the tetracetylmorphine of Wright). This compound, when boiled with water loses only one acetyl group, and α -monoacetylmorphine is formed; by the addition of hydrochloric acid, this can easily be obtained as the sparingly soluble hydrochloride. The β -monoacetyl (β -diacetyl of Wright) compound was prepared by Becket and Wright's method (this Journ., 1874, 1033), but their γ -compound was not obtained. The stability of morphine was not found to be increased by the entrance of the acetyl group, as shown by the reaction of diacetylmorphine with dilute nitric acid and with bromine, although this is known to be the case with codeine and the methyl group. Anhydrous morphine, when heated at 100 — 110° with twice the amount of benzoic chloride, yielded dibenzoylmorphine, which supports the view that the morphine molecule contains only two hydroxyl groups. Polstorff's tribenzoylmorphine could not be detected. By heating oxydimorphine with acetic chloride, tetracetyloxydimorphine is obtained, which doubtless is identical with Hesse's diacetylpsedomorphine, obtained by the action of acetic anhydride on pseudomorphine. The entrance of the four acetyl groups indicates that four hydroxyl groups exist intact in the oxydimorphine, and that the hydrogen atoms replaced must have been united with carbon. Apomorphine, when treated with excess of acetic chloride, yields monacetylapomorphine; hence only one hydroxyl group is present in apomorphine, the second hydroxyl group of morphine during its conversion into apomorphine going to form a molecule of water. Probably the alcoholic hydroxyl of morphine is the one expelled, the phenyl hydroxyl having greater stability. This, to some extent, will account for the chemical and physiological difference between morphine and apomorphine. J. T.

Cinchonamine. By ARNAUD (*Ann. Chim. Phys.* [6], 19, 93—131) See this vol., p. 362.

Berberine and Hydroberberine. By R. GAZE (*Arch. Pharm.*, 228, 604—662; compare Abstr., 1890, 1012).—Chloroformberberine, dissolved in a little hot chloroform and treated with alcohol, quickly gives long, prismatic crystals of *dichloroformberberine*,

The crystals soon lose their transparency when preserved, and decompose with evolution of chloroform when warmed. J. T.

Eegonine. By U. MUSSI (*Chem. Centr.*, 1890, ii, 516—517; from *L'Orosi*, 13, 152—158).—The author has already (*L'Orosi*, 11, 270—277) recommended that, since the direct detection of cocaine is difficult, the products of its decomposition should be sought for in toxicological investigations. With this object, he has examined the behaviour of eegonine with various reagents. According to EINHORN this alkaloid is *methyltetrahydropyridyl-β-hydroxypropionic acid*,

and reacts both as a base and an acid; it crystallises in colourless, lustrous, monoclinic prisms with 1 mol. H_2O , which is lost at 120—130°. It is very readily soluble in water, less easily in absolute alcohol, insoluble in ether, chloroform, and carbon bisulphide. Its solutions are neutral, and have a somewhat bitter taste. It melts at 193° with partial decomposition. With phosphomolybdic acid, it forms a yellow precipitate; with somewhat concentrated gold chloride solution, a yellow, amorphous precipitate; with platinic chloride in dilute alcoholic solution a red-brown, crystalline precipitate, $(\text{C}_6\text{H}_{15}\text{NO}_3)_2\cdot\text{H}_2\text{PtCl}_6$, which is readily soluble in water, and loses hydrogen chloride when heated, forming the salt $(\text{C}_6\text{H}_{15}\text{NO}_3)_2\cdot\text{PtCl}_4$. With stannic chloride, mercuric chloride, tannin, and picric acid, it forms no precipitates which distinguish it from cocaine. Especially is the reaction with Wenzell's reagent (200 parts of sulphuric acid and 1 part of potassium permanganate) delicate, a clear wine-red coloration being formed which disappears only after some time.

In an experiment with a rabbit, 1.26 grams of eegonine per kilo. of live weight was found to be fatal. After 48 hours, the entrails were divided into five parts, and each part digested several times at 60° with twice its weight of alcohol, and the extract concentrated nearly to dryness. The residue was taken up with water, and shaken several times with ether in order to extract fatty substances. The aqueous solution was precipitated with basic lead acetate, filtered, the lead removed as sulphide, the liquid again filtered, evaporated to dryness, and the residue finally extracted with a little absolute alcohol, in which the eegonine exists as acetate and was readily detected. The alkaloid was found in the heart, blood, lungs, liver, brain, and spinal cord.

Eegonine Salts.— $(\text{C}_6\text{H}_{15}\text{NO}_3)_2\text{Mg} + 3\frac{1}{2}\text{H}_2\text{O}$, very hygroscopic plates, soluble in water and alcohol, insoluble in ether, melting at 190°. $(\text{C}_6\text{H}_{15}\text{NO}_3)_2\text{Ca}$ is soluble in water and alcohol, insoluble in ether. $\text{C}_6\text{H}_{15}\text{NO}_3\text{Ag}$, orange-coloured, decomposing readily when exposed to the light. *Eegonine acetate*, $\text{C}_6\text{H}_{15}\text{NO}_3\cdot\text{C}_2\text{H}_3\text{O}_2 + 2\frac{1}{2}\text{H}_2\text{O}$, needle-like, hygroscopic crystals, melting at 196°, very soluble in water and alcohol, insoluble in ether. J. W. L.

New Alkaloid from *Chrysanthemum cinerariæfolium*. By F. MARINO ZUCCO (*Chem. Centr.*, 1890, ii, 560—561; *Rend. Accd. Lincei*, 6, i, 571—575).—In addition to the two substances, the one a paraffin and the other a homologue of cholesterol, which the author has already described (*Abstr.*, 1890, 757), he has further separated a glucoside and an alkaloid from the flowers of *Chrysanthemum cinerariæfolium*. Both were obtained from the blossoms by extraction with ether. The glucoside is crystalline, but could not be obtained

in sufficient quantity for proper investigation. The alkaloid, named *chrysanthemine* by the author, is readily soluble in water, and its solution may be concentrated on the water-bath without decomposition, whereby the base is obtained as a colourless syrup. The majority of its salts are soluble in water, alcohol, and ether, and are crystalline. The most characteristic of these is the aurochloride, which crystallises in small, golden-yellow needles, very soluble in hot water, sparingly so in cold water, readily in alcohol, and moderately soluble in a mixture of alcohol and ether (1 : 1). Potassium bismuth iodide forms a yellow precipitate with it, and potassium mercury iodide forms a yellowish-white precipitate. Platinum chloride, tannin, and picric and phosphotungstic acids do not form precipitates with it. The analysis of the aurochloride agrees with the formula $C_{14}H_{30}O_3N_2 \cdot 2AuCl_4$, according to which the formula of the hydrochloride would be $C_{14}H_{30}O_3N_2Cl_2$. J. W. L.

Ulexine and Cytisine. By A. W. GERRARD and W. H. SYMONS (*Pharm. J.* [3], 20, 1017).—The authors enumerate the following differences between ulexine, the alkaloid of *Ulex europaeus*, already described by them, and cytisine, the alkaloid of *C. laburnum*, which has been supposed to closely resemble, or be identical with, the former. Ulexine has the formula $\frac{1}{2}(C_{22}H_{28}N_4O_2)$; is very hygroscopic, cannot be sublimed, even in a vacuum, without decomposition, and dissolves readily in chloroform. Cytisine has the formula $C_{20}H_{27}N_3O$, is permanent in air, sublimes completely, forming splendid crystals, and is almost insoluble in chloroform. The formula given for ulexine differs only by CO from that of nicotine, and by H_2O from that of pilocarpine, and there is a certain likeness in the physiological action of these alkaloids, notwithstanding the differences in their chemical behaviour. Some progressions of properties are traced in the alkaloids from leguminous plants arranged according to the percentage of carbon, thus:—sparteine, pyridine, nicotine, cytisine, ulexine, eserine, and pilocarpine; in this series, the physiological activity becomes more powerful, and the instability greater with decrease in the percentage of carbon. R. R.

Alkaloids and other Active Principles from Plants Growing in the Dutch Indies.—By M. GRESHOFF (*Ber.*, 23, 3537—3550).—I. *Carpaine, the Alkaloid of Carica papaya, L.*—The leaves of the papaya (*Carica papaya, L.*) contain, in addition to the caricine and papaine discovered by Wurtz and Peckolt, an alkaloid which has not previously been prepared, and for which the name *carpaine* is proposed. The young leaves are richest in the alkaloid, and contain about 0.25 per cent.; the sap, seeds, and roots only contain traces. Carpaine is readily soluble in alcohol, chloroform, and ether, the freshly precipitated compound being more readily taken up by the latter solvent than when crystallised, a fact which is made use of in isolating the alkaloid. It is completely separated from solutions of its salts by sodium carbonate solution, but is insoluble in potash, and cannot be extracted from acid solution. It gives precipitates with Mayer's solution, iodine, phosphomolybdic acid, picric acid, gold chloride, tannin, potassium thiocyanate, &c., melts at 115° , and sub-

limes partly without decomposition. Its *hydrochloride* crystallises in beautiful, lustrous needles, and is readily soluble in water. The base, even when dissolved in 100,000 parts of water, has a bitter taste, and is only poisonous in large doses, but small quantities readily kill smaller animals, the action taking place on the heart.

II. *Investigation of Indian Leguminous Plants*.—The plant known as *Derris* (*Pongamia*) *elliptica*, Benth., is largely used in Java in fishing, and appears also to be a constituent of the Borneo arrow-poison. It has an exceedingly poisonous action on fish, a decoction of the roots being fatal even when diluted with 300,000 parts of water. The only active constituent isolated is a resinous substance termed *derrid*, which does not contain nitrogen and is not a glucoside; it readily dissolves in alcohol, ether, chloroform, and amyl alcohol, but is very sparingly soluble in water and potash solution. On fusion with potash, it yields salicylic and protocatechuic acids. It occurs almost entirely in the cortex of the root, but has not yet been obtained pure. Its alcoholic solution has a slightly acid reaction, and a sharp aromatic taste, causing a partial insensibility of the tongue, which remains for hours. A solution of 1 part in 5 millions is almost instantly fatal to fish. A very similar compound is found in the seeds of *Pachyrhizus angulatus*, Rich., a decoction of which is quickly fatal in a dilution of 1:125,000. It is probably identical with *derrid*, but until this has been experimentally proved it may be distinguished as *pachyrhizid*. It is very readily prepared from *Pachyrhizus*, which occurs in all tropical countries, as the tannin compounds, usually so difficult to separate, are not found in this plant. The seeds also contain a non-poisonous, crystalline compound, which is readily soluble in alcohol, and has at 30° the consistence of butter.

The plant *Sophora tomentosa*, L., formerly renowned as a medicine ("Anticholeric *Rumphii*"), contains a poisonous alkaloid, soluble in ether, which is contained in largest quantity in the seeds. Alkaloids have previously been found in *S. speciosa* and *S. angustifolia*, but have not been closely investigated.

The cortex of *Erythrina* (*Stenotropis*) *Broteroi*, Hassk., contains considerable quantities of an alkaloid, which may be readily isolated by Stas's method, and is easily soluble in ether. Its sulphate may be obtained in crystals from concentrated aqueous solution. It gives precipitates with many metallic salts and with the usual alkaloid reagents; it is a fairly strong poison, being fatal to fowls in doses of 0.025 gram. A poisonous alkaloid likewise exists in *Erythrina* (*Hypnophorus*) *subumbrans*, Hassk., and is best isolated as a metallic double compound.

The leaves of different kinds of cassia are employed in Java as a remedy for herpes; they contain a glucoside which yields chrysophanic acid as a product of hydrolysis.

The leaves of *Orotolaria retusa*, L., contain considerable quantities of indican; the seeds contain an alkaloid, which is found in larger quantities in the seeds and leaves of *O. striata*, L. The base is a strong poison, and is probably closely related to the known alkaloids of other Genistæ, such as *Oytisus*, *Ulex*, *Spartium*, and *Lupinus*.

The seeds of *Milletia atropurpurea*, Benth., contain a poisonous

glucoside, the chemical and toxicological properties of which closely resemble those of saponin. The plant is also employed for poisoning fish. The cortex of *Acacia tenerrima*, Jungh., contains a bitter, poisonous alkaloid, readily soluble in ether and chloroform. No alkaloid has previously been found in an acacia. The leaves of *Albizia saponaria*, Bl., contain cathartic acid, whilst the leaves and cortex contain saponin in quantity.

The cortex of *Pithecolobium bigeminum*, Mart., contains 0·8 per cent. of a non-volatile, amorphous alkaloid, which forms crystalline salts, and separates as a heavy, yellow oil on the addition of alkalis to solutions of the latter. With 100 parts of water, it forms a turbid liquid, which on warming assumes the appearance of milk, but becomes clear on the addition of an acid. The solutions have a burning taste, and give the usual alkaloid reactions. It has a strong corrosive action on the skin, and is fatal to fish in a dilution of 1 : 400,000. The same compound appears also to occur in *P. saman*, Benth.

III. *Apocynææ containing Alkaloids, occurring in the Dutch Indies*.—The leaves, cortex, and seeds of *Melodinus lavigatus*, Bl., all contain a poisonous alkaloid, which is present in the largest quantity in the seeds (0·8—1·0 per cent.). It is decomposed by dilute hydrochloric acid, but is not a glucoside, and gives the ordinary alkaloid reactions in very dilute solutions, and with feeble oxidising agents in sulphuric acid solutions gives a greenish coloration, which then becomes deep blue and finally orange.

Leuconotis eugenifolia, Dec., yields a poisonous, crystalline alkaloid which is readily soluble in ether, and shows the general reactions of the alkaloids, but gives no colour reactions. The cortex of *Rauwolfia canescens*, W., yields an alkaloid which gives a beautiful, blood-red coloration with nitric acid. *Rauwolfia* (*Ophioxylon*) *serpentina* and *trifoliata*, which is highly prized in Java as a drug, also contains a crystalline alkaloid which gives the same reaction with nitric acid, and its presence may be easily recognised microscopically in the various parts of the plant by this reaction. The substance recently described as ophioxylin is identical with Dulong's plumbagin, the error being caused by a confusion between *Ophioxylon serpentinum*, L., and *Plumbago rosea*, L., which, though very different plants, are both termed "Poeleh Pandak" in Java. The above alkaloid also occurs in *Rauwolfia* (*Cyrtosiphonia*) *spectabilis* and *madurensis*. All these species of *Rauwolfia* contain a brown substance also; this likewise appears to be an alkaloid, and yields a beautiful, blue, fluorescent solution in ether. It is constituent of many *Apocynææ*.

The cortex of *Hunteria corymbosa*, Roxb., contains 0·3 per cent. of a crystalline alkaloid, which also forms crystalline salts, and gives a beautiful violet coloration with Erdmann's and Fröhde's reagents. It is a strong poison, and has a sharp, burning taste, even when diluted to 1 : 10,000. The cortex of *Pseudochrosia glomerata*, Bl., also contains a poisonous, crystalline alkaloid, and the above fluorescent compound.

The cortices of *Ochrosia* (*Lactaria*) *acuminata*, *Ackeringia*, and *Coccoloba* are rich in alkaloid constituents. Three products have been isolated, namely, a colourless, crystalline alkaloid soluble in ether, which is moderately poisonous, an alkaloid insoluble in ether but

soluble in amyl alcohol, which is best isolated as the mercuriochloride, and also the above-mentioned fluorescent compound. These substances also occur in the seeds and the sap. The cortex of the stem of *Ochrosia* (*Bleekaria*) *kalocarpa* contains 1·2 per cent. of alkaloids.

The seeds of *Kopsia fluviala*, Bl., contain no less than 1·85 per cent. of a homogeneous alkaloid, which is soluble in ether and readily prepared pure and crystalline; it likewise occurs in *Kopsia arborea*, Bl., the leaves of which contain in addition a fluorescent substance. *Kopsia* (*Calpicarpum*) *Roxburghii* yields quite a different alkaloid, which causes tetanus. The seeds and leaves of *Kopsia* (*Calpicarpum*) *albiflorum* contain an alkaloid, as also do *Vinca rosea*, L., and *Alstonia* (*Blaberopus*) *villosa*.

Voacanga (*Orchipea*) *foetida* yields a bitter alkaloid readily soluble in ether, and the fluorescent compound already frequently mentioned. *Tabernaemontana sphaerocarpa*, Bl., also contains an alkaloid, and a wax-like compound, which is free from nitrogen and melts at 185°. Alkaloids are also present in *Rhynrodia* (*Cercocoma*) *macrantha* and in *Chonemorpha macrophylla*, Don, which is of interest, inasmuch as these species both belong to the *Echitidie*, the other members of which are free from alkaloids.

IV. *Cerbera odollam*, Hamilt.—The sap, leaves, and cortex of this plant have no toxicological action, but the seed kernel contains, in addition to a non-poisonous fatty oil, the compound *cerberin*, which has a poisonous action on the heart. It resembles thevetin, thevetosin, and tanghinin, but is identical with none of them. It most nearly resembles the last-named substance, which is obtained from *Tunghinia renemifera*, Poir., the “test-plant” of Madagascar. Cerberin is free from nitrogen and crystallises well, and although decomposed by acids, is not a glucoside. It is insoluble in water, but dissolves readily in alcohol, chloroform, acetic acid, and 80 per cent. ether, and melts at 165°. It gives a violet coloration with sulphuric acid, has a sharp, burning but not bitter taste, and is very poisonous. The seeds contain another very poisonous substance, which is readily soluble in water, alcohol, and amyl alcohol, but insoluble in chloroform, for which the name *odollin* is proposed. It is not precipitated by lead acetate, and gives the same colour reaction with sulphuric acid as *cerberin*.

V. *Laurotetanine*, the Active Constituent of certain *Lauraceae*.—Many of the Javan varieties of *Lauraceae* contain, in addition to other not yet clearly defined bases, a crystalline alkaloid termed *laurotetanine*, which has a strong tetanic action on animals. It is contained in quantity in the cortex of the stem of *Litsa chrysocoma*, Bl., and is sparingly soluble in ether, more readily in chloroform. It is precipitated by sodium carbonate from solutions of its salts, but readily redissolves in an excess of potash or soda, and is precipitated by the usual alkaloid reagents. The freshly prepared alkaloid commences to crystallise after some days in stellate groups of needles; it gives a dark indigo-blue coloration with Erdmann's reagent, a pale rose-red with pure sulphuric acid, and a reddish-brown with nitric acid. A base which seems to be identical with *laurotetanine* is also found in the varieties of *Tetranthera*, in *Notaphæbe*, Bl., *Aperula*, Bl., and *Actinodaphne*, Nees. It is possible, also, that *laurotetanine* is identical

with the alkaloïd discovered in 1886 by Eykmann in *Hansia squarrosa*, Z. et M., as the author has also found it in *H. firma*, Bl.

Hernandia sonora, L., and *H. ovigera*, L., both yield an alkaloïd closely resembling the bebeerine obtained from *Nectandra*, whilst *Illigera pulchra*, Bl., contains laurotetanine.

VI. *The Distribution of Hydrocyanic Acid in the Vegetable Kingdom.*—The leaves of *Gymnema latifolium*, Wall, an Indian *Asclepiadea*, contain large quantities of amygdalin, which can, however, only be obtained in the amorphous condition. The leaves do not contain any enzyme, and may, therefore, be distilled with water or dilute sulphuric acid without any hydrocyanic acid or benzaldehyde passing over. On the addition of emulsin, hydrolysis readily takes place.

The fresh bark of many Javan forest trees gives off an odour of bitter almond oil. It was found that *Pygium parviflorum*, T. et B., and *P. latifolium*, Miq., both contain amygdalin, which on botanical grounds was not improbable, as the species *Pygium* is closely related to *Amygdalus*.

When the fruit of certain Javan Aroïdes (the genera *Lasia* and *Cyrtosperma*) is cut, a strong odour of hydrocyanic acid is observed, and it was found on investigation that it is present in the free state. It also occurs in the leaves of these plants. It is found, however, in much larger quantity in a Javan tree known as *Pangium edule*, Reinw., the seeds of which, after cooking in a certain manner, are looked on by the Malays as a valuable food. If this cooking is insufficient, the seeds are a frightful poison, and are used in Java for killing fish and insects. It was found on investigation that all parts of the tree contain free hydrocyanic acid. Thus the leaves, on distillation, yielded 0.34 per cent. which is equal to 1 per cent. on the dried leaves; in the other parts the proportion, although less, is still considerable. The amount of hydrocyanic acid is not constant, old *Pangium* leaves having been examined which only contained 0.045 per cent.

The leaves and seeds of the *Pangium* contain a substance which reduces ammoniacal silver solution and Fehling's solution in the cold, and whose solutions become dark-coloured in the air. Although no crystalline compound could be obtained with phenylhydrazine, it is probably a sugar, with which the hydrocyanic acid forms an unstable compound. The seeds, which are originally white, gradually become dark, the hydrocyanic acid disappearing at the same time.

The only poisonous constituent of the genus *Hydnocarpus* is also hydrocyanic acid. The fatty oils of certain species of *Hydnocarpus* are used externally in skin diseases, their value being possibly due to the antiseptic action of hydrocyanic acid. H. G. C.

Coagulation. Preparation of Soluble Casein. By A. BÉCHAMP (*Bull. Soc. Chim.* [3], 4, 181—186).—The author takes exception to the undefined meaning of the word coagulation, as applied to the separation of the proteïds from milk, under varying conditions, and describes the following method for preparing a soluble casein which is not coagulable by heat. Pure acetic acid is dropped into milk just drawn from the cow or goat, until the milk turns litmus-paper a pale pink, and the coagulum which soon separates out is

collected, and, after drying by a filter pump, is treated with ether to remove fat; it is then suspended in a volume of water equal to that of the original milk, and containing ammonium carbonate, and the mixture is filtered. To the limpid solution thus obtained, acetic acid is added exactly sufficient to precipitate the casein, which, by a repetition of the above treatment, is obtained pure.

The rotatory power of this substance in ammoniacal solution is $[\alpha] = -130^\circ$. It is soluble in water, 1 litre dissolving, on agitation for 56 hours, 1.005 grams, and the rotatory power of this solution is $[\alpha]_D = -117^\circ$. A paste of casein and water softens at $70-80^\circ$, and appears to be quite soft at 90° , the water separated from this product contains 2.37 grams casein per litre; and, although the paste hardens on cooling, it is soluble in ammonium carbonate solution, and on precipitation by acetic acid, manifests its original properties. Casein behaves like a feeble acid, its solutions redden litmus, and it forms compounds with the alkali metals and with ammonia which also redden litmus, and are neither precipitated by carbonic anhydride, nor by alcohol, nor by heating. Calcium caseinate behaves like calcium saccharate in becoming turbid on ebullition, and in the disappearance of the turbidity on cooling. The author ascribes the incorrect results hitherto obtained to the practice of boiling the milk before adding the acid, by which lactalbumin and galactozymase are precipitated as well. These substances are separated from the whey left after removal of the casein, by adding to it alcohol of 95° as long as a precipitate falls; the latter is collected and washed with alcohol of 80° , to remove lactose, and is then air-dried and suspended in water; after some time, it is filtered, and the precipitate is washed with water as long as the washings give a precipitate with alcohol.

Lactozymase is separated from the filtrate by the addition of alcohol and a trace of sodium acetate; it is soluble in water, and has the power of determining the dissolution of starch without subsequent hydrolysis; it is coagulable by heat and then loses this property.

Lactalbumin is obtained by dissolving the residue in dilute ammonium carbonate solution and precipitating by acetic acid; when it is suspended in water and heated to 100° , it contracts in volume and is no longer soluble in ammonium carbonate solution.

T. G. N.

Proteids of Milk. By W. D. HALLIBURTON (*J. Physiol.*, 11, 448-463).—Attention is drawn in this paper to the following points:—

(1.) The principal proteid in milk precipitable by saturation with certain neutral salts or by acetic acid, should be called *caseinogen*. It may be most satisfactorily prepared free from impurities by a combination of the two methods just mentioned. The term *casein* should be restricted to the curd formed from caseinogen by the action of rennet.

(2.) In the classification of proteids, casein should be grouped with other insoluble proteids, like fibrin and gluten, formed by ferment activity from pre-existing more soluble proteids. Caseinogen should be classified in a new group, made to include it and whey-proteid. These are very similar to the globulins; the chief difference being

that their solutions are not coagulated by heat like the globulins, but only rendered opalescent. This opalescence, if the heating has not been continued too long, disappears on cooling.

(3.) Lactalbumin is very similar in its properties to serum-albumin. Not only does it differ, however, from serum-albumin in its specific rotatory power, as has previously been shown, but in its behaviour on heat-coagulation, and in precipitability by certain neutral salts.

(4.) Caseinogen and lactalbumin are the only proteids contained in milk. The proteid described as lactoglobulin does not exist; it is owing to the error of not recognising that the two salts, sodium chloride and magnesium sulphate, when both present to saturation, precipitate albumin, that this proteid has been supposed to exist. The proteids variously called lactoprotein, peptone, and hemi-albumose, do not exist in milk. This mistake has also arisen from faulty methods of analysis.

(5.) The proteid called whey-proteid, which passes into solution simultaneously with the formation of the rennet curd, is not of the peptone or proteose class, but should be included with caseinogen in a new class of proteids allied to the globulins. It differs from caseinogen in not being convertible into casein.

(6.) When milk turns sour owing to the lactic acid fermentation, primary proteoses, chiefly proto-proteose, are developed.

W. D. H.

Note.—Hammarsten, in his text-book of Physiological Chemistry recently published, also recognises that caseinogen should not be grouped with alkali albuminates, as has hitherto been the case. He classifies it with the nucleo-albumins.

W. D. H.

Action of Lime Salts on Casein and on Milk. By S. RINGER (*J. Physiol.*, 11, 464—477).—Casein, prepared by adding commercial rennet to milk, was found to be freely soluble in lime-water; on the addition of calcium chloride to this solution, a compound of casein is formed which is more soluble in cold than in hot solutions. A few drops of calcium chloride solution does not cause precipitation at all in the cold, but, on warming, a precipitate forms closely resembling a rennet curd, and, like it, it contracts, squeezing out a whey. On cooling this, however, it completely redissolves. Larger quantities of calcium chloride cause a precipitate in the cold, which increases when the mixture is heated. Sodium chloride in 0.5, 1, and 2 per cent. solutions does not modify this action; whilst lactose greatly aids the action of the calcium salt.

Similar experiments were then tried with milk. Calcium chloride causes no curdling of milk at the atmospheric temperature (10° to 15°), in this respect differing strikingly from solutions of casein in lime-water, from which 1 to 3 drops of a 10 per cent. solution of calcium chloride precipitates abundance of curd or sets the fluid to a jelly. Calcium chloride, however, abundantly precipitates curd from milk with the assistance of heat, the smaller the quantity of calcium chloride the higher the temperature required. Slight acidity favours, sodium chloride and to a less extent potassium chloride and magnesium sulphate hinder this action of calcium chloride. Hence

milk differs from casein dissolved in lime-water in respect to the action of sodium chloride. Lactose, which greatly favours the clotting of a lime-water solution of casein by calcium chloride, does not influence the clotting of caseinogen as contained in milk.

Calcium chloride solution does not clot milk which has been previously boiled and then cooled. Hence it is evident that the high temperature necessary in the experiments does not alter the caseinogen, and thus enable calcium chloride to precipitate it, but that the high temperature is necessary to enable calcium chloride to precipitate (combine with) caseinogen.

Caseinogen can be prepared as follows :—10 per cent. acetic acid is added to milk; the resulting precipitate is washed with distilled water until the washings are neutral and free from calcium salts. The curd is rubbed in a mortar with calcium carbonate, and distilled water added; the caseinogen rapidly dissolves, and the butter separates and floats on the top. After some hours, the milky fluid below is siphoned off. Rennet clots this solution if a small quantity of calcium chloride is added, but not without. The rennet used (Crosse and Blackwell's) contains a good deal of calcium, but this is either insufficient, or in inappropriate form. But, although the fluid does not clot, the caseinogen is converted into casein, which remains in solution, and this is at once deposited on adding calcium chloride, each drop producing an abundant deposit, insoluble in solution of sodium chloride. Sodium and potassium salts antagonise the clotting of caseinogen solutions, as in the case of milk; in the former case they lessen, too, the subsequent contraction of the clot. If phosphoric acid is essential, as Hammarsten stated, the minute quantity present in the preparation of rennet must have sufficed, as none was added in the experiments.

Calcium chloride solution precipitated caseinogen from its solution without the assistance of rennet; only larger quantities are necessary than is the case with solutions of casein. Lactose has no effect on the precipitation of caseinogen by calcium chloride. Corroborative results were obtained with caseinogen precipitated by saturating milk with sodium chloride.

Among further differences between caseinogen and casein, the two following may be noted :—

(1.) Casein is insoluble in a fairly strong solution of sodium chloride; caseinogen is soluble.

(2.) Caseinogen precipitated by acetic acid and mixed in a mortar with calcium carbonate is freely soluble in distilled water. Casein similarly treated is insoluble.

The process of ordinary curdling in milk by rennet is believed to consist of two parts :—

(1.) The change from caseinogen to casein, produced by the ferment.

(2.) The combination of the casein so formed with a lime salt, the precipitation of this compound being assisted by the lactose, but opposed by the sodium and potassium salts of the milk. These salts also lessen the degree of contraction of the clot, and hence a bulky clot instead of a compact one is obtained.

W. D. H.

Digestion Products of Gluten-casein. By R. H. CHITTENDEN and E. E. SMITH (*J. Physiol.*, 11, 410—434).—The methods of investigation are essentially the same as those adopted in the similar researches of Kühne, Chittenden, and others. Although it is questionable whether gluten exists in fresh wheat grains, it is nevertheless true that gluten is formed whenever wheat flour is mixed with water, and of this gluten the insoluble portion, characterised by Ritthausen as gluten-casein, is the most important constituent. The percentage composition of this material (the average of analyses of seven preparations) may be contrasted with the numbers obtained by Ritthausen, and with the percentage composition of the casein of milk, as in the following table:—

	Gluten-casein.		Casein of milk.	
	Chittenden and Smith.	Ritthausen.	Chittenden and Painter.	Hammarsten.
C	52·87	52·94	53·30	52·96
H	6·99	7·04	7·07	7·05
N	15·86	17·14	15·91	15·65
S	1·17	0·19	0·82	0·72

On subjecting gluten-casein to artificial gastric digestion, it was found that solution occurs very slowly, probably the result of the prolonged washing with alcohol in its preparation. Artificial pancreatic digestion also proceeds slowly, but there is a more abundant formation of true peptone, as compared with primary cleavage products (proteoses), than is the case with gastric digestion. The soluble products formed in each case bear essentially the same relation to the parent substance as the albumoses of albumin or fibrin do to the parent proteid. There are slight differences in minor reactions, but no essential difference in the general character of the products formed in this case, at least between the animal and vegetable proteid. Both yield by the action of pepsin acid a proportionately large amount of proteoses and a small amount of true peptone. The gluten-caseoses, both in composition and reactions, show the ordinary proteose characteristics, and the composition of the individual products (proto-, hetero-, and deutero-gluten-caseose), as indicated by the gradually diminished percentage of carbon, suggests that they are formed by a gradual process of hydration.

W. D. H.

Crystalline Vitellin and Vitelloses. By R. H. CHITTENDEN and J. A. HARTWELL (*J. Physiol.*, 11, 435—447).—This research, carried out on the same lines as the preceding, confirms in the main the work of Neumeister (*Abstr.*, 1887, 286); it was judged advisable to repeat the experiments, as vitellin (crystallised in this research from extracts of squash or pumpkin seeds by Drechsel and Grubler's method) is the purest proteid obtainable. Scarcity of material prevented the

investigation of many points, but the general conclusion is that, in gastric digestion, the changes, as in the case of other proteids, are hydrolytic in nature; proto-proteose, deuterio-proteose, and peptone resulting from a series of gradual hydrations, as indicated by the gradually diminished percentage of carbon. The amount of hetero-vitellose formed was small.

Attention was particularly directed to the percentage composition of the products, and the following table collects a few of the averages obtained:—

	C.	H.	N.
Vitellin.....	51·60	6·97	18·80
Proto-vitellose.....	51·52	6·98	18·67
Deutero-vitellose (1)	50·42	6·74	18·43
" " (2)	49·27	6·70	18·78

The results agree very closely with those previously obtained with the globulin body, myosin, the composition of the myosinoses bearing almost exactly the same relationship to myosin as the vitelloses do to the crystallised globulin. A single experiment on tryptic digestion showed nothing noteworthy.

W. D. H.

Crystallisation of Hæmoglobin. By S. M. COPEMAN (*J. Physiol.*, 11, 401—409).—This is a full account of experiments a preliminary notice of which has already appeared (*Abstr.*, 1889, 1092). Among new points noticed, is the fact that some crystals of human hæmoglobin were after the lapse of some months changed into crystals of hæmochromogen. Hoppe-Seyler has previously prepared crystalline hæmochromogen (*Abstr.*, 1889, 788).

It was found that, using the method of adding putrid serum to the blood, the hæmoglobin crystals of the squirrel obtained were not the usual hexagons, but rhombic prisms. (Compare Halliburton, *Abstr.*, 1886, 637).

W. D. H.

Compounds of Hæmoglobin with Carbonic Anhydride. By C. BOHR (*Chem. Centr.*, 1890, ii, 521; from *Centr. Physiol.*, 4, 253—254).—As already communicated (*Abstr.*, 1890, 1450), there are several compounds of hæmoglobin and carbonic anhydride, containing varying proportions of the latter, but showing dissociation curves which are approximately similar. The author now describes the three following:—*γ-carbohæmoglobin*, which contains about 3·0 c.c. of carbonic anhydride per gram at 18° under a pressure of 60 mm. of carbonic anhydride; *δ-carbohæmoglobin*, which contains about 6·0 c.c. of carbonic anhydride under the same conditions of temperature and pressure; *β-carbohæmoglobin*, which contains about 1·5 c.c. of carbonic anhydride per gram. If hæmoglobin is shaken with a mixture of carbonic anhydride and oxygen, both the gases are absorbed in the same manner as though each of the gases was present alone. The spectrum of these hæmoglobin compounds appear to be the same as that of oxyhæmoglobin. The author concludes that the carbonic anhydride

and the oxygen combine differently and independently with the hæmoglobin, and the possibility exists that arterial blood fully charged with oxygen may, nevertheless, absorb carbonic anhydride. J. W. L.

Physiological Chemistry.

Effect of Acetic Acid on Respiratory Changes. By A. MALLÈVE (*Compt. rend.*, 111, 826—828).—Rabbits which had been subjected to tracheotomy were placed under artificial respiration, voluntary movements being prevented by injection of curarine. The products of respiration under these conditions were collected and analysed. A 3 per cent. solution of sodium acetate was introduced into the blood drop by drop, and the products of respiration were again examined. Before injection, the extreme values of the respiratory ratio CO/O were 1.04 and 0.77, but during injection, they sank to 0.86 and 0.69 respectively, a result due to oxidation of the sodium acetate. During injection, the blood becomes alkaline, but afterwards again becomes acid. Part, and part only, of the energy of the acetate is used with profit to the organism, and in this respect acetic acid differs from the majority of food stuffs. C. H. B.

The Specific Quantities of Oxygen in Blood. By C. BOHR (*Chem. Centr.*, 1890, ii, 521—523; from *Centr. Physiol.*, 4, 254—257).—As already intimated (*Abstr.*, 1890, 1450), hæmoglobin does not always absorb the same quantity of oxygen. Pursuing this investigation, the author has estimated the amounts of hæmoglobin and of oxygen in blood taken systematically from dogs, the latter estimation being made after first shaking the blood with oxygen of constant temperature and pressure. The ratio between these two quantities has been named the *specific quantity of oxygen of the blood*. This ratio varies not only with different animals, but depends also on the exterior conditions under the will of the operator, and it varies further in the different parts of one and the same animal at the same time. From these facts, it may be deduced that the oxygen present in the blood exerts a varying pressure, and that this pressure has a material regulating influence on the respiratory organs. Moreover, the variations in the pressure thus exerted occur within very small limits of time, and depend on the number of blood corpuscles which are influenced. In the author's experiments, strong anæmia was brought about when the arterial blood showed a constant and lower specific quantity of oxygen than before. A similar effect was produced by inhaling air poor in oxygen. On the other hand, suffocation produced an increase in the specific quantity of oxygen, and morphine exerted a like influence (compare preceding page). J. W. L.

Influence of Proteid on the Digestion of Foods free from Nitrogen. By T. ROSENHEIM (*Pflüger's Archiv*, 46, 422—432).—In recent researches by Kumagawa (*Virchow's Archiv*, 116), and

Hirschfeld (Abstr., 1889, 174) on metabolism, these observers stated that equilibrium is possible on smaller quantities of proteid food than has hitherto been considered possible. Their experiments, however, lasted for too short a time for such a sweeping conclusion to be drawn; and in the present research it is shown that in a dog, proteid food is not only valuable in itself, but that it aids the digestion of other foods which contain no nitrogen, such as carbohydrates and fats. The fæces were examined for undigested residues of carbohydrates and fats, and it was found that these were always smaller when there was admixture of proteid in the food; also that these residues were smaller in direct proportion to the amount of albuminous material administered.

These general results are supported by six series of analyses in which full details are given. W. D. H.

The Influence of Glycerol and Fatty Acids on Gaseous Metabolism. By I. MUNK (*Pflüger's Archiv*, 46, 303—334).—Numerous observations have been made on the question whether glycerol and fatty acids affect gaseous metabolism in any way, and particularly if they act as proteid-sparing or fat-sparing foods. Scheremetéeffsky (*Arbeits. physiol. Anstalt, Leipzig*, 1869, 194) stated that in rabbits the intake of oxygen and output of carbonic anhydride were correspondingly increased after two-grain doses of glycerol. Zuntz and v. Mering (*Pflüger's Archiv*, 32, 174) pointed out errors in Scheremetéeffsky's methods and conclusions. They found the intake of oxygen practically unaltered by the intravenous injection of glycerol. Their experiments were, however, not performed on curarised animals, and it is possible that the increased discharge of carbonic anhydride observed might have been due to the muscular movements of the animals. Under these circumstances, it was judged advisable to repeat these experiments, precluding the source of error

Oxygen used.	Carbonic anhydride given out.	Respiratory quotient.	Period of observation.	Dose of glycerol.

just alluded to, by curarisation, and to extend the research to include certain fatty acids. The apparatus used was a modification of the Zuntz-Röhrig respiration apparatus, which is fully described. The experiments were made on rabbits; and the accompanying tables of analyses are averages obtained in each case from a number of observations, each of which was for a period of 15 minutes. The glycerol was injected slowly into the jugular vein.

These experiments show that during the injection, the intake of oxygen falls slightly, and the output of carbonic anhydride increases to a small extent, thus raising the respiratory quotient; and the conclusion is drawn that glycerol when burnt in the body protects from oxidation a fraction of the body fat.

A similar series of experiments were then made, injecting sodium butyrate instead of glycerol, and again the results may be given in tabular form:—

Oxygen used.	Carbonic anhydride given out.	Respiratory quotient.	Period of observation.	Dose of butyric acid.
260.9	196.1	0.75	Before injection	} 0.4 gr. per kilo.
280.0	190.5	0.68	During "	
258.3	181.2	0.71	After "	
290.9	228.8	0.78	Before "	} 0.5 " "
325.2	214.6	0.66	During "	
299.4	230.9	0.78	After "	
305.3	243.4	0.79	Before "	} 0.56 " "
330.9	238.0	0.72	During "	
306.6	235.3	0.77	After "	
278.9	201.0	0.72	Before "	} 0.76 " "
297.6	197.9	0.68	During "	
278.1	205.2	0.78	After "	

These experiments show that during the injection, the intake of oxygen increases, and the output of carbonic anhydride falls slightly; the respiratory quotient therefore falls. Just as in the previous experiments with glycerol, none of the substance injected appeared in the urine; it was, therefore, burnt in the body, and thus must protect a small fraction of the body fat from oxidation. The increased intake of oxygen appears to be chiefly due to the increased frequency of the heart that the soap produces. The increased necessity for oxygen is seen when one notes that, whereas each molecule of glycerol requires $3\frac{1}{2}$ mols. of oxygen for complete oxidation, a molecule of sodium butyrate requires 5 mols. of oxygen for the same purpose.

A few experiments were then made with sodium oleate; the effect of doses similar to those given of the other substances just described produced a rapid decrease of the gaseous exchanges, a weakening of the heart, then syncope and death. A dose of 0.04 gram of oleic

acid per kilo. of body weight produced no alteration; a repetition of this dose caused a diminution of the gaseous exchanges by 75 per cent.

W. D. H.

Transfusion of Mixtures of Blood and Salt Solution. By J. MARSHALL (*Zeit. physiol. Chem.*, 15, 62—70).—Transfusion of salt solution is now so often used in medical practice, that it is important we should have an accurate knowledge of the process of blood regeneration that follows this procedure. Rabbits were bled until convulsions were imminent, and then a solution of one part of defibrinated blood to nine parts of 0.6 sodium chloride solution was injected; tables are given with enumeration of blood corpuscles, and percentages of hæmoglobin before and at intervals after the operation. When regeneration was complete, the animals were killed, but in no case was anything abnormal found at the autopsy. The blood corpuscles reach the normal number in a few days, but the percentage of hæmoglobin is not normal for some days, in one experiment not until 15 days later. These results coincide closely with those of J. G. Otto (*Pflüger's Archiv*, 36, 67), who used no injection, but simply watched the course of regeneration after hæmorrhage in rabbits.

W. D. H.

Amount of Dry Residue and Fat in Arterial and Venous Blood. By F. RÖHMANN and J. MÜHSAM (*Pflüger's Archiv*, 46, 381—397).—The statement was made by Bornstein (*Zeit. Biol.*, 13, 133) that the dry residue and fat in venous, especially portal, blood is greater than in arterial blood. In the present research, the blood was taken direct from the circulation of the living animal (dog), and no difference in the amount of dry residue could be made out in the two varieties of blood taken from the femoral vein and carotid artery respectively. Such small differences as were observable fell within the limits of experimental error. If, however, stasis of the blood within the vessels is allowed to occur, the solid residue of venous blood rises.

After hæmorrhage, the specific gravity of the blood falls, but equally so in both arterial and venous blood.

Comparative estimations of the amount of fat showed that there was no appreciable difference between the two varieties of blood. Portal blood was, however, not investigated.

W. D. H.

Alkalinity of the Blood after Large Doses of Sodium Sulphate. By J. SWIATECKI (*Zeit. physiol. Chem.*, 15, 49—61).—C. Schmidt (*Uharakt epid. Cholera*, 1850) stated that in the algid stage of cholera the alkalinity of the blood is diminished, or it may become acid, and this observation has been, since his time, often confirmed. In order to ascertain whether this is merely dependent on excessive diarrhoea, various laxative drugs were administered by Mya and Tassinari (*Virchow's u. Hirsch Jahresh.*, 1887, i, 232), but their examination of the blood gave no positive results. In the present research, doses of sodium sulphate, sufficiently large to make the blood very concentrated owing to excessive loss of water *per rectum*,

were given to dogs with the same object in view. The results obtained were—

(1.) The alkalinity of the blood increases with its density as a consequence of the drug treatment.

(2.) This occurrence can be explained by the greater transudation of acids than alkalis from the blood into the alimentary tract, in accordance with laws of osmosis.

(3.) The increase of alkalinity of the blood which follows the use of mineral waters cannot therefore be explained by a passing of basic salts into the blood from the alimentary canal. W. D. H.

New Method of Hemato-alkalimetry. Relative Alkalinity of the Blood of Vertebrates. By R. FROUIN (*Compt. rend.*, 111, 828—830).—0.5 c.c. of serum is heated with water and a drop of an alcoholic solution of phenolphthalein, and the alkalinity is determined by means of very dilute sulphuric acid (1 : 1000). The alkalinity is due to salts, such as sodium hydrogen phosphate, sodium hydrogen urate, &c. 0.5 c.c. of serum is treated in a closed tube with more than sufficient sodium hydroxide to neutralise all the acids, and barium chloride is added in quantity more than sufficient to precipitate all carbonates, phosphates, and urates. The liquid is rapidly filtered, and the filtrate is titrated, the sodium hydroxide that has disappeared giving the real acidity of the serum.

The estimation of water is likewise made with 0.5 c.c. of serum.

The alkalinity of the blood of the vertebrates is practically the same in the same groups, but different in different groups. It is too small to be estimated in fishes, is high in mammals, and highest in birds, increasing, in fact, with the rapidity of respiration. The tortoise and the rabbit occupy abnormal positions; the former showing even a higher alkalinity than birds, whilst the latter has less alkalinity than the frog. C. H. B.

Formation of Lactic Acid in Muscles. By M. WERTHER (*Pflüger's Archiv*, 46, 63—92).—Sarcoplactic acid is the variety of lactic acid formed both during the activity of living muscle and during the rigor which accompanies the death of muscle. In cold-blooded animals, this acid passes, under certain conditions, into the urine (Marcuse, Nebelthan). During *rigor mortis*, the percentage of glycogen in the muscle diminishes, the possibility that this is due to putrefaction being excluded. This last conclusion is opposed to that of R. Böhm, who states that the glycogen remains unaltered in amount during rigor (*Pflüger's Archiv*, 23). W. D. H.

Formation of Lactic Acid in Muscles. By R. BÖHM (*Pflüger's Archiv*, 46, 265—266).—In answer to the preceding paper, the author reaffirms his previous statements. W. D. H.

The Influence of drinking large quantities of Water on the Excretion of Uric Acid. By B. SCHÖNDORFF (*Pflüger's Archiv*, 46, 529—551).—After a very complete summary of the literature relating to the influence of various drugs and other agents on the excre-

tion of uric acid, the paper is more particularly concerned with the influence of taking large quantities of water on the excretion of the acid. Several investigators, especially Genth (*Unters. u. d. Einfluss d. Wassertrinkens a. d. Stoffwechsel*, Wiesbaden, 1856), have stated that such a procedure, whilst increasing the total output of nitrogen (a statement since confirmed by many physiologists), diminishes that of uric acid. Genth, and those who agree with him on this latter point, used for the estimation of uric acid the very imperfect method of Heintz; in the present research, which was carried out on the author's own person, uric acid was estimated by the Fokker-Salkowski process. The total nitrogen was estimated by titration with mercuric nitrate. The outcome of the experiments is that whilst the total nitrogen is increased, the drinking of large quantities of water has practically no influence on the uric acid.

Observations were made daily, and the following table gives the average amounts of water taken and of uric acid excreted *per diem*.

Condition of experiment.	Total nitrogen.	Uric acid.
Ordinary diet	18.5 grams.	1.18 grams.
Ordinary diet + 2000 c.c. water..	20.4 "	0.93 "
Ordinary diet + 4000 c.c. water..	20.6 "	1.01 "
Ordinary diet + 1000 c.c. water..	23.1 "	1.14 "

W. D. H.

Sweat of the Horse. By F. SMITH (*J. Physiol.*, 11, 497—503).—The composition of the secretion of horse's sweat was investigated because debility follows excessive sweating in these animals. The explanation probably is that proteids leave the system in the sweat of horses (see also Leclerc, *Abstr.*, 1888, 1320). The excretion can be kept under control by the process of clipping horses in the winter.

500 c.c. of the secretion was collected; it was alkaline, and was found to have the following percentage composition:—

Water.....	94.3776	
Organic matter..	0.5288	<div> Serum albumin 0.1049 Serum globulin 0.3273 Fat 0.0020 Chlorine 0.3300 Lime..... 0.0940 Magnesia 0.2195 </div>
Ash	5.0936	<div> Phosphoric acid } Sulphuric acid..... } traces Soda 0.8265 Potash 1.2135 </div>

Peptones and albumoses are absent, so also is sugar. The amount of proteid is much increased when the horse is in "bad condition." The small amount of fat formed probably indicates that the material investigated was really sweat, and not sebum. Ether extracts from the sweat an organic, crystalline substance, which is not benzoic acid, but the exact nature of which was not definitely determined. The mineral substances are nearly ten times larger than the organic, the two most prominent metals being potassium and sodium. There

would appear to be a close connection between the amount of these salts excreted by the skin and by the kidneys, for during work, when the skin is active, less potash and soda are eliminated in the urine than during rest. W. D. H.

Excretion of Nitrogen in Sweat. By P. ARGUTINSKY (*Pflüger's Archiv*, 46, 594—600).—It is shown that there is an increase of the output of nitrogen during excessive muscular work; and that, moreover, the sweat poured out during such work contains more nitrogen than it normally does.

No reference is made to the experiments of North (Abstr., 1886, 569), of which these are merely confirmatory. W. D. H.

Influence of Muscular Work on the Output of Urea. By L. BLEIBTREU (*Pflüger's Archiv*, 46, 601—607).—The urea in the urine obtained in one of Argutinsky's series of experiments (preceding abstract) was estimated by the method introduced by the author and E. Pflüger (Abstr., 1890, 308). Represented by curves, the output of total nitrogen and of urea are shown to be closely parallel; the increase of both is most marked during the day of the work (walking), and it was not until three days afterwards that they reached the normal level. W. D. H.

The Relation of Dextrose to the Proteïds of the Blood. By F. SCHENK (*Pflüger's Archiv*, 46, 607—615).—If dextrose is added to blood, serum, or solutions of proteïds, and the fluid is boiled and filtered to separate the proteïds, a portion only (often less than half) of the sugar is discoverable in the filtrate and washings of the coagulum. If the clot is washed with water and with alcohol until no reducing substance passes into solution, and the clot is then boiled with dilute hydrochloric acid, a reducing substance passes into solution in quantities corresponding with the amount of sugar formerly lost. It is, therefore, probable that, during coagulation, some of the dextrose combines with the proteïds. W. D. H.

Diamines and Cystinuria. By L. v. UDRÁNSZKY and E. BAUMANN (*Zeit. physiol. Chem.*, 15, 77—92).—In a previous communication (Abstr., 1889, 1024), it was shown that the urine and fæces of patients suffering from cystinuria contain diamines (ptomaines), and that their formation is the result of bacterial activity in the intestinal canal. The cystin, on the other hand, is the result of disordered metabolism. In dogs, it is possible to produce a sort of artificial cystinuria; on administering halogen substitution products of benzene to these animals, mercapturic acid (from cystin) is passed in the urine in combination with glycuronic acid; this, however, does not occur in the human subject. A possible explanation of the association of cystinuria with diaminuria is that the diamines produced in the intestine unite with cystin in the tissues (which under normal circumstances is further metabolised); and that this compound is dissociated during the act of secretion in the kidneys. In order to see whether this will hold, dogs were fed on diamines, and their urine examined. The first diamine used was ethylenediamine; 1.5 grams

of this was given to a dog, but the search for it in the urine passed subsequently gave a negative result. The method employed in the isolation of diamines from the urine was that of forming benzoyl compounds of these substances (Abstr., 1888, 1296). A larger dose was then given, namely, 3·6 grams, and 0·4 gram of dibenzoyl ethylenediamine was separated from the urine. No trace of the base was found in the fæces. Cystin was absent from the urine, or at least there was no more lead sulphide formed on boiling the urine with sodium hydroxide and lead acetate than normally is the case.

With tetramethylenediamine (putrescine), the results were the same; with a large dose, 3 grams, a mere trace (0·05 gram) of the benzoyl compound was separated from the urine.

With pentamethylenediamine (cadaverine), the results were also practically the same. The specimen of the base used was found to consist of two isomerides; the one with the higher melting point was the least abundant, but in the small amount of the benzoyl compound separated from the urine, it was the more abundant, being seemingly less readily destroyed in the organism. Such experiments entirely negative the idea that the cause of cystinuria is the formation of diamines in the alimentary canal. The possibility, however, remains that some other unknown substance accompanying the diamines may act in this way. If this hypothesis is correct, and if this substance is produced by bacteria, anti-bacterial drugs should lessen the amount of cystin in the urine. Mester has already shown (Abstr., 1890, 189) that salol and sulphur have no such effect. In the present research, the influence of washing out the large intestine of patients suffering from cystinuria, with large quantities of water, was observed. The cystin in the urine was estimated as benzoylcystin, and its amount, and also the amount of diamines in the urine, remained practically unaltered. The estimation of oxidised and non-oxidised sulphur, by Mester's method (Abstr., 1890, 189), confirmed this conclusion.

The question of the relation of cystinuria to diaminuria is, therefore, at present unanswered.

W. D. H.

Absorption of Mercury Salicylate. By L. BÜHM (*Zeit. physiol. Chem.*, 15, 1—36).—Much of the present paper is a dissertation on the methods of detecting and estimating mercury in organic mixtures like the urine and fæces. The method adopted in the research is a modification of that of Winternitz (*Arch. exper. Path. u. Pharm.*, 25, 225). Doses of mercury salicylate were given to a cow, but no mercury was found in the urine or milk. An experiment was then made on a dog; the urine, bile, blood, fæces, and tissues, were examined. 1·5 grams of mercury salicylate (containing 0·85 gram of mercury) was given. Of this the fæces yielded 0·4; the remainder was absorbed, and found either in the tissues or excretions. Comparing this with previous similar researches with non-poisonous doses of calomel, the conclusion is drawn that much more mercury can be absorbed into the system from the salicylate than from calomel.

W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Apparatus for the Manufacture of Pure Yeast. By A. FERNBACH (*Bull. Soc. Chim.* [3], 4, 113—116).—The apparatus consists of a tinned-copper cylinder provided with a movable head, which can be adapted hermetically to the body by means of screw clamps and a caoutchouc washer; through orifices in the head, tubes pass by which steam can be passed into the vessel, as also filtered air, which makes its escape into the liquid from small orifices in a flat coil at the base of the cylinder. The clear wort is boiled in the vessel, and steam is passed through to completely sterilise it; all the orifices are then closed by tubes containing cotton-wool; on cooling, the yeast is sown, and while growing a current of filtered air is driven through the spiral, so that the fungus is grown under aërobic conditions. The yield obtained is very good; a wort derived from 3 kilos. of malt at 63—65° furnishing a crop of 300 grams of pressed yeast in eight days.
T. G. N.

The Nitrifying Process and its Specific Ferment. By P. F. FRANKLAND and G. C. FRANKLAND (*Proc. Roy. Soc.*, 47, 296—298).—Nitrification was induced in an ammoniacal solution by means of a small quantity of garden soil, and then carried through 24 generations. Gelatin plates were prepared from several of the generations, and the resulting colonies inoculated into ammoniacal solutions, but in no case did nitrification ensue.

Experiments were then made to isolate the nitrifying organism by dilution with sterilised distilled water. When an attenuation of 1 part of original solution in 1,000,000 had been reached in three different cases, the liquids thus produced behaved as follows: One nitrified but refused to grow in gelatin-peptone; another produced a growth but would not nitrify; whilst the third did both. It was thus shown that the organisms were reduced to two, one of which caused nitrification. Under the microscope, this appeared to be a bacillus scarcely longer than broad. Although it will not grow in gelatin when inoculated from dilute media, it produces a characteristic slow growth in broth, which nitrifies ammoniacal solutions, and also grows in gelatin. The form of the organism from the broth is slightly different from the original organism, but the identity of the two is established by the former returning to the original form when grown again in ammoniacal solution.

A Bacteria-killing Globulin. By E. H. HANKIN (*Proc. Roy. Soc.*, 48, 93—101).—The results described in this paper were arrived at by the author while trying to discover the nature of the substance to which the bacteria-killing powers of the blood serum is due. Halliburton's cell-globulin- β was extracted from the lymphatic glands of an animal by sodium sulphate solution. It was found to have the power of killing anthrax bacilli, which property seems to distinguish it from fibrin ferment. This bacteria-killing power is of

the same nature as that possessed by blood serum, which, therefore, probably acts in virtue of the same or of some allied substance. From his experiments, the author further concludes that, inasmuch as it is possible to obtain from the cells that are, or can become, phagocytes, a substance having bacteria-killing powers, it may be supposed that phagocytes can not only kill microbes that they have ingested, but also do this by breaking down, and liberating their contents.

J. W.

Antiseptic Action of Methylene Fluoride. By C. CHARRIÉ (*Compt. rend.*, 111, 743—750).—Methylene fluoride prevents the development of the pyogenic bacterium of urine and kills the bacteria already developed. It has no irritating action on the digital membrane or mesentery of a frog.

C. H. B.

Acquisition of Atmospheric Nitrogen by Plants. By W. O. ATWATER and C. D. WOODS (*Amer. Chem. J.*, 12, 526—544).—The authors describe a very large number of experiments with peas, oats, and corn, which confirm the view that nitrogen is readily absorbed from the atmosphere by these plants, when treated with "soil-infusion," and that the gain of nitrogen is dependent on the number of root-tubercles which the application of "soil-infusion" induces. (Compare Lawes and Gilbert, *Abstr.*, 1889, 814, and *Phil. Trans.*, 1889, 1—107.)

G. T. M.

Fixation of Gaseous Nitrogen by Leguminosæ. By T. SCHLOESING, JUN., and E. LAURENT (*Compt. rend.*, 111, 750—753).—Leguminosæ were grown in closed vessels, so arranged that the gases introduced and withdrawn (air, carbonic anhydride, nitrogen, and oxygen) could be accurately measured and analysed. When the legumes had been watered with an infusion of nodosities from other plants of the same order, there was an absorption of nitrogen much greater than could be attributed to errors of experiment. Where the legumes had not been inoculated in this way, and, consequently, were free from nodosities, no such absorption of nitrogen was observed. The results obtained by direct measurement, therefore, agree with the result obtained indirectly from gravimetric analyses.

Berthelot (*ibid.*, 753) regards these results as a final proof that, under the influence of microbes, legumes can utilise and fix the gaseous nitrogen of the atmosphere.

C. H. B.

The Fungus-symbiosis of the Leguminosæ. By B. FRANK (*Landw. Jahrb.*, 19, 523—640).—A large part of the paper is devoted to the description and discussion of experiments and microscopic observations relating to the mode of acquisition of organisms by leguminous plants; the cultivation of the organisms, their relations to the plants, and the rôle of the infected plant, &c.

In order to ascertain the influence exerted by the organism (which he terms *Rhizobium leguminosarum*), quantitative experiments were made with beans, peas, and lupins, grown in ignited sand, in sandy soil, and in humous soil. In some experiments, the soil was sterilised, in others it was seeded with soil organisms, and to some nitrato was

applied. The results of the experiments, as well as those obtained with oats and rape, are given in the following table. Three or four, or more, pots were used for each experiment; at the conclusion the soil of all the similar pots was mixed; and the produce was also united and mixed for analysis. The soils used for microbe seeding were:—Sandy soil (3 and 16), bean soil (4), pea soil (9), meadow soil (17), and lupin soil (18). 4 grams of soil was given to each pot, for the purpose of seeding. The amount of soil used for each experiment (not pot) is given at the headings of each series.

With regard to beans, the growth was always only slight in poor soil, whether microbe-seeded or not; beans therefore resemble non-leguminous plants. The fungus in symbiosis with beans has the character of a parasite, and is fed by the plant without assisting it in return. Lupins assimilate a small amount of nitrogen when free from organisms, but much more when seeded. Peas are only able to fix nitrogen when microbe-seeded, or when grown in soil, or in sand containing organic matter (compare Abstr., 1890, 1020). In every case (except those of peas grown in sandy soil) there was a gain of nitrogen in the soil. The gain which takes place in bare soil (Experiment 24) is attributed to the presence of algæ under the influence of light and moisture. The results obtained with oats and rape are given in support of the author's view that the power of assimilating free nitrogen by plants is not confined to the *Leguminosæ*, but is as general as the assimilation of carbonic anhydride. The nodule-organisms could not be cultivated except in nitrogenous menstrua, and are, therefore, assumed to be incapable of assimilating nitrogen. The high percentage of nitrogen in the nodules, and the presence of starch in them, indicate that the building up of proteïds takes place in them. At the same time, it is hardly conceivable that the fixation of free nitrogen takes place in the underground organs of the plant. It might be suggested that nitric nitrogen is formed, which yields proteïds with starch; but the fact that no nitrates or nitrites could be detected (by diphenylamine) in the nodules, although nitric acid was found in the roots of peas (but not lupins), is opposed to this view. On the other hand, amides occur in all parts of the plants, and also in the nodules; and it is probable that in the first instance, the free nitrogen of the air combines with the elements of a non-nitrogenous carbon compound present in the leaves, where it is first produced, to form an amide, and that this finds its way into the nodules, where it reacts with starch and yields proteïds. The fixation therefore, takes place in the leaves.

The author considers that there is only one nodule organism, common to all leguminous plants, and that it is present in all natural soils, although in varying amounts (compare Hellriegel and Wilfarth, *Ber. deut. bot. Ges.*, 7, 138). N. H. J. M.

NOTE.—Prazmowski's experiments with pure cultivations of nodule-organisms from peas indicate that the organisms have the power of assimilating free nitrogen, in absence of any other source, although the amount of nitrogen assimilated by the organisms apart from the plant is only small. In view of the great change which the organisms undergo in symbiosis with plants, the difference is not remarkable (*Landw. Versuchs-Stat.*, 38, 55). N. H. J. M.

Nature of Reserve Cellulose and its Mode of Solution during Germination of Seed. By REISS (*Ann. Agron.*, 16, 478—480).—The cellulose forming the thickened walls of the albumen (botanical) containing cells of many seeds dissolves during germination, and assists in the nutrition of the young seedling; it is, therefore, called reserve cellulose. In date seeds, it is the portion of the cell-wall nearest the cell-centre which dissolves; in asparagus seeds, the middle layer between neighbouring cells and the inner layer next the protoplasm both dissolve; garlic seeds are similar, but the thickened walls have innumerable fine branching canals, which the author calls canals of corrosion, and which facilitate the solution. Even in seeds whose cell-walls are not thickened, the cellulose dissolves, commencing at the middle layers and proceeding towards the internal linings. In other seeds (balsam, monkshood, cyclamen, for example), this reserve cellulose is replaced by an amyloid substance, which also is traversed by canals of corrosion and dissolves. It is more soluble in 50 per cent. nitric acid than reserve cellulose. Reserve cellulose cannot be separated by Hofmeister's process for "crude fibre," since a portion dissolves in ammonia. The product of its hydrolysis (studied in the "albumen" of *Phytelphas*) with sulphuric acid is *seminin*, a lævogyratory substance or mixture; the dextrins of ordinary cellulose formed in the same way being dextrogyratory. Submitted to further hydrolytic treatment, *seminin* gives a new sugar, fermentable, reducing, and dextrogyratory, which the author calls *seminose*.

Seminose gives with phenylhydrazine acetate, in the cold, a colourless hydrazone sparingly soluble in water; it gives also an isonitroso-compound in fine, colourless crystals, analogous to the compound Rischbieth obtained with galactose, but not with dextrose, lævulose, or arabinose. Seminose is precipitated by lead acetate in neutral aqueous solution, and this, according to the author, distinguishes it from Fischer and Hirschberger's *mannose*, the only other known sugar giving a slightly soluble phenylhydrazone; mannose is precipitable only by ammoniacal lead acetate. The abstractor to the *Ann. Agron.*, however, points out that Fischer and Hirschberger have recently found that mannose is rapidly precipitated from strong solutions by lead acetate, and that these authors consider *seminose* to be identical with mannose. *Seminin* exists ready formed in the seed

of *Phytelephas*; it has been obtained by saccharifying the reserve cellulose of seeds of date, *Chamarops*, *Lodouea*, *Elaeis guineensis*, *Allium cepa*, asparagus, *Iris pseudoacorus*, fennel, coffee, and nux vomica. The seedlings contain only ordinary cellulose, the reserve cellulose having been perhaps transformed into seminose during germination. Seminose, however, was not discovered in germinating date seeds, but plenty of (probably) dextrose. Hydrolysis of the amyloid substance of balsam, monkshood, primrose, and peony seeds gave dextrose, not seminose.

J. M. H. M.

Conversion Products of Starch. By A. MARGACCI (*Bied. Centr.*, 19, 792; from *Staz. sper. agr. ital.*, 18, 618—619).—Potato starch, even in quite ripe potatoes, becomes converted into cane-sugar; and barley and wheat grains, in germinating, double the amount of cane-sugar at the expense of the starch they originally contained. Samples of potato meal and finely-cut potatoes were dried, some in the sun, and some in a drying oven at 45°; an increase of cane-sugar was observed in the artificially dried potato; in the cut potatoes, the amount of sugar was more than doubled when dried at 45°. In germination, potatoes gain saccharose; the starch is probably converted, first into saccharose, and then into glucose. The formation of dextrin is not necessary.

Starch is formed by the elimination of water. Unripe wheat grains contain much glucose and saccharose; when the same amount of grains were examined after being dried in the sun, the sugar had disappeared, and was found to be replaced by starch.

N. H. J. M.

The Presence of Cholesterol and a Soluble Carbohydrate in Melon Seeds. By C. FORTI (*Chem. Centr.*, 1890, ii, 581—582; from *Staz. sperim. agric. ital.*, 18, 580—588).—Determinations of the amount of phosphorus in the ether extract of the seeds of melons showed it to be present in the proportion of 0.0189 to 0.02 per cent. It exists as lecithin, and is equivalent to 0.494 to 0.526 per cent. of the latter. Adopting the views of Schulze and Steiger (*Abstr.*, 1889, 645), that the substance should be extracted with alcohol in order to obtain all the lecithin, the author found 0.024 per cent. of phosphorus, equivalent to 0.629 per cent. of lecithin. The seeds contain about 49 per cent. of oil, which is almost free from free fatty acids; the distillate of 25 grams neutralised 3.2 c.c. of decinormal barium hydroxide solution.

Having saponified the fat with sodium hydroxide, the dry soap was treated with ether, which extracted a substance, soluble in alcohol; this crystallised in yellowish, fatty scales, and did not consist entirely of fat and wax. When treated with alcoholic potash, a non-saponifiable residue was left, which proved to be cholesterol. It melted at 160°, contained 1 mol. of water of crystallisation, and has the formula $C_{26}H_{44}O, H_2O$; the water separates at 100°. A minute portion of this cholesterol, when treated with a drop of nitric acid and evaporated to dryness, left a yellow residue, which became coloured bright red by ammonia; the coloration was intensified by the addition of sodium hydroxide. The chloroform solution was coloured brown by

sulphuric acid, the coloration changing to violet and finally yellow after a time, whilst the sulphuric acid layer became reddish-brown and fluoresced. The chloroform solution, when shaken with a little ferric chloride and hydrochloric acid and evaporated to dryness, left a yellow residue, which, when again treated with chloroform in the cold and then gently warmed, became violet, and left a dirty-green residue on evaporating to dryness. The specific rotatory power of the substance in chloroform solution was $[\alpha]_D = 14.17$.

The *acetyl derivative*, $C_{26}H_{44}OAc$, crystallised from absolute alcohol in lustrous plates melting at $170-173^\circ$ to a lemon yellow fluid. When boiled with potash, potassium acetate and the original cholesterol are obtained. The acetyl derivative of cholesterol from bile crystallises in needles and melts at 111° . The *benzoyl derivative* is very slightly soluble in alcohol, and separates from the solution, on cooling, in small crystals which melt at $172-174^\circ$. These properties of this cholesterolin differ from those of the better-known cholesterol, and require further investigation.

The soluble carbohydrate of melon seeds is dextro-rotatory, even after treatment with acids, and appears to belong to the galactan group. It forms an amorphous, yellowish-white, very hygroscopic powder. After boiling with hydrochloric acid, the phenylhydrazine derivative of the product was prepared; this melts at $184-186^\circ$.

J. W. L.

Amount of Theine in Tea. By B. H. PAUL and A. J. COWNLEY (*Pharm. J. Trans.*, [3], 21, 61).—Believing that the amount of theine in tea has commonly been understated, owing to defective methods of determination, the authors have made a further series of analyses. Eight samples, purchased at grocers' shops in the ordinary way, yielded from 2.93 to 3.93, average 3.39, per cent. of theine calculated on the dried tea. Four samples of China tea gave 2.42, 3.50, 3.63, and 3.78 per cent. respectively. Four samples of cheap Japan Congou averaged 2.80 per cent. theine, but as much as 4.10 per cent. was found in a Java tea. Japan and China teas appear, therefore, generally inferior as regards content of theine to Indian or Ceylon teas, which, on the other hand, are approached by Java tea. In these analyses duplicate determinations of the theine were made with magnesia and with lime—the only methods that are trustworthy.

R. R.

Acidity of Potato Starch. By SAARE (*Ann. Agron.*, 16, 471).—Most samples of potato starch are slightly acid, and the acid is said to increase with age, but the author believes that perfectly neutral starch can be obtained, and that it will, if properly dried, keep without developing the slightest acidity. Discussing the source of the acid, the author remarks that potato-juice is naturally acid, and that the starch, if imperfectly washed, will retain some of this; that lactic and butyric acids may be developed by bacterial fermentations during manufacture; and that sulphuric and sulphurous acids are sometimes used in the process of manufacture. The acid, whatever it is, cannot be perfectly removed by washing with pure water, but if hard water be used, the acid becomes neutralised by the lime. J. M. H. M.

Maize dried in the Field and as Silage. By H. P. ARMSBY and W. H. CALDWELL (*Bied. Centr.*, 19, 753—756; from *Agric. Science*, 4, 119—146).—A maize field, manured with farm-yard manure, Carolina phosphate, and blood meal, was divided into three parts, the produce of two divisions put into two silos, and that of the third division kept for a month on the field to dry. The one silo was filled quickly (one day) and contained 17,000 kilos.; the second was filled slowly (seven days), and contained about 15,600 kilos. The weight of the hay was 4300 kilos.

The maize put into the silos had the following composition; (1) refers to the quickly and (2) to the slowly filled silo :—

	Water.	Ash.	Proteid.	Non-proteid.	Crude fibre.	Non-nitrogenous extract.	Fat.
1.	76.90	1.97	1.63	0.15	5.16	13.42	0.77
2.	76.26	1.43	1.44	0.30	5.65	14.26	0.66

The temperature rose quickly at first, especially at the surface, and more in the slowly-filled silo than in the other one. The following table shows the total amount of produce (in kilos.) in the two silos (1 and 2, as before) and of hay (3) :—

	Dry substance.	Ash.	Proteid.	Non-proteid.	Crude fibre.	Non-nitrogenous extract.	Fat.
1.	3920	333	277	27	876	2276	131
2.	3713	238	228	48	832	2284	104
3.	2677	195	176	26	617	1579	82

Experiments were made with two Devonshire bullocks to determine the digestibility of the different preparations, the food being given for seven days before the experiments began. Samples of food and fæces were taken daily for analysis, and the animals were weighed each day before and after drinking. The amounts given were: silage, (1) 20.412 kilos., (2) 15.889 kilos. of fresh, or 5.655 and 4.662 kilos. of dry substance; hay, 7.265 or 5.263 kilos. of dry matter. The results show that the dry substance of the maize hay is the most readily digested, and that that of the silage from the slowly filled silo is the least digestible. The digestibility of the proteid is nearly the same in each case, whilst the fat of the hay seems to be less digestible than that of the ensilage. The variation in the digestibility of the dry substance is chiefly due to differences in the digestibility of the crude fibre and the non-nitrogenous extract. The results are given in tables, together with those of Woll and of Sturtevant. The results do not indicate any great difference of digestibility between maize ensilage and maize hay.

The ensilage lost (in the silo) half as much dry matter and two-fifths as much proteid as the hay lost; but a quarter of the proteid was converted into non-proteid. The hay lost 14 per cent. of crude fibre; no such loss was observed in the case of the ensilage.

N. H. J. M.

Wine Analyses. By E. BOSSHARD (*Zeit. anal. Chem.*, 1890, 551—556).—The results are given of the analysis, by the usual methods,

of 24 specimens of wine from the Valtellina, 24 from the Coire Valley, 5 specimens of Medoc (1883—1887), and 4 Tuscan wines. The composition of the Valtellina wines does not differ notably from that of other red wines, the alcohol ranging from 7.83 (in a cheap specimen of Veltliner) to 14.43 vols. per cent. (in a fine Valgella), with an average of 10.97, and the solid residue from 17.24 to 26.45 (average 23.0) grams per litre. The ash of several of the varieties contained much manganese.

The wines of the Coire Valley are, on the average, less alcoholic (max. 11.44, min. 8.01; average 9.73), but contain rather more extractive matter (max. 25.61, min. 19.86; average 24.05). In composition they show considerable resemblance to Burgundy, and, if more carefully fermented, they would take a much higher position than they do at present.

M. J. S.

Analytical Chemistry.

Iodometric Estimation of Acids and Alkalis. By M. GRÖGER (*Zeit. ang. Chem.*, 1890, 353—356).—The author has made a careful study of the conditions under which acidimetry and alkalimetry can be performed by means of the reaction $\text{KIO}_3 + 5\text{KI} + 3\text{H}_2\text{SO}_4 = 3\text{K}_2\text{SO}_4 + 3\text{H}_2\text{O} + \text{I}_2$. A neutral mixture of iodide and iodate cannot be made by dissolving iodine in potash, but must be prepared by mixing, in the proper proportions, neutral solutions of the respective salts shortly before use. On adding an excess of such a mixture to a mineral acid, and titrating the liberated iodine by thiosulphate, the result agrees exactly with that of a direct titration by an alkali. The hydroxides of potassium, sodium, and ammonium can all be estimated by adding an excess of standard acid and titrating the excess as above. Alkaline carbonates can be approximately titrated in the cold by a similar procedure, if the first disappearance of the iodine is taken as the end point; but the carbonic acid in solution slowly liberates a further quantity of iodine, so that to obtain exact results it is advisable to boil out the carbonic anhydride and cool before adding the iodine salts. The same applies to alkaline sulphides. This method may be used in many cases for dark-coloured liquids in which the change of litmus or methyl orange could not be seen. It cannot be employed for organic acids, unless the iodine be distilled out. The author is investigating this point.

M. J. S.

Detection of Minute Quantities of Hydrogen Peroxide and of Uranium. By T. FAIRLEY (*Chem. News*, 62, 227).—0.24 milligram of hydrogen peroxide may be detected by adding 1 or 2 c.c. of ether to 5 c.c. of the peroxide solution, and a small drop of a 10 per cent. chromic acid solution, and even 0.10 milligram can be detected by using 1 c.c. of peroxide solution and 1 c.c. of ether; but by the use of 5 c.c. of a dilute uranium nitrate solution 0.05 to 0.025

milligram of hydrogen peroxide in 5 c.c. can be rendered evident; moreover, as little as 0.5 to 0.25 milligram of uranium can be detected and very small quantities determined by this method of treatment.

D. A. L.

Direct Estimation of Bromine in Mixtures of Alkaline Bromides and Iodides. By F. A. GOOCH and J. R. ENSIGN (*Amer. J. Sci.* [3], 40, 145—152).—In a former paper (*Abstr.*, 1890, 920), two methods were described for the direct estimation of chlorine in mixtures of alkaline chlorides and iodides, based on the action of oxidising agents, in the presence of free sulphuric acid, on dilute solutions of the haloid salts at the boiling temperature. A study of the behaviour of mixtures of alkaline bromides and iodides, when treated in a similar manner, leads to the conclusion that only one of the above two methods is applicable to the separation of bromine from iodine, and then only under modified conditions. With the necessary modifications, however, it is good, and may be applied in the following manner:—The neutral solution containing the bromide or iodide is diluted to 600 or 700 c.c., and 1 to 1.5 c.c. of concentrated sulphuric acid, or better, 2 to 3 c.c. of the mixture made by diluting the acid with an equal volume of water, is added, a sufficient amount of pure sodium or potassium nitrite is introduced (or, if it is preferred, the gas generated by the action of dilute sulphuric acid on the ordinary nitrite, and introduced from the outside, may be employed instead) and the liquid is boiled, after trapping the flask as formerly described, until the colour has vanished and the escaping steam no longer gives to litmus the colour characteristic of iodine (see next abstract). The residual liquid is treated with an excess of silver nitrate, and the precipitated bromide collected, dried, and weighed. The process of boiling need not extend beyond half an hour, or a little more, and care should be taken that the volume of the liquid shall never be less than 500 c.c. The solution should not contain more than about 0.5 gram each of the bromide and iodide. The presence of 0.5 gram of potassium chloride does not affect the sharpness of the separation. H. C.

Rapid Method for the Detection of Iodine, Bromine, and Chlorine in presence of one another. By F. A. GOOCH and F. T. BROOKS (*Amer. J. Sci.* [3], 40, 283—290).—The solution of the substance under examination is acidified with dilute sulphuric acid, and treated with a drop or two of a solution of sodium or potassium nitrite free from chlorine. Unless the amount present is small, the iodine shows itself in the colour of the solution and in the vapours which escape. Small amounts may be detected by shaking with carbon bisulphide, or by heating the solution and testing the escaping fumes with red litmus paper, which is coloured greyish-blue by iodine. The whole of the iodine must be removed previous to making the tests for bromine and chlorine; and this is done by adding a sufficient amount of nitrite and sulphuric acid to liberate the iodine, and heating the liquid until the vapour has no effect on red litmus paper. A portion of the solution is then tested for bromine by cautiously adding a dilute solution of sodium hypochlorite and shaking with colourless carbon bisulphide. Another portion of the solution is

evaporated to dryness, and treated with potassium dichromate and sulphuric acid; the fumes of chromyl chloride which are given off on warming are condensed and converted into chromic acid, and the latter detected by means of lead acetate. H. C.

Priestley's Method of Measuring Oxygen in Air. By J. A. WANKLYN (*Chem. News*, 62, 263).—Priestley's method for measuring oxygen in the air by observing the diminution of volume on the addition of a measured volume of nitric oxide has been condemned as inaccurate; the author of the present note states that the inaccuracy was due to the oxygen present in the water through which the nitric oxide bubbled. This source of inaccuracy can be avoided, when using a Hempel apparatus, by measuring the air in the gas burette, and then passing it into an absorption pipette containing water. The nitric oxide is introduced into the gas burette and measured, and then (without bubbling through water) passed to the air in the absorption pipette; after the nitric peroxide formed has been absorbed by the water in the absorption pipette, the gas is passed back into the gas pipette and again measured.

D. A. L.

Estimation of Sulphur in Copper. By H. J. PHILLIPS (*Chem. News*, 62, 239—240).—Dissolve 10 grams of the sample in nitric acid of sp. gr. 1.430, evaporate to dryness, redissolve in dilute nitric acid, examine any residue for sulphur, dilute the filtrate to 800 c.c., heat to 70°, add a small quantity of hydrochloric acid, and, after 12 hours, remove and estimate any silver chloride. The filtrate is evaporated considerably, 50 c.c. of hydrochloric acid of sp. gr. 1.16 added, and the evaporation continued to dryness; the residue is dissolved in a minimum quantity of water, again treated with hydrochloric acid, and evaporated. It is now dissolved in 300 c.c. of hydrochloric acid, diluted to 700 c.c., heated to boiling, barium chloride stirred in, and, after 24 hours, the precipitate collected and treated as usual. Lead sulphate, being soluble in copper nitrate solution, frequently passes completely into solution, and has to be determined in the manner suggested.

D. A. L.

The Kjeldahl-Wilfarth Method. By P. ARGUTINSKY (*Pflüger's Archiv*, 46, 581—593).—In a large number of experiments, the Kjeldahl method of estimating nitrogen was employed, and found most satisfactory; the actual manipulations demand care, and the following points are especially insisted on:—The advisability of adding mercury to hasten the oxidation; the fact that the addition of potassium permanganate is not necessary; the collection of the distillate in a U-shaped Peligot's flask; the continuation of the distillation for 45 minutes, and the use of cochineal as indicator.

The substances investigated were urine, sweat, and feces.

W. D. H.

Cinchonamine as a Test for Nitrates. By ARNAUD (*Ann. Chim. Phys.*, [6], 19, 93—131).—By far the greater part of the subject-matter of this paper has been previously published by the author (*Abstr.*, 1882, 229 and 1884, 87) and by Hesse (*Abstr.*, 1885, 64).

The qualitative test for nitrates in plants described by the author and Padé (Abstr., 1884, 1074) can also be employed for estimating nitrates in natural waters, in the following manner:—The water is neutralised with soda or sulphuric acid, as the case may be, the chlorine in solution precipitated with silver acetate, and the slight excess of silver employed precipitated with sodium phosphate; the solution is then evaporated almost to dryness, filtered if necessary, rendered very slightly acid with a drop of dilute acetic acid, and the boiling solution mixed with a warm solution of cinchonamine sulphate. Cinchonamine nitrate is at once precipitated in a crystalline condition, and, after keeping for 12 hours in a cool place, it is separated by filtration, washed first with a cold, saturated aqueous solution of cinchonamine sulphate and then with a very small quantity of cold water, and dried at 100°. The same method can be employed with slight modifications for estimating the nitrates in plants. For this purpose, the triturated plant is extracted with boiling water, the solution evaporated to a syrup, and the residue extracted with 40 per cent. alcohol; after evaporating the alcohol, the chlorine in the solution is eliminated by means of normal lead acetate, the excess of lead removed with a few drops of sodium sulphate, and the nitric acid then precipitated with cinchonamine sulphate as described above.

F. S. K.

Phosphorus in Pig-iron, Steel, and Iron Ore. By C. JONES (*Chem. News*, 62, 220—222, 231—232).—Various authorities are quoted and numerical analytical data furnished in proof of the efficiency of oxidation with permanganate; of washing the molybdate precipitate with sulphuric acid and ammonium sulphate instead of nitric acid and ammonium nitrate; of the use of ferrous sulphate instead of an organic acid to dissolve the precipitated manganic hydroxide, and of the employment of the author's reducing agent (filtering through powdered zinc with strong suction; Abstr., 1889, 1248) in place of adding zinc directly in the estimation of phosphorus in pig-iron, &c. The following modification of Drown's method (Abstr., 1889, 1245) is then recommended. For pig-iron and steel, dissolve in nitric acid of sp. gr. 1.135, boil for one minute, oxidise with potassium permanganate, dissolve the manganese hydroxide precipitate by adding a few fragments of ferrous sulphate free from phosphate, filter, add ammonia of sp. gr. 0.90, test the cleared solution with permanganate to be sure that the oxidation is perfect, heat to 85°, add prepared ammonium molybdate (Drown's formula), agitate for 5 minutes, filter, wash with ammonium sulphate, dissolve the phosphomolybdate in ammonia of sp. gr. 0.96, wash with water, filter, acidify with sulphuric acid, pass through the zinc powder, and titrate as usual. The correction for the zinc is ascertained by blank tests. Numerous results are given showing the efficiency of the method. Iron ores, after being treated in the usual manner, can be examined by this method; titanium and arsenic interfere with the working of the method, but in the absence of these elements an estimation of phosphorus in iron or steel can be executed in less than an hour; iron ore estimations take a little longer time.

D. A. L.

Distinction between Arsenic and Antimony. By G. DENIGÈS (*Compt. rend.*, 111, 824—825).—The stain obtained in Marsh's test is placed in a porcelain capsule and heated with a few drops of pure nitric acid, and a small quantity of a solution of ammonium molybdate in nitric acid is added. Antimony gives no precipitate, but if arsenic is present, arsenomolybdic acid separates as a yellow precipitate which under the microscope is seen to consist of stellate crystals with triangular arms, generally six, arranged in rectangular planes along the axes of a cube. They act on polarised light. The author believes this to be the most sensitive and characteristic test for arsenic.

To prepare the ammonium molybdate solution, 10 grams of this salt and 25 grams of ammonium nitrate are dissolved in 100 c.c. of warm water. The solution is allowed to cool, and 100 c.c. of pure nitric acid of sp. gr. 1.20 is added drop by drop with vigorous agitation. The liquid is heated on a water-bath for 10 minutes, allowed to cool, and filtered after 48 hours.

C. H. B.

Sodium Carbonate: Detection of Traces of Alkaline Hydroxides. By R. KISSLING (*Zeit. ang. Chem.*, 1890, 262—263).—The author believes that his earlier experiments (*Zeit. ang. Chem.*, 1889, 323), from which he concluded that sodium carbonate gave off considerable proportions of carbonic anhydride at 400°, were vitiated by the presence of an impurity. He has repeated his experiments with several of the purest specimens of sodium carbonate and sodium hydrogen carbonate to be found in commerce. After drying at 150°, during which the sodium hydrogen carbonates lost from 36.82 to 36.84 per cent., 100 parts, heated until fritted, lost in different cases quantities which ranged from 0.03 to 0.27 parts, and, when fully fused, 0.71 to 1.05 parts. Both after fritting and after fusion sodium oxide could be detected, although after simple drying at 150° no evidence of hydroxide could be obtained. The conclusion is that ignited sodium carbonate cannot safely be employed for standardising an acid.

Dobbin's reagent for the detection of traces of alkaline hydroxides is prepared as follows:—A solution of about 5 grams of potassium iodide is mixed with sufficient mercuric chloride to just give a permanent precipitate. This is filtered off, 1 gram of ammonium chloride is added, and then dilute sodium hydroxide until a permanent precipitate is again obtained. The filtered liquid is made up to a litre. The smallest trace of an alkaline hydroxide produces a yellow colour with this reagent.

M. J. S.

Analysis of the Barium Group. By C. LÜDEKING (*Zeit. anal. Chem.*, 29, 556—561).—The sensitiveness of calcium sulphate as a test for barium (cold) and strontium (hot) is not sufficient to render it a satisfactory reagent, and the presence of large proportions of calcium chloride impairs its sensitiveness to an extraordinary degree. Similarly, a solution of strontium chloride hinders the precipitation of barium by calcium sulphate to such an extent that notable proportions of barium might be entirely overlooked in a solution containing much strontium. On the other hand, very strong solutions of stron-

tium chloride give a precipitate so instantaneously on addition of calcium sulphate that the presence of barium would certainly be inferred. Potassium chromate is free from these objections. It is a more delicate test than calcium sulphate for barium when occurring alone, and it is in no way affected by the presence of strontium or calcium. The ammonium carbonate precipitate should be dissolved in acetic acid, a saturated solution of potassium chromate added, and the mixture boiled. If 0.1 per cent of barium chloride is present, a precipitate will be produced. The strontium and calcium should be again thrown down from the filtrate by ammonium carbonate, the well washed precipitate dissolved in hydrochloric acid and tested for strontium by the spectroscope. The blue line is the best for observation. An excess of sulphuric acid is then added, the mixture boiled, filtered from strontium sulphate, and the filtrate tested for calcium.

M. J. S.

Metallurgical Assay of Lead Waste. By W. STAHL (*Zeit. anal. Chem.*, 29, 630; from *Berg. Hutt. Zeit.*, 48, 237).—From 5 to 10 grams of the substance is intimately mixed with 1 or 2 grams of spongy silver, reduced from the chloride by zinc, and 3 parts of a flux consisting of 1 part of soda, 1 part of potash, and 20–30 per cent. of flour, together with enough borax to dissolve the earths which may be present. The mixture is placed in a crucible, heated gently as long as combustible gases are evolved, and then more strongly for 45–60 minutes. From the weight of the button, that of the silver taken is to be deducted, and the remainder is the lead present in the waste.

M. J. S.

Analysis of Sodium Aluminate. By G. LUNGE (*Zeit. ang. Chem.*, 1890, 227).—A weighed quantity is dissolved, during which operation the insoluble matter may be filtered off for estimation, and an aliquot part of the solution, mixed with a drop of phenolphthalein, is titrated with hydrochloric acid until the pink colour disappears. The quantity used indicates the amount of soda in combination with alumina and silica. To the same portion, is now added a drop of methyl-orange, and titration with the same acid is continued until the pink colour remains permanent for five minutes. The change of colour at this stage is sluggish. This gives the amount of the alumina, since methyl-orange does not indicate the presence of acid until all the alumina is converted into chloride. The method can only be used in cases where the silicate present is small enough to be neglected.

M. J. S.

Volumetric Estimation of Alumina. By G. LUNGE (*Zeit. ang. Chem.*, 1890, 293–300).—A similar process to that of the author (see preceding abstract) had already been proposed by Cross and Bevan, who, however, used litmus instead of phenolphthalein. The original proposal to estimate alumina by titration is, however, due to Bayer (*Abstr.*, 1886, 281, 651). Cross and Bevan found that free acid appeared in the mixture when the ratio $5\text{SO}_3 : 2\text{Al}_2\text{O}_3$ was passed. The author shows that this was most likely due to their working at too low a temperature, since towards the end of the process the

alumina dissolves in the highly dilute acid with such extreme slowness, that several hours must be allowed to elapse before it can be with certainty decided that the acid is in excess. The acid consumed corresponds ultimately with the ratio $3\text{SO}_3 : \text{Al}_2\text{O}_3$, and with a moderately warm liquid ($30-37^\circ$), the solution of the alumina proceeds rapidly enough to make the process a practical one. The titration with phenolphthalein is best performed at a boiling heat, and that with methyl-orange should be completed at about the above temperature.

M. J. S.

Rapid Estimation of Manganese in Slags, Ores, &c. By F. G. MYHLETTZ (*Chem. Centr.*, 1890, ii, 607—608; *Journ. anal. Chem.*, 4, 267).—0.5 gram of the finely pulverised mineral is mixed with 5 grams of a mixture of sodium carbonate (3 parts) and potassium nitrate (1 part) and fused carefully. After allowing it to cool, the melt is digested in hot water, and the manganate reduced by addition of 3 c.c. of alcohol, without, however, filtering. The insoluble portion containing the manganese as dioxide is then collected and washed with hot water. The filter with the insoluble part is returned to the dish, and 100 c.c. of ferrous sulphate of known strength added, stirred until all is dissolved, and the excess of ferrous sulphate determined with potassium dichromate. From the amount of ferrous sulphate oxidised by the manganese dioxide, the amount of the latter may be calculated. The estimation occupies from two to three hours.

J. W. L.

Estimation of Chromium in Chrome Iron. By L. P. KENNICUT and G. W. PATTERSON (*Zeit. anal. Chem.*, 29, 596).—A very refractory Pennsylvanian ore was satisfactorily attacked by the following method:—About 0.3 gram of the fine powder is mixed in a platinum crucible with about 10 parts of dry sodium carbonate and 10 parts of barium peroxide, and heated over a Bunsen burner for half an hour. The mass is then treated with hydrochloric acid until a clear solution is obtained; potash is added to strongly alkaline reaction, then 5 or 6 c.c. of a 5 per cent. solution of hydrogen peroxide to re-oxidise any traces of chromic oxide, and lastly the liquid is boiled for twenty minutes to remove excess of the peroxide. After acidifying with hydrochloric acid, the chromic acid is titrated in the usual way.

M. J. S.

Separation of Tin and Antimony. By H. N. WARREN (*Chem. News*, 62, 216).—The pulverised material, after fusion in a nickel crucible with sodium carbonate and borax, is dissolved in hydrochloric acid, and an aliquot part of the solution precipitated with hydrogen sulphide. This precipitate is collected on a plug of cotton, boiled with sodium hydroxide, and the solution of sodium sulphostannate and sulphantimonate obtained is divided into two portions: in the one, only the antimony sulphide is precipitated by boiling with excess of oxalic acid, whilst in the other, the tin and antimony sulphides are precipitated together by warming with dilute hydrochloric acid, but in both cases, the sulphides are decomposed by ignition and weighed as oxides, from which data the relative proportions are easily obtained.

D. A. L.

Estimation of Cyanogen in Coal Gas. By W. LEYBOLD (*Chem. Centr.*, 1890, ii, 531; from *Journ. Gasbeleucht. Wasserversorg.* **33**, 383—384, 427—428).—In each of three Woulff's bottles, 20 c.c. of aqueous soda (1 : 3) is placed, to which is added a quantity of suspended ferrous hydroxide, prepared by adding 20 c.c. of soda (1 : 3) to 30 c.c. of ferrous sulphate (1 : 10), the first Woulff's bottle receiving 25 c.c., the second 15 c.c., and the third 10 c.c. of the mixture. 100 litres of the gas under examination is passed through the bottles during 1 to 1½ hours, after which the contents of the three bottles are transferred to one flask and boiled for a quarter of an hour. After settling and allowing to cool, the supernatant fluid is decanted into a 500 c.c. flask, and the insoluble ferrous hydroxide washed until free from cyanide, the filtrate being then diluted to the mark. According to whether the gas under examination has passed the first purifier or not, 100 c.c. or 200 c.c. of the solution is acidified with hydrochloric acid, excess of ferric chloride added, and the precipitated Prussian blue collected and washed with small quantities of water until free from ferric chloride. The filter, with the precipitate, is transferred to a beaker, dissolved in soda, and the solution filtered. The filtrate is evaporated in a platinum dish to 30 c.c., a considerable excess of dilute (1 : 10) sulphuric acid added, and the liquid evaporated to dryness, and ignited. The residue is dissolved in 100 c.c. of dilute (1 : 10) sulphuric acid, washed into a 250 c.c. flask with a little water, the volume being now about 150 c.c., 1 c.c. of copper sulphate solution (1 : 10) and 10 grams of pure zinc added, and the ferric oxide reduced and determined with potassium permanganate solution. J. W. L.

Estimation of Ferrocyanides in Gas Refuse. By R. ZALOZIECKI (*Zeit. ang. Chem.*, 1890, 301—302; see this vol., p. 247).—20 grams of the waste product is heated for a quarter of an hour on the water-bath with about 20 c.c. of 10 per cent. potash solution, then cooled, made up to 100 c.c., and filtered. As the solid residue occupies 10 c.c., 45 c.c. of the filtrate is taken and boiled until all the ammonia is driven off. A clearer solution can be obtained if the original extraction is made with lime (Leschlhorn, *Zeit. ang. Chem.*, 1888, 616), and the calcium then removed from the solution by potassium carbonate. A drop of phenolphthalein is now added, and then acid to exact neutrality. The separation of sulphur at this stage does not prejudice the later operations. In consequence of the presence of the chlorides or sulphates formed during the neutralising, some normal alkaline carbonate (20 c.c.) must now be added, together with 5 grams of moist zinc carbonate, and the mixture heated whilst carbonic anhydride is passed through it for half an hour. It is then cooled, made up, and one-half of the clear filtrate titrated with N/10 acid, using methyl-orange as indicator. The volume of acid corresponding with the normal alkali added is subtracted, and the remainder gives the alkaline carbonate produced by the reaction. The amount of potassium carbonate found, multiplied by 46, gives the percentage of $K_4FeC_6N_8 + 3H_2O$. M. J. S.

Analysis of Wort and Beer. By H. ELION (*Zeit. anq. Chem.*, 1890, 291—298, 321—326).—For the estimation of the solid residue, the author prefers to dry at 96–97° in a stream of air of low tension. The liquids are evaporated and the residues dried in small stoppered glass vessels, 40 mm. diameter and 35 mm. high, which are placed in a cylindrical oven with a steam-jacket and exhausting pump, a regulated stream of dry air being admitted so as to maintain a pressure of only 35–45 mm. of mercury. Complete desiccation is obtained in 10–15 hours, and so little decomposition of the residue takes place that it may safely be neglected. The percentage of residue from a wort of given gravity is much smaller when estimated in this way than was found by Schultze, who dried his residues at 70–75° under atmospheric pressure, and this is shown to be only partially due to the dehydration of the maltose at the higher temperature. A complete table is given, showing the correspondence between specific gravity and percentage of extractive matters, from 1.0001 to 1.0992.

The ordinary method of estimating maltose by means of the reduction of Fehling's solution gives results which do not agree with those of practical brewing. The method employed by the author is as follows:—A flask, with a Pasteur's tube, is half filled with sterilised wort and inoculated with a trace of a pure culture of *Saccharomyces cerevisiae*. It is then kept for several days at 25°. The yeast grows, and in about two days the wort is in full fermentation, which gradually decreases and finally stops completely. The power of reducing copper solution is now found to have greatly diminished, but not disappeared. It is shown that the amount of the diminution, if calculated as maltose, agrees almost exactly with the diminution in the amount of solid residue, and that on estimating the dextrose produced by the action of hydrochloric acid, and calculating into maltose the difference between that found in the original and that in the fermented wort, this amount agrees closely with that found by the other methods. The sugar destroyed by the fermentation is, therefore, practically all maltose, and it is shown that no maltose remains unfermented. Of these three methods, that depending on the loss of solid residue is the most free from sources of error. The essential features of the process are the use of a pure culture, and of only traces of it. The maltose is found to constitute only 86–92 per cent. of the total copper-reducing constituents of the wort.

The same process can be applied to beer. It is best to work with the sterilised beer itself, since, if the alcohol is first distilled off, a small part of the unfermentable matters is converted into sugar. When making estimations of copper reduction by the method of collecting the cuprous oxide and weighing, it is advisable to oxidise by ignition in order to get rid of some co-precipitated organic matter, but a constant weight of cupric oxide cannot be obtained. It should, therefore, be again reduced and weighed as metallic copper, when the results are perfectly constant. From numerous experiments, it is found that the largest yield of dextrose is obtained by using a solution containing about 1.5 per cent. of solid residue with $\frac{1}{10}$ of its volume of hydrochloric acid of 1.19 sp. gr., and heating for three hours in the water-bath.

The value for practical brewing of a correct knowledge of the amount of maltose in wort and beer is pointed out. It especially becomes evident that for a beer to keep well it must contain a low proportion of maltose. As long as the total copper-reducing power of the extractive matters in beer was the only guide to the amount of maltose present, this fact was obscured by the preponderance of the non-fermentable reducing substances. M. J. S.

Volumetric Estimation of Glycerol in Wine. By V. OLIVIERI and M. SPICA (*Chem. Centr.*, 1890, ii, 611—612; from *Staz. speriment. agric. ital.*, 19, 34—41).—10 to 15 c.c. of the wine is warmed on the water-bath until all the alcohol is evaporated, the volume being maintained by addition of water. Lead acetate is then added, the precipitate filtered off, the excess of lead precipitated from the filtrate with sodium carbonate, and the filtrate concentrated on the water-bath to 15 to 20 c.c. This is distilled under diminished pressure, by which means the glycerol passes over below 200°. After all has distilled, the retort is rinsed down with 5 c.c. of water, and the distillation repeated. The mixed distillates are acidified with 5 c.c. of sulphuric acid, heated to 100°, and titrated with decinormal potassium permanganate solution, an excess of the latter being used, and finally determined by means of standard oxalic acid. The results obtained by the authors are satisfactory. J. W. L.

The Chemical Detection of Glycosuria. By A. JOLLES (*Chem. Centr.*, 1890, ii, 609—610; from *Internat. klin. Rundschau*, 1890, Nos. 31, 32).—The author considers that a sharp distinction exists between glycotie and diabetic urines. The former contain but mere traces of sugar, about 0.4—0.5 per cent., and otherwise are not characterised by abnormal chemical and physical properties. The diabetic urines, on the other hand, have a high density, a pale-yellow colour, a less quantity of uric acid than normal urine, and contain acetone or acetoacetic acid, or acetic acid. Sugar usually occurs in them in considerable quantities, although this is not always the case. A new method, namely, to paint a visiting card first with copper sulphate solution and, after drying, to apply the suspected urine with a match, dry and heat, which has recently been proposed by v. Becker, is considered wholly untrustworthy by the author. Trommer's method, and Seegen's modification of the same, are also considered valueless by the author. Böttger's bismuth reagent and Fischer and Jaksch's phenylhydrazine test are found by him to be trustworthy.

With Böttger's bismuth reagent, 0.08 per cent. of sugar may be detected, and if the urine be first boiled with a solution of sodium chloride the delicacy is heightened, 0.01 per cent. being then detectable. At least 50 c.c. of urine must be employed to 5 c.c. of Nylander's reagent, and should not be boiled for more than two minutes. The presence of such substances as rhubarb, kairine, oil of turpentine, quinine, arsenious and salicylic acids, sulphur, mercury salts, and iodides should be avoided. In the case of considerable quantities of uric acid, it is to be observed that the brown coloration produced by

it remains constant, whereas that produced by the presence of sugar becomes continually darker.

The phenylhydrazine test enables 0.015—0.038 per cent. of sugar to be detected, the delicacy being the greater the less the amount of reducible substances present. At the same time crystals, very similar to those of phenylglucosazone, are formed with glycuronic acid. The latter are, however, not so fine, and have not the same striated arrangement as those of phenylglucosazone. J. W. L.

Test for Resorcinol and Thymol. By H. BORNTRÄGER (*Zeit. anal. Chem.*, 29, 572).—When treated in warm acid solutions with nascent nitrous acid, resorcinol gives a blood-red colour, thymol a yellowish-red. If aqueous solutions are used, that of resorcinol remains clear, whilst that of thymol gives a flocculent precipitate; alcoholic solutions remain clear in both cases. Very minute quantities can be detected and distinguished by operating as follows:—About equal quantities of a nitrite, solid gypsum, and sodium hydrogen sulphate are mixed in a test tube, and moistened with water; the liquid to be tested is added, and the whole is warmed. Thymol produces a chrome-red colour and resorcinol a dark chrome-green, magenta-red drops separating in the upper part of the tube. M. J. S.

Estimation of Acetone. By F. COLLISCHONN (*Zeit. anal. Chem.*, 29, 562—572).—Messinger's method (*Abstr.*, 1889, 313) is both more rapid and more exact than that of Krämer (*Abstr.*, 1880, 826; see also Hintz, *Abstr.*, 1888, 759). By attention to the following considerations, results of almost theoretical accuracy can be obtained. The formation of iodoform from acetone is actually effected by the alkaline hypoiodite (MIO) which is the first product of the reaction of iodine with an alkaline hydroxide. Since, however, the hypoiodite rapidly passes into a mixture of iodate and iodide, which has no action on acetone, it is important to shake well the mixture of acetone and alkali during the addition of the iodine. If this is done, the quantity of iodine to be added need be only one-sixth more than the theoretical amount, but if it is neglected, a much larger quantity of iodine is necessary. The time prescribed by Messinger (15—30 seconds) is insufficient at low temperatures, except when the excess of iodine is large. Four or five minutes' shaking is enough in the cold, but two minutes will suffice if the mixture is warmed to 60—70°. The temperature must not exceed 70°, and the mixture must be recooled before acidifying. In presence of methyl alcohol, warming must be avoided. The degree of dilution of the acetone is unimportant, but 1 per cent. is suggested as convenient. The error due to nitrites in the alkali, for which Messinger found it necessary to make a correction, may be avoided by using soda, which can be obtained free from nitrites. M. J. S.

Estimation of Acetone in Urine. By H. HUPPERT (*Zeit. anal. Chem.*, 29, 632).—Messinger's method (*Abstr.*, 1889, 313; also preceding abstract) may be used, but the acetone must be distilled from the urine, and be free from phenol, ammonia, and nitrous

acid. To this end, the urine (100 c.c.) should first be distilled with 2 c.c. of pure 50 per cent. acetic acid, and then with 1 c.c. of dilute sulphuric acid, and, if nitrous acid is present, a third time with some urea.

M. J. S.

Estimation of Hydrogen Potassium Tartrate, Free Tartaric Acid, and Malic Acid and Mineral Salts in Wine. By M. SCHNEIDER (*Chem. Centr.*, 1890, ii, 277—278; from *Mitt. pharm. Inst. Erlangen*, 1890, 57—92).—The author considers that the hydrogen potassium tartrate in wine is completely precipitated by concentration and treatment with alcohol, but that it is accompanied by other salts, such as phosphates, and that the tartrate thus separated must be incinerated, and the carbonic anhydride in the ash determined, from which the amount of the tartrate may be calculated.

The following method is recommended by him :—100 c.c. of wine is evaporated, with the addition of sand, to a thin syrup, which is transferred, finally by the aid of small quantities of 96 per cent. alcohol, to a flask, and sufficient alcohol added to make up the volume of the latter to 200 c.c.; the flask is then closed and allowed to remain for 12 hours in a cool place. The solution is filtered, and the insoluble portion washed with alcohol until the washings are neutral. The filter with its contents is returned to the flask and digested with hot water, filtered, and the filtrate exactly neutralised with decinormal alkali: it is then evaporated to dryness and the residue incinerated. The carbonic anhydride in the latter is equivalent to half the quantity of hydrogen potassium tartrate in the wine. From the filtrate, the alcohol is evaporated, and 0.5 c.c. of potassium acetate (20 per cent. rendered acid with acetic acid) added, whereby the formation of hydrogen potassium tartrate is facilitated. It is then evaporated with sand, treated with 96 per cent. alcohol (200 c.c.), and the amount of acid tartrate determined as above. The carbonic anhydride contained in the ash is equivalent to the free tartaric acid present in the wine.

For the estimation of the malic acid, 100 c.c. of the wine is exactly neutralised with decinormal alkali, evaporated to dryness, incinerated, and the carbonic anhydride estimated. From this, is deducted the quantity equivalent to the tartaric acid and hydrogen potassium tartrate, the remainder being equivalent to the malic acid. The author considers that the acids and bases are combined in wine in the following manner :—The potassium is present as hydrogen potassium tartrate; the sodium as chloride; calcium as sulphate and acid phosphate; magnesium as tertiary phosphate; and iron as phosphate.

J. W. L.

Estimation of Malic Acid in Wine. By M. SCHNEIDER (*Chem. Centr.*, 1890, ii, 278—279; from *Pharm. Centralhalle*, 31, 406—407).—Replying to a criticism of Niederhäuser (this vol., p. 128) on the author's method for determining malic acid in wine, the author contends that the amounts of tannin and succinic acid are rarely worth noticing, but that in applying the method described in the foregoing abstract, the amount of carbonic anhydride which corresponds with the volatile acids must be deducted.

J. W. L.

Analysis of Tartar and Wine Lees. By B. PHILIPS and Co. (*Zeit. anal. Chem.*, 29, 577—579; see Abstr., 1889, 657).—To estimate the total tartaric acid, 10 grams of the substance is boiled with 150 c.c. of water and 7 grams of potassium carbonate for 30 minutes. To estimate that as potassium hydrogen tartrate alone, the potassium carbonate is omitted, and the solution accurately neutralised with sodium hydroxide. This leaves the calcium tartrate undecomposed. In either case, the whole is made up to 200 c.c. (203 c.c. for lees) and 100 c.c. of the filtrate is evaporated to 25 c.c., then mixed with 5 c.c. of glacial acetic acid and warmed for 15 minutes on the water-bath. After cooling, 100 c.c. of absolute alcohol is added, the mixture vigorously stirred, and after 15 minutes filtered by suction through a filter of 10 cm. diameter. The precipitate is washed with 96 per cent. alcohol, until 20 c.c. of the washings, diluted with an equal bulk of water, is rendered alkaline by three drops of N/5 alkali. The filter, with the precipitate, is returned to the basin, boiled with 200 c.c. of water, and titrated with N/2 alkali. The mixture should be well boiled just before reaching neutrality, and the addition of the alkali continued until a distinct excess is shown by sensitive, neutral tint, litmus paper.

Estimation of Caffeine in Tea. By F. VITÉ (*Chem. Centr.*, 1890, ii, 274—275; from *Mitt. pharm. Inst. Erlangen*, 1890, 113—143).—Of several methods for the estimation of caffeine, the author has found those of Hilger (*Ziemssen-Pettenkoffer, Handb. f. Hyg.* 1, 278) and of Schimoyama (*Orig. Arb. über Japanische Theekultur*) give the most trustworthy results. He recommends that of Hilger, since the caffeine obtained is in the purest condition, and he applies it in the following form:—5 grams of tea, pulverised and passed through a hair sieve of 4 c. mm. mesh is extracted three times for one hour with 300 c.c. of water; the extract is then concentrated to one-fourth the volume and treated with freshly precipitated lead oxide with addition of sand. The mixture is evaporated to dryness on the water-bath, the residue extracted during three hours with chloroform, the latter distilled off, and the residue extracted with hot water. This aqueous extract may then be evaporated to dryness in a weighed dish, and the residual caffeine dried at 100° and weighed. The author has employed a sieve to contain the tea during the extraction.

J. W. L.

Detection of the Colouring Matter of Alkanna Root. By A. BUJARD and A. KLINGER (*Zeit. ang. Chem.*, 1890, 26—27).—From an ammoniacal solution, ether extracts the alkanna red. In this respect it resembles orchil, but differs from the colouring matters contained in logwood, Brazil wood, bilberries, elderberries, grapes, &c. The alcoholic solution is turned red by acetic acid, and then gives a well-defined absorption spectrum of three bands, of which the first is near and on the more refrangible side of D, the second commences at E and extends beyond b, and the third, which is faint, is close to F. On rendering the solution alkaline by soda, it turns blue, and then shows two bands, of which one is about midway between C and D, and the other, of about equal width, commences at D. M. J. S.

General and Physical Chemistry.

Molecular Refraction of Substances containing Nitrogen. By R. LOEWENHERZ (*Zeit. physikal. Chem.*, 6, 552—563).—The author has measured the refractive indices n_D and n_C of a number of organic compounds, and compared the observed molecular refraction with that calculated. The molecular refractions were obtained from both the formulæ $M(n-1)/d$, in which $n = n_C$, and $M(n^2-1)/d(n^2+2)$, in which $n = n_D$, and the numbers used in calculating the refractions in the two cases were $C = 5.0$ and 2.501 , double linkage $= 2.4$ and 1.707 , $H = 1.3$ and 1.051 , $O' = 2.8$ and 1.521 , $O'' = 3.4$ and 2.287 . The values taken for nitrogen itself were those of Brühl, 5.75 and 2.900 , but the results were afterwards used for calculating the atomic refraction of nitrogen.

Four amines were examined, diethylamine, dipropylamine, diisobutylamine, and diisooxylamine. The calculated values for the atomic refraction of nitrogen obtained from these compounds were 5.67 and 2.781 . Four nitrates also were examined, ethyl, propyl, isobutyl, and amyl nitrate. Two constitutions are possible for these compounds $R \cdot O \cdot N < \overset{O}{\underset{\cdot}{O}}$ and $R \cdot O \cdot N \leq \overset{O}{\underset{\cdot}{O}}$. The numbers calculated for the first are, however, much smaller than those observed, and the second is therefore taken as the correct constitution, the numbers calculated for this being in agreement with those observed. Similar observations with nitromethane and nitroethane lead to the constitution $R \cdot O \cdot N : O$ for these compounds, and from the examination of propyl, butyl, and amyl nitrites the constitution $R \cdot N \leq \overset{O}{\underset{\cdot}{O}}$ is derived. Dimethyl- and diethyl-nitrosamine were also examined, the constitution of these compounds being $R > N : N : O$.

From the results, it appeared that:—

1. Oxygen united by a double linkage to nitrogen has the same atomic refraction that it has when united by a double linkage to carbon.

2. Triad or pentad nitrogen united by either single or double linkage to oxygen has the same atomic refraction that is possessed by nitrogen in the amines. The mean values of the atomic refraction calculated from the above observations for the two formulæ employed are 5.38 and 2.780 .
H. C.

Refraction and Dispersion in Certain Metals. By H. E. J. (†. DU BOIS and H. RUBENS (*Phil. Mag.* [5], 30, 365—378).—Thin wedge-shaped films of iron, cobalt, and nickel were deposited electrolytically. These acted as prisms, and refracted light for small angles

of emission approximately according to the law of sines. The dispersion results agreed well with those of Kundt in the case of nickel, but with iron somewhat different values were found. Numerous tables and curves illustrate the paper. J. W.

Absorption Spectra of Iodine Solutions. By H. RIGOLLON (*Compt. rend.*, 112, 38—40).—The author has made spectroscopic and spectrophotometric observations with solutions of iodine in benzene, toluene, and metaxylene, chloroform, bromoform, the methyl, ethyl, and amyl haloid salts, and methyl, ethyl, and amyl alcohol. For homologous compounds, and for derivatives of the same radicle, as the molecular weight of the solvent increases, the absorption band of the iodine is very slightly displaced towards the violet, and the minimum of light transmitted diminishes. C. H. B.

Gas Battery. By P. SCHARF (*Dingl. polyt. J.*, 276, 26—40).—The author has patented a gas battery, in which it is proposed to use two gases or vapours producing a voltaic current by mutual action. He employs gases of the following groups: (1) Hydrogen, water-gas, generator-gas, coal gas, and the vapour of light hydrocarbons, such as petroleum, naphtha, or the like; (2) air, oxygen, chlorine, and fluorine. In cases where a liquid and a gas are used, the former is substituted for a gas belonging to the second group, hydrogen peroxide or nitric acid being the most suitable. The gases are prepared in separate apparatus according to the usual methods, and are collected in suitable receivers, into which they are compressed by well-known means. They are then conducted to the battery, a full description of which is given in the original paper, accompanied by detailed drawings. D. B.

Development of Electromotive Force between Mercury and an Electrolyte. By F. PASCHEN (*Ann. Phys. Chem.*, 41, 801—832 and 899—900).—Time is required for the full development of the E.M.F. between a metal and an electrolytic solution, for a movement of the ions is necessary to effect the charge of the metallic surface, and this can only take place at a finite rate. The author by the use of dropping electrodes measures the E.M.F. between mercury and solutions of sulphuric acid, hydrochloric acid, cupric sulphate, and zinc sulphate, when the mercury is flowing at different rates. The speed of outflow may be so small that single drops are formed at the end of the capillary and fall separately through the liquid, or it may be great enough to give a continuous jet of mercury for some distance from the mouth of the tube. By measuring the length of this jet (from the capillary to the point where breaking up into drops commences), and dividing by the speed of outflow, the time is obtained during which a surface-particle of mercury is in electrical contact with the electrolyte and the electrometer simultaneously.

The results show that the mean difference of potential at a mercury surface which is increasing in size in an electrolyte does not depend so much on the nature of the increase, as on the time during which each surface-particle is in contact with the electrolytic solution. The

phenomenon is to be conceived as a charging of the surface; and the mean E.M.F. at the surface is composed of those of the separate particles during the time of their contact with the electrolyte. The beginning of the charging curve is to be sought at times less than 10^{-3} seconds. The charging goes on rapidly up to 10^{-3} seconds, after which the E.M.F. increases much more slowly, the increase being very little for hydrochloric acid, considerable for sulphuric acid and the sulphates of zinc and copper. This last increase is probably due to the formation of a mercury salt on the surface. J. W.

Conductivities of Isomeric Organic Acids and their Salts. By D. BERTHELOT (*Compt. rend.*, 112, 46—48).—Free isomeric acids usually have different conductivities, but normal salts of acids of simple function, such as maleates and fumarates, itaconates, mesaconates, and citraconates, have the same conductivities. This is true also of all the tartrates, and of the three amidobenzoates, and it is very nearly true for the three hydroxybenzoates.

Dextrogyrate tartaric acid and racemic acid have identical conductivities, and since the levogyrate acid is identical with the dextrogyrate acid in all symmetrical properties, this result affords further proof of the dissociation of racemic acid in solution. Mesotartaric acid has a very different conductivity when in the free state.

When an excess of alkali is added to the normal salts, the equality of conductivity persists for acids of simple function, and also for amidobenzoates and the tartrates, a result which indicates that the alcoholic function of the latter is practically inoperative in very dilute solutions. Acids with a phenolic function yield salts with conductivities which are only approximately equal, and they begin to vary still more on addition of excess of alkali, the results showing that ortho-acids yield no more basic salt in dilute solutions, whilst the meta- and para-acids form polybasic salts.

If increasing quantities of acid are added to a normal salt, the results are different from those with excess of base, but the general phenomena are identical for a large number of acids. With monobasic acids, the liquid behaves simply as a mixture of the normal salt and the acid: with bibasic and polybasic acids, this does not hold good, in consequence of the existence, in the solution, of partially dissociated acid salts. Differences are observed between isomerides, such as fumaric and maleic acids, mesotartaric acid, and the other tartaric acids. The proportions of acid salt formed are almost identical with citraconic and maleic acids, on the one hand, and mesaconic and fumaric acids, on the other. In the case of the amidobenzoic acids, the basic function seems to be most energetic with the meta-derivative, and weakest with the ortho-derivative.

C. H. B.

Connection between the Theoretical and Empirical Isothermals of Mixtures. By A. BLÜMCKE (*Zeit. physikal. Chem.*, 6, 153—160 and 407—410).—The theoretical and empirical isothermals of a single substance only coincide when the substance is homogeneous; if one portion is in the liquid and another in the gaseous

molecules as in the conversion of dihydro- into tetrahydro-, and of tetrahydro into hexahydro terephthalic acid, causes an increase in the heat of combustion of 45.3 Cal for each molecule, (3) the addition of the fourth molecule of hydrogen, which brings about the splitting open of the benzene ring as in the conversion of hexahydro-terephthalic acid into suberic acid, and the addition of the fifth molecule, which splits up the open chain into two different molecules, both cause an increase of 54.8 Cal in the heat of combustion.

The correctness of these three figures is fully confirmed by the thermal values obtained for the successive hydrogenation of benzene into hexane, benzoic acid into heptylic acid, &c. The same three figures obtain also in the hydrogenation of compounds containing the pyridene and thiophen rings.

The agreement between the numbers 45.3 and 54.8 on the one hand, and the numbers representing the hydrogenation of compounds of the fatty series on the other hand leads the authors to the following conclusion—The thermal value of the hydrogenation of compounds containing the benzene and thiophen nuclei is entirely different in the first stage from what it is in the second and third stages, and in both these latter stages is in agreement with the thermal values of the hydrogenation of ordinary double bond compounds in the fatty series (compare Horstmann, *Abstr.*, 1888, 1069) A. G. B.

Endothermic and Exothermic Reactions of Organic Bases. By A. CURSON (*Compt. rend.*, 111, 864—886).—Piperidine displaces calcium from calcium chloride (*Abstr.*, 1890, 1368) only when the solution of the latter contains not less than 55.5 grams per litre. Precipitation is more complete when the liquid is heated, and the precipitate consists of calcium hydroxide with small but variable quantities of calcium chloride and of the double calcium piperidine compound described by Berthelot.

There are many other cases in which a reaction is determined by the solubilities of the products and not solely by the thermal disturbances. The formation of barium oxalate from the dissolved chloride and oxalic acid develops +5.6 Cal and that of diisobutylamine oxalate from the dissolved hydrochloride +6.5 Cal; the formation of the two oxalates from the bases and a solution of ammonium oxalate would develop +8.0 Cal and +7.5 Cal respectively, and yet diisobutylamine oxalate cannot be obtained in this way. On the contrary ammonia displaces the amine at once from its oxalate, even at the ordinary temperature, although the change corresponds with an absorption of -10.8 Cal.

If normal diisobutylamine is added to an aqueous solution of trimethylamine (1 gram-mol per litre), it first dissolves with an absorption of -6.6 Cal, and then the diisobutylamine separates with a further absorption of -7.0 Cal. Other amines behave like ammonia and trimethylamine in contact with diisobutylamine oxalate, and give analogous endothermic reactions. In these phenomena, the coefficient of distribution of the acid between the two bases has to be taken into account. 3 mols. of trimethylamine are required to displace 1 mol. of diisobutylamine from its hydrochloride, and 3 mols. of

trimethylamine are required to dissolve 1 mol of normal diisobutylamine oxalate the solutions containing 1 gram-mol of base per litre

The following experimental data are given —

Diisobutylamine diss + $\frac{1}{2}$ H ₂ C ₂ O ₄ diss	
= solid salt	develops +16.4 Cal
Diisobutylamine liquid + $\frac{1}{2}$ H ₂ C ₂ O ₄ solid

New Method of Investigating the Compressibility of Liquids and Gases: Results with Oxygen, Hydrogen, Nitrogen, and Air. By E. H. AMAGAT (*Compt rend.*, 111, 871—875) — The author has investigated the effects of pressures varying from 100 to 1000 atmospheres at 0°, 100°, and 200°. For hydrogen, the values of dv/dt are practically independent of the temperature, and the coefficient of dilatation diminishes regularly as the pressure rises, whilst for nitrogen, oxygen, and air, it passes through a maximum corresponding with the pressure at which p_v has its minimum value. The values dp/dt for hydrogen are practically independent of the temperature. Air and nitrogen approximate to hydrogen in their behaviour. Hydrogen seems, in fact, to represent the limit towards which all the other gases tend, and which is characterised by values of dv/dt and dp/dt , independent of the temperature, the first decreasing and the second increasing regularly as the pressure rises.

Further experiments have shown that the isothermals at pressures up to 3000 atmos, and at all temperatures, are not strictly right lines, but have a slight concavity towards the axis of the abscissæ

C H B

Dalton's Law. By B. GALIZINE (*Ann Phys Chem*, 41, 770—800)

—Taking the gas equation of Clausius, $(p + \frac{a}{T(l + \beta)})(v - b) =$

RT as his basis, the author develops a theory of the behaviour of a mixture of two gases with respect to compression. The internal cohesion of such a gaseous mixture is first considered, it being assumed that the cohesive forces between both like and unlike molecules depend on the masses of the attracting bodies, and that they decrease with rise of temperature. No assumption is made, in the first place as to how the attraction varies with the distance between the attracting molecules, but afterwards, the inverse second, third, and fourth powers are introduced into the formulæ obtained, and the consequences tested. It is found that the inverse square alone yields consistent results. The influence of the extension of the molecules on the pressure of the gaseous mixture is next investigated; and then follows a comparison of the theoretical numbers with the compression experiments of Andrews and other physicists.

on mixtures of gases. Under considerable pressures, the law of the inverse square seems no longer to hold good, the attraction being smaller than that deduced from theory.

The equations are finally applied to the critical state, and calculations of the critical temperature of mixtures of carbonic anhydride and nitrogen are found to be in satisfactory accordance with the experimental values of Andrews. (For previous paper, see Abstr., 1890, 105.) J. W.

Method for Determining the Absolute Density of a Gas.

By J. JOLY (*Phil. Mag.* [5], 30, 379—386).—The author weighs the gas in a strong copper sphere under a pressure of 20 or more atmos. A portion is then allowed to enter a volumometer of 1—2 litres capacity at atmospheric pressure. Volume, pressure, and temperature are then read off, and the sphere with its remaining contents again weighed. Thus, all the data necessary for a density determination are obtained. The experimental error is considered by the author to affect only the fifth significant decimal. J. W.

Relation between the Boiling Points, Molecular Volumes, and Chemical Characters of Liquids. By O. MASSON (*Phil. Mag.* [5], 30, 412—423).—The following law is formulated by the author:—If liquid compounds of the same group be compared at temperatures at which their vapour pressures are equal, the volumes occupied by unit weights will be inversely proportional to the molecular weights, and directly proportional to the absolute temperature; or, for each group at equal vapour pressure, $V_T/T = \text{const.}$, T being the absolute temperature of ebullition, and V_T the molecular volume at T° . By compounds of the same group are meant those of a hydrocarbon radicle with elements of the same natural family; for instance, ethyl chloride, bromide, and iodide. Small, but real deviations from this law occur, the bromide in most haloid compounds, for instance, having the lowest value of the constant. Since the same relation holds good for vapours under equal pressure, it follows that different compounds of the same group are expanded equally in changing from liquid to vapour at the boiling point (compare Groshans, *Phil. Mag.* [5], 20, 197).

In homologous series, the constant seems to increase by the same amount with each successive addition of CH_2 .

Ramsay and Young have shown that $T \times dp/dt$ is a constant for closely allied substances. This law, taken in conjunction with the above relation and the thermodynamical equation $L/V - v = T \times dp/dt$, gives the result that in each group the molecular heat of vaporisation divided by the absolute temperature of ebullition is constant (compare Trouton, *Phil. Mag.* [5], 18, 54). J. W.

Relation between the Boiling Points, Molecular Volumes, and Chemical Characters of Liquids. By S. YOUNG (*Phil. Mag.* [5], 30, 423—427).—If V and V' represent the molecular volumes of two liquids at "corresponding" pressures p and p' , at which pressures their boiling points in the absolute scale are T and T' ,

then, according to Van der Waals, $V, V' = T/T' \times p/p'$. The author finds that, whilst this equation holds good in general for substances which are closely related, it shows deviations of as much as 17 per cent. from experimental results when the substances compared are not so related. J. W.

Connection between the Critical Data of Liquids and their Chemical Constitution. By E. HELLBORN (*Zeit. physikal. Chem.*, 6, 578—585).—In this preliminary note, the author first shows how the molecular volumes at the critical temperatures may be calculated, and that, at the critical temperature, isomeric compounds have equal molecular volumes, the molecular volumes of all compounds being equal to the sum of the atomic volumes. He also shows that the critical molecular volume, the constant b of the Van der Waals' equation, is subject to similar laws, and that, from this, it follows that the critical data of liquids are purely functions of their chemical composition. H. C.

Viscosity of Liquid Carbon Compounds, and its Relation to Chemical Constitution. By R. GARIENMEISTER (*Zeit. physikal. Chem.*, 6, 524—551).—The viscosity of a liquid is defined as the resistance of its particles to shear, and is constant for any liquid of constant temperature. It is measured by the work which is required to overcome the above resistance, this being, according to Finkener, $\tau = r^4 \pi p 8lv - vs^2 8 \pi gl$. In this expression, r is the radius and l the length of a capillary through which a volume v of the liquid of sp. gr. s flows under a pressure p in unit of time. The author has determined the value of τ for a large number of organic compounds, by measuring the rate of flow from pipettes of suitable size. The results are given in tabular form, and the values of τ/m and τ/m^2 , where m is the molecular weight, are also given, important relations between these values and the constitution of the compounds being established.

It is found that for any series of homologous compounds, with the exception of the acids, the values of τ/m^2 are practically constant. The presence of a double linkage does not appear to exercise any marked effect on the viscosity, but for ring compounds the value of τ/m^2 is greater than for open chain compounds, dipropyl and diallyl, for instance, giving the values 4.3 and 4.2, whereas benzene and ethylbenzene give 11.1 and 6.1. The influence of the presence of an hydroxyl group is very marked, for whereas the values of τ/m^2 for the hydrocarbons are from 4.2 to 11.1, those for the normal alcohols lie between 54 and 63. In this respect, the following series of values is of interest: $C_3H_7OH = 63$, $C_8H_9(OH)_2 = 791$, and $C_6H_5(OH)_3 =$ about 10,000. The values for the isomeric benzyl alcohol and metacresol of 49 and 161 respectively are also noteworthy, as showing the much greater effect which seems to result from the introduction of the hydroxyl group into a closed chain. The above facts serve to account for the great viscosity of the carbohydrates. The viscosity of the acids is much less than that of the corresponding alcohols, but here also the presence of the hydroxyl group exercises a marked influence.

This is shown more particularly when an alcohol radicle is substituted for the hydrogen of the hydroxyl group, the viscosity of the ethereal salts being much less than that of the acids. From the low viscosity of acetoacetic acid, the author concludes that this compound does not, as indicated by Geuther's formula, contain a hydroxyl group other than that present in the carboxyl radicle.

The influence of temperature on the viscosity is also studied. A decrease in the viscosity takes place with rise of temperature, this decrease becoming smaller and smaller the higher the temperature, the influence of temperature being greatest with those substances having the greatest viscosity. H. C.

Influence of Pressure on Dissociation. By B. PAWLEWSKI (*Ber.*, 23, 3752—3755).—According to the author, the critical temperature of a mixture of liquids is calculable by the simple mixing formula $T_m = nT + (1 - n)T'$, where T and T' are the critical temperatures of the components, n and $1 - n$ the proportions in which these are present. On this basis, one should be able to calculate the amount of dissociation of a liquid such as C_2H_5Cl at high pressures from the observation of its critical temperature, provided those of the dissociation products ($C_2H_6 + HCl$) are known. The great pressures under which the experiments must be conducted would appear to prevent the dissociation in such cases, for the observed critical temperature is much higher than that calculated from the formula, supposing the dissociation to be complete. On the other hand, with substances like $Cl-COOC_2H_5$, which, on heating, decompose into products that have no tendency towards recombination ($C_2H_5Cl + CO_2$), the results of observation are in agreement with the calculated critical temperature. J. W.

Continued Dissociation and the Vapour Density of Sulphur. By E. RIECKE (*Zeit. physikal. Chem.*, 6, 430—436).—By "continued" dissociation is meant, for example, that of a compound represented by the symbol ($abcd$), which first dissociates into (abc) and d , the molecule (abc) being afterwards capable of dissociating into the simpler molecules a , b , and c .

The author, from thermodynamical principles, deduces the mathematical law of continued dissociation, and afterwards applies it to the instance of gaseous sulphur; which, from the vapour density observations of Biltz (*Zeit. physikal. Chem.*, 2, 920), appears to exist at the boiling point as S_8 , dissociation at once taking place into S_6 and S_2 , and finally entirely into S_2 . A general solution of the equation applicable is impossible; but by making probable assumptions as to the form of the density curve of S_2 and of S_6 , the author obtains figures which exhibit a close agreement with the numbers obtained by Biltz. J. W.

Effusion of Gases through a Narrow Aperture at Different Temperatures. By W. TIMOFÉEFF (*Zeit. physikal. Chem.*, 6, 586—589).—The apparatus used is that shown in the accompanying sketch. A is a glass pipette containing 150 c.c., with small bulbs

above and below, and supported by an iron tripod. *D* is a tube of copper, in which at *o* a platinum plate pierced by a narrow opening is soldered. The side tube *ef* can be connected with *A* by means of india-rubber tubing. *A* is filled with the gas to be examined and connected with *D*, the connection being, however, closed by a pinch-cock. *D* is brought to the desired constant temperature, and *A* is

then immersed in the cylinder of water *C*. On opening the pinch-cock, water enters *A*, and the gas escapes through *c*, the time occupied by the water in rising from the mark *a* to the mark *b* being noted and giving the rate of effusion.

If c_1 and c_2 are the rates of effusion, at the temperatures t_1 and t_2 , of a gas of mass m , volume v , and pressure p , the work required for the effusion of the above mass in each case will be $pv(1 + \alpha t_1) = \frac{1}{2}mc_1^2$ and $pv(1 + \alpha t_2) = \frac{1}{2}mc_2^2$. Dividing the first equation by the second, and placing $c_1 = r(1 + \alpha t_1)/z_1$ and $c_2 = r(1 + \alpha t_2)/z_2$, where z_1 and z_2 represent the time of effusion in each case, we get

$$\frac{1 + \alpha t_1}{1 + \alpha t_2} = \frac{(1 + \alpha t_1)^2}{(1 + \alpha t_2)^2} \cdot \frac{z_1^2}{z_2^2},$$

and hence $(1 + \alpha t_1)/(1 + \alpha t_2) = z_1^2/z_2^2$ or $T_1/T_2 = z_1^2/z_2^2$, where T_1 and T_2 are the absolute temperatures. This result is of interest as it is in apparent contradiction to the deductions from the kinetic theory of gases. For since the velocity of the moving molecules increases with rising temperature, instead of a decrease in the rate of effusion at the higher temperature as indicated by the above formula, an increase might have been expected. The author's experiments with

carbonic anhydride and air confirm, however, the above result, the rate of effusion becoming smaller as the temperature is raised. A quantitative test of the formula gave values for T_1 calculated as equal to $T_2 z_2^2 / z_1^2$, which were greater than those observed. This the author attributes to unavoidable inequalities in the aperture, which cause alterations in the area with change of temperature.

H. C.

Law of Diffusion of Liquids. By H. M. VERNON (*Chem. News*, 62, 275—276).—Graham, in his experiments on the diffusion of aqueous solutions of various salts, did not show the existence of any general law bearing on the relations between the salts and the amounts of them diffused under similar conditions as to time, temperature, and concentration, yet several series of isomorphous salts were found to diffuse at approximately equal rates, and he endeavoured to show that the rates of diffusion of several of the different groups were to one another as the square roots of simple numbers. The author of the present note does not see why such complex relations should exist, and is of opinion that there probably is a general law for the diffusion of aqueous solutions of salts. In accordance with the kinetic theory of molecular motion, solutions of the same density should have equal rates of diffusion supposing no combination takes place between the solvent and the substance dissolved, then in a series of salts arranged regularly according to the densities of their solutions, the amounts of salts diffused ought to vary regularly from one end of the series to the other. The author has arranged two such series from Graham's numbers, reducing all to a common period of eight days; for Graham tried to find numerical relations between the periods required to obtain equal amounts of diffusate in all cases; therefore his numbers were for varying periods.

The numbers taken are also for 1 per cent. solutions only in each case, as stronger solutions do not give such regular results. Disregarding the numbers for ammonium hydrogen carbonate, potassium and sodium thiosulphates, and aluminium sulphate, which were vitiated by dissociation taking place, and those for magnesium nitrate, potassium iodide, silver nitrate, and barium chloride, which were abnormal for some reason, the diffusion values for potassium, sodium, ammonium, magnesium, manganese, calcium, zinc, and copper chlorides, potassium and sodium bromides, chromates, carbonates, sulphites, sodium iodide, potassium, sodium, magnesium, zinc, and hydrogen sulphates, and sodium, copper, strontium, calcium, and barium nitrates are shown to decrease more or less regularly with the increasing density of the solutions, and it is inferred "that solutions of the same density have equal rates of diffusion, or that with solutions of varying density, the rate of diffusion decreases regularly with increase in density of the solutions." Hydrochloric acid, nitric acid, and sodium and potassium hydroxides gave diffusion values very much greater than the normal, and so were not included in the tables.

D. A. L.

Hydrodiffusion. By O. WIEDERBURG (*Ann. Phys. Chem.*, 41, 675—711).—The author completely fills a small glass cylinder with a salt solution of known concentration, places it inside a much larger vessel,

and then carefully fills up the latter with pure water. After the diffusion has proceeded far enough, the liquid in the larger vessel is slowly run off, and the contents of the small cylinder are then analysed photometrically. The experimental results are contained in numerous tables, and the mathematical theory of diffusion for the above arrangement developed. J. W.

Evaporation and Dissolution considered as Processes of Diffusion. By J. SIEFAN (*Ann. Phys. Chem.*, **41**, 725—747).—Experiments were formerly made by the author (*Wien. Ber.*, **68**, 2 Abth., 385), on the evaporation of various liquids from tubes of 1—6 mm. diameter. Two simple laws regulating the evaporation were discovered:—(1) the speed of evaporation is inversely proportional to the distance of the liquid surface from the top of the tube; (2) the speed is independent of the section of the tube. These two laws were found to be direct consequences of the theory of gaseous diffusion applied to the above process. The author now describes a parallel experiment made on the dissolution of a solid instead of the evaporation of a liquid. A rectangular prism of rock salt was enclosed on all sides (except one end) by glass plates fastened on by means of Canada balsam. This prism was placed in an upright position in a capacious vessel containing water, and the rate at which the salt dissolved was observed. When the uncovered end was upmost, the rate of dissolution was small and inversely proportional to the distance of the free salt surface from the top of the glass plates. When the uncovered surface was pointed downwards, solution took place much more rapidly owing to convection, and at a rate practically independent of the distance of the free surface from the edge of the plates. An experiment of the first kind can be used to calculate the coefficient of diffusion of a solid.

In the mathematical part of his paper, the author deduces the laws of evaporation and dissolution by making application of the theories of gaseous and liquid diffusion. J. W.

The Solubility of Gases in Water. By L. W. WINKLER (*Ber.*, **24**, 89—101).—The solubility was determined by shaking up a known weight of water with a known volume of gas, and measuring the gas remaining unabsorbed. The absorption apparatus consists of a large glass globe to which a long tube *b* is sealed; the inside measurement of the tube is 15 mm., and the length from below the level of the bottom of the globe to the open end about 850 mm.; the tube is graduated in millimetres. The capacity of the absorption globe is from 2 to 2½ litres; it is connected to the manometer tube *m* by an india-rubber tube. The apparatus *d* is provided in order to determine the tension of water vapour under the same conditions as those existing in the absorption globe, and is also connected with a manometer. The whole is surrounded by a water-bath which is stirred by air currents passing through *f* and *g*.

Solubility of *hydrogen* in water. The hydrogen was prepared from dilute sulphuric acid and pure zinc, and collected over mercury and a small quantity of potash. The gas so prepared was entirely without smell, and had no action on moist silver nitrate paper. On ex-

ploding 100 parts of the gas in an eudiometer with excess of oxygen, the contractions which took place were 150.00 and 150.01. The expansion coefficient of hydrogen was taken as 0.00366.

The mean values of the results were the following :—

	Temperature.	Absorption coefficient.
(1.)	0.57° C.	0.02131
(2.)	9.97 „	0.01955
(3.)	20.01 „	0.01819
(4.)	30.00 „	0.01639
(5.)	39.96 „	0.01644
(6.)	49.98 „	0.01608

The following interpolation formulæ were calculated :—

$$\begin{aligned}
 0-20^\circ \beta &= 0.02148 - 0.0002215t + 0.00000285t^2. \\
 10-30 \beta &= 0.01955 - 0.000144(t-10) + 0.0000008(t-10)^2. \\
 20-40 \beta &= 0.01819 - 0.0001525(t-20) + 0.00000325(t-20)^2. \\
 30-50 \beta &= 0.01699 - 0.0000645(t-30) + 0.00000095(t-30)^2.
 \end{aligned}$$

The solubility was calculated from the absorption coefficient by the formula $\beta' = \beta \frac{760 - f}{760}$ (Abstr., 1889, 936).

The absorption coefficient of hydrogen decreases with rise of temperature and becomes constant about 60°. Bunsen found it constant between 0° and 20° within the limits of experimental error. The author's results agree fairly closely with those of Timoféeff; the latter are somewhat higher.
E. C. R.

Vapour Pressures of Solutions. By F. M. RAOULT (*Ann. Chim. Phys.* [6], 20, 237—371).—In former papers (Abstr., 1887, 631; 1888, 1145; 1889, 7; 1890, 554), the author has recorded his experiments on the vapour pressures of solutions in ether, alcohol, and acetic acid; the present paper contains the results of his examination of solutions in other solvents. The method of determining the pressures was in part that described in the previous papers, but in some cases the vapour pressure was found from the boiling point of the liquid. To make this method applicable, the thermometer bulb, which must of course be placed directly in the liquid, is surrounded by a spiral of palladium wire which has been electrolytically charged with hydrogen. On heating the solution, the vapour of the liquid is generated solely on the surface of the wire, a regular ebullition results, and the thermometer is found to register a constant boiling point to within $\frac{1}{100}$ of a degree. The boiling points of the solvents used were determined under different pressures, and it was satisfactorily established that at equal distances from their boiling points under atmospheric pressure, all the liquids in question showed the same vapour pressure.

The experiments were made with a large number of different solvents, among others carbon bisulphide, acetone, amylene, and benzene. The results are similar to those obtained in the author's study of ethereal solutions (Abstr., 1888, 1145). The general law $(f - f') f \times (n - n') n = k$, holds good for all solutions, the values of f and f' being the vapour pressures of the pure solvent and the solution, and n and n' being the number of molecules of the solvent and of the dissolved substance present. The normal value for the constant k is 1.04, but some solutions are found to give only half this value, and in others the number is very much higher. The first series of exceptions may be explained by assuming that the molecules of the dissolved substance are double the ordinary chemical molecule, in which case n' becomes $\frac{1}{2}n'$, and therefore in dilute solution the value of k is halved. The second series of exceptions are those which occur in aqueous and acetic acid solutions. The exceptions in aqueous solution are explained by the theory of electrolytic dissociation, whereas those with acetic acid may be referred to the well-known anomalous character of acetic acid vapour at low temperatures. These results are in accordance with those found experimentally by other observers, and with the theoretical deductions of Van't Hoff.

The reduction of the vapour pressure may be used to determine the molecular weight of the dissolved substance. In this case it is best to employ the boiling point method above described, which, as the

author shows, gives accurate results. The cryoscopic method is, however, recommended in preference to the above, as being simpler and more accurate.
H. C.

Determination of Solubility Coefficients. By J. W. DÖLLER (*Zeit. physikal. Chem.*, 6, 481—489).—If a known amount of an indifferent gas is passed through solutions of definite concentration at a fixed temperature, then the tension of the dissolved substance may be calculated from the amount of it which is carried away, assuming that the concentration remains the same during the experiment. Assume that V litres of air at the barometric pressure B and temperature t are passed through a solution with tension x and temperature T , and that g grams of the dissolved substance are removed. Then, if γ is the weight of a litre of the dissolved gas at 0° and 760 mm.,

$$g = \gamma \frac{1}{1 + \alpha T} \times \frac{\tau}{760} \times \frac{V(1 + \alpha T)B}{(1 + \alpha t)(B - x - W_{T-t})},$$

where W_{T-t} is the difference between the pressure of the water vapour at T° and at t° . From this

$$x = (B - W_{T-t}) \left\{ 1 + \frac{BV}{\gamma} g(1 + \alpha t) \right\}.$$

The experiments practically may be carried out in the apparatus described by Will and Bredig (*Abstr.*, 1889, 820). Preliminary experiments with ammonia and some of the amines led to the following results for the values of x in normal solutions, calculated from experiments with solutions of different concentrations on the assumption that the tension is proportional to the concentration: ammonia, 53.7; methylamine, 40.6; dimethylamine, 90.3; ethylamine, 64.5; diethylamine, 233; propylamine, 89. The results are expressed in millimetres of mercury. The temperature of the air was 15° , that of the solution 60° . From these numbers, Ostwald's solubility coefficient, the number expressing the ratio between the concentration of the gas within and without the solutions, may be calculated, as also Bunsen's absorption coefficient. The first is equal to V/v , the second to $V/v(1 + \alpha t)$, V being the volume of the gas which is dissolved in the volume v of the solution. For the above substances we have—

	NH ₃	NH ₂ Me.	NHMe ₂	NH ₂ Et.	NHEt ₂	NH ₂ Pr.
Solubility coefficient..	386	511	30	321	89	233
Absorption coefficient.	316	419	188	263	73	191

The solubility coefficient is independent of the concentration of the solution, as required by the law of Henry, and the correctness of the experimental method is in so far confirmed. Former experiments of Sims gave 381 as the solubility coefficient of ammonia at 60° , a number with which the author's is sufficiently in agreement.

The author proposes to employ the above method for further investigations on solubility coefficients.
H. C.

Augmented Solubility. By M. LE BLANC and A. A. NOYES (*Zeit. physikal. Chem.*, 6, 385—412).—From the law of mass-action, taken in conjunction with the theory of electrolytic dis-ociation, it has been deduced by Nernst that the solubility of an electrolyte in water should be diminished by the addition to its solution of another electrolyte containing one ion in common with the first. This conclusion has been experimentally verified by Noyes (this vol., p. 142) in a considerable number of instances; but there are several well-known cases of *augmented* solubility that appear to contradict the theory. The present paper contains an account of the cryoscopic and electrolytic behaviour of some of these apparently exceptional solutions.

The solubility of lead nitrate in a solution of potassium nitrate is greater than its solubility in pure water, and *vice versa*. This anomaly was attributed by the authors to the formation of compound molecules, and therefore a number of freezing point determinations of various solutions containing the salt in different proportions were made, in order to throw some light on the number of molecules of dissolved substance present. It was found that the addition of lead nitrate to solutions of potassium nitrate depressed the freezing point by less than the normal amount, as judged by the behaviour of corresponding solutions of sodium nitrate, which are normal in respect of their solubility in water and in solutions of lead nitrate. This result points to the formation in solution of compound molecules of lead nitrate with potassium nitrate. The latter salt by itself would seem inclined to form double molecules, for its molecular depression is much less than that of sodium nitrate. Strontium nitrate with the alkaline nitrates gives results similar to those given by lead nitrate, as far as freezing points are concerned, so that it might be expected that it would be more soluble in potassium nitrate solution than in water alone. This the authors found to be the case.

Other instances of augmented solubility investigated were: mercuric chloride in solutions of hydrogen, sodium and potassium chlorides; silver cyanide in solution of potassium cyanide; and iodine in potassium iodide solution. In all these cases the results obtained clearly indicated the existence of compound molecules in solution; and some idea of the nature of the actual molecules present was obtained. A compound, $\text{KCl} \cdot \text{HgCl}_2 \cdot \text{H}_2\text{O}$, was isolated in the course of the investigation.

J. W.

Cryohydrates of Mixtures of Salts. By D. MAZZOTTO (*Uhem. Centr.*, 1890, ii, 779; from *Rend. Reale Ist. Lombardo* [2], 23, 565, 633).—The author's investigations include the determination of the freezing points of saturated solutions of the chlorides, nitrates, and sulphates of potassium, sodium, and ammonium, and of the temperatures at which the so-called cryohydrates separate. The temperatures were determined by means of mercurial, alcoholic, and air thermometers, the last of which was one specially constructed by the author. The lowest temperature employed (-31.4°) was obtained by a mixture of sodium chloride and ammonium nitrate, or sodium nitrate and ammonium chloride. The tempera-

ture at which a cryohydrate of two salts was precipitated, was always lower than the freezing point of the saturated solution of either separately, and was approximately equal to the sum of the depression of the freezing points of the individual salts. In mixtures of two salts which contain different acids and bases, only those are capable of forming a saturated solution which contain that salt, which, of the four formed from the combination of both acids and bases under the existing conditions of the experiment, is the least soluble. The others are unstable, that is, they exchange their radioles during cooling. The author's experiments support Nernst's statements (Abstr., 1890, 3) on the mutual influences of the solubility of salts.

J. W. L.

New Application of the Cryoscopic Method to the determination of Molecular Weights. By W. NERNST (*Zeit. physikal. Chem.*, 6, 573—577).—In a former paper (Abstr., 1890, 1368), the author showed how, when the solubility of a liquid in any solvent was decreased by the presence of some third substance soluble in the liquid but not in the solvent, the freezing point of the original solution was raised, and that this raising of the freezing point could be used in molecular weight determinations. As then pointed out, solutions of ether in water are suitable for such determinations, and in the present paper a number of new determinations with such solutions are recorded which demonstrate the great accuracy of the method. It is, of course, necessary that the substance taken should be quite insoluble in the water, otherwise greater values than the theoretical will be obtained.

H. C.

Determination of Molecular Weights by the Ebullition Method. By E. BECKMANN (*Zeit. physikal. Chem.* 6, 437—473).—The apparatus employed has already been described by the author (Abstr., 1889, 933). The present paper contains his experimental results presented in numerous tables and curves. Benzene, chloroform, and carbon bisulphide as solvents give normal numbers for the hydrocarbons, carbonyl compounds, and ethereal salts; but for acids they yield results which point to a dissociation of double molecules. In acetic acid or alcohol, the acids have the normal molecular weight. Ethyl acetate, ethyl ether, and acetone give normal numbers, increasing somewhat with the strength of the solution, as is usually the case. The values for cadmium iodide in aqueous solution scarcely vary at all with the concentration; those for mercuric chloride, on the other hand, increase rapidly with it.

Tables of the molecular elevation of the solvents at different temperatures are given, and also a table of the elevation caused by solution of one gram-molecule in 100 c.c. of solvent. The author especially recommends the use of ether as solvent.

J. W.

Osmotic Pressure from the Standpoint of the Kinetic Theory of Gases. By L. BOLTZMANN (*Zeit. physikal. Chem.*, 6, 474—480).—The author considers a cylinder closed at each end by a piston, and divided in the middle by a semipermeable septum. In one compartment is contained a dilute solution, the solvent of

which alone can pass through the septum; the other compartment contains the pure solvent. The pressures on the pistons are adjusted so as to produce equilibrium. This system is treated, with respect to the forces in play between the different parts, after the manner adopted in the kinetic theory of gases. It is found in this way that the resultant of all the forces in the two compartments producing pressure on the septum, that is, the osmotic pressure, is equal to the gaseous pressure which the dissolved substance would exercise were it distributed as a gas throughout the volume occupied by the solution, provided that the mean kinetic energy of a dissolved molecule is assumed to be equal to that of a gas molecule at the same temperature.

The author also discusses the phenomenon of diffusion in liquids from the same point of view. J. W.

The Molecular Theory and Electrolytic Dissociation. By G. CIAMICIAN (*Zeit. physikal. Chem.*, 6, 403—406).—The author, reasoning from the generally accepted ideas of the nature of molecules in the various states of aggregation, seeks to show that we might expect dissociation of salts (together with powerful acids and bases) into their ions in aqueous or alcoholic solution, and in the liquid state. J. W.

The Association Hypothesis in its Relation to the Theories of Clausius and Van't Hoff. By J. TRAUBE (*Ber.*, 23, 3582—3589).—The dissociation theory of Arrhenius has been criticised by the author in a former paper (this vol., p. 255). For this theory he now proposes to substitute another, the association hypothesis, which is based, not on the decomposition of simple molecules, but rather of molecular aggregates (compare Armstrong, *Trans.*, 1898, 116). To bring such a hypothesis into accordance with Clausius's theory of electrolytic conduction, he considers it sufficient to assume that double and more complex molecules take no part in conveying the current. He illustrates his theory by the discussion of the behaviour of a double molecule (KCl)₂, and adduces the existing evidence in favour of the assumption of complex molecules in pure liquids and in solution. The validity of Avogadro's law for dilute solutions he would still consider an open question. J. W.

Concordance in Atomic Weight Determinations. By F. W. CLARKE (*Amer. Chem. J.*, 13, 34—37).—Partridge, in his recent determination of the atomic weight of cadmium (this vol., p. 399), does not state the values he assumed for the atomic weights of carbon and sulphur in his calculations. Working back from his figures, the author finds the numbers taken were 12 and 32 respectively, which numbers gave as a mean, $Cd = 111.8015$, with the extreme range from lowest to highest result of only 0.075. If, however, the weights adopted by Stas, $C = 12.005$ and $S = 32.074$, be taken, the different values for cadmium, calculated from Partridge's three series of experiments, vary by nearly one-fourth of a unit, the small variations in the low atomic weights being multiplied in the higher figure. On

the other hand, if $O = 16$ be taken as the standard of comparison, and the symbols of the elements carbon and sulphur are used algebraically to represent their atomic weights, the numbers obtained in the three series of experiments may be respectively transformed into the three linear equations:—

- (i.) $36.036 \text{ Cd} = 127.928 \text{ C} + 2493.696,$
- (ii.) $30.801 \text{ Cd} = -30.801 \text{ S} + 4428.736,$
- (iii.) $28.027 \text{ Cd} = 143.946 \text{ C} - 10 \text{ S} + 4606.272,$

which may be solved without previously assuming the value of either, and give the numbers $\text{Cd} = 111.7850$, $\text{C} = 11.9958$, and $\text{S} = 32.0002$, which are independent of all errors, except those of the investigator's work, which are divided into three portions instead of being accumulated on that of cadmium (compare Strecker, *Annalen*, 59, 280). The author suggests the desirability of attempting new determinations of atomic weights which would lie between and connect the existing data. For example, in the case of cadmium, the numbers obtained by Dumas and by Huntington, on the one hand, and Partridge, on the other, differ by half a unit; the ratios $\text{CdO} : \text{CdSO}_4$, $\text{Cd} : \text{O}$, $\text{Cd} : \text{S}$, $\text{Cd} : \text{Ag}$, $\text{Cd} : \text{Cl}$, and $\text{Cd} : \text{Br}$ all seem to be capable of direct measurement, and would, if determined, check each other and the older values. A system of such interlacing ratios can be collectively discussed by the method of least squares, so as to distribute errors of observation, the constant error of any one series of data being equivalent to an accidental error in its relations to the other series. In a large system of ratios, the constant errors will tend to neutralise each other to a considerable degree, and would partially eliminate errors which are magnified and accumulated by the current methods of computation.

G. T. M.

Sulphonation of Quinoline and Phenol. By H. FULDA (*Zeit. physikal. Chem.*, 6, 490—523) —The object of the experiments detailed in this paper was that of studying other cases of non-reversible reactions similar to that investigated by Gierbach and Kessler in the nitration of benzene (*Abstr.*, 1889, 10). The sulphonation of quinoline was effected with fuming acid of varying concentrations, an acid containing no anhydride having no action on quinoline below 100° . In the case of phenol, a dilute acid was used, the action of the concentrated acid being too rapid. Both changes were studied as time reactions. The results obtained were very similar to those in the case of the nitration of benzene above mentioned. Quinoline and phenol exercise a retarding influence on the reaction between these substances and sulphuric acid similar in effect to that of the benzene in its reaction with nitric acid. Hence the simple laws of mass action do not apply to these cases, the reaction being complicated by other factors, these being probably the amount of sulphonic acid and of water formed. The course of the reaction in the case of the fuming acid is a perfectly similar one to that with the dilute acid. With the fuming acid, the anhydride alone is the active agent, the sulphuric acid serving only as a diluent, that is to say, it has the same function that water has in the case of the dilute acid.

H. C.

Inorganic Chemistry.

Hydrogen. By J. A. WANKLYN and W. J. COOPER (*Phil. Mag.* [5], 30, 431–433).—The passivity of hydrogen gas is illustrated by its remaining unaltered in presence of solutions of the following substances at the ordinary temperature:—Ferric chloride, platinic chloride, potassium ferricyanide, nitric acid (sp. gr. 1.42) with or without strong sulphuric acid, aqua regia, and chromic acid. Potassium permanganate solution, on the other hand, whether it be alkaline, acid, or neutral, is attacked by hydrogen at the ordinary temperature.

J. W.

Purification of Iodine from Chlorine. By F. MUSSET (*Zeit. anal. Chem.*, 30, 45).—The iodine is fused beneath a solution of potassium iodide sufficiently concentrated not to boil at the temperature employed. After crushing, draining, and washing, it is free from chlorine. The same solution may be used repeatedly.

M. J. S.

Utilisation of Atmospheric Oxygen. By G. KASNER (*Dingl. polyt. J.*, 278, 468–478).—The present paper is a continuation of a previous communication (*ibid.*, 274, 136) in which the author described a new process for the utilisation of atmospheric oxygen and the compounds on which the process is based.

With regard to the preparation of the calcium plumbate, further investigations have shown that, instead of heating two equivalents of calcium carbonate and one of lead oxide, it is preferable to use a slight excess of the former, say about 5 per cent. In this way, a spongy product is obtained which admits of the conversion of nearly the whole of the lead oxide into plumbate. It is more advantageous to employ limestone instead of whiting, and it has also been found unnecessary to use mechanical contrivances for keeping the mixture in the form of a powder during the heating operation. This may be effected in an ordinary or reverberatory furnace supplied with a good current of atmospheric oxygen. For the production of oxygen on a large scale, the author now recommends heating the calcium plumbate in an ordinary furnace in the presence of carbonic anhydride, when oxygen is freely given off according to the following equation:— $\text{Ca}_2\text{PbO}_4 + 2\text{CO}_2 = 2\text{CaCO}_3 + \text{PbO} + \text{O}$. It will thus be seen that by this process unlimited quantities of oxygen may be obtained from one and the same material.

The author considers his process superior to the methods of Brin and Bonssingault for the following reasons:—The formation of calcium plumbate is effected in the course of a few minutes, its decomposition by means of carbonic anhydride is complete, whilst the working expenses, cost of plant, and the value of material are extremely small.

D. B.

Selenium. By O. HINSBERG (*Annalen*, **260**, 40—52).—As selenious anhydride combines readily with aromatic orthodiamines with elimination of 2 mols. of water, experiments have been made in order to ascertain whether it behaves like an orthodiketone in other reactions; it has been found, however, that it has no other properties in common with ketones.

Selenious anhydride dissolves freely in hot acetic acid containing water, and, on cooling the solution, selenious acid is deposited in crystals having the composition H_2SeO_3 . It is only sparingly soluble in boiling acetic anhydride, from which it crystallises unchanged, but when heated with acetic anhydride at 180 — 200° , it is reduced to selenium, the anhydride being oxidised to carbonic anhydride and other compounds. When a solution of selenious anhydride in 96 per cent. alcohol is evaporated over sulphuric acid, there remains a syrup which slowly loses water and alcohol, leaving a residue of selenious anhydride. If, however, an absolute alcoholic solution of selenious anhydride is evaporated over calcium chloride, large, transparent, quadratic plates, having the composition $\text{SeO}_3 \cdot \text{C}_2\text{H}_6\text{O}$, are deposited; these crystals lose their alcohol over sulphuric acid.

When selenious anhydride is treated with phenylhydrazine or with phenylhydrazinesulphonic acid under various conditions, it is reduced to selenium; hydroxylamine has the same action. Selenium tetrachloride reacts energetically with phenylhydrazine in benzene solution, the products being selenium, phenylhydrazine hydrochloride, and a thick, liquid oxidation product of the hydrazine.

A crystalline compound, which is probably impure *selenious cyanide*, $\text{Se}_2(\text{ON})_2$, is formed when powdered selenious anhydride (1 mol.) is heated at 100° with anhydrous hydrogen cyanide (about 6 mols.) and acetic anhydride (2 to 3 mols.) in sealed tubes until solution is complete. On evaporating the solution over potassium hydroxide, the product is deposited in yellowish crystals which, under the microscope, are seen to consist of brownish plates mixed with a few needle-shaped crystals; the two kinds of crystals could not be separated. It is readily decomposed by warm alcohol, water, dilute acids, and alkalis, yielding selenium, selenious acid, and hydrocyanic acid or a cyanide; it has an intensely disagreeable smell, and its vapours are very poisonous.

Aniline selenite, $\text{H}_2\text{SeO}_3 \cdot \text{C}_6\text{H}_5 \cdot \text{NH}_2$, is precipitated in crystals when an absolute alcoholic solution of selenious anhydride (1 mol.) is mixed with an ethereal solution of aniline (2 mols.) and then a little water added; it crystallises from water, in which it is readily soluble, in colourless needles, and melts at 95° . It is completely decomposed by water at 100 — 110° , yielding an amorphous, dark-blue substance which contains selenium, carbon, hydrogen, and nitrogen, and is insoluble in all solvents except concentrated sulphuric acid, from which it is reprecipitated on the addition of water.

Selenious anhydride seems not to combine with carbamide, but it reacts readily with phenyl mercaptide, yielding phenyl bisulphide and a selenium compound, the nature of which could not be determined.

The author is of the opinion that, in order to account for the

stability of piaselele derivatives, it must be assumed that the piaselele nucleus has the constitution

F. S. K.

The Discovery of Nitrogen Hydride, Azoimide. By D. MENDELÉEFF (*Ber.*, **23**, 3464—3472).—The preparation of nitrogen hydride, azoimide (Curtius, this vol., p. 56), and the preparation of nickel carbon monoxide (Mond, Langer, and Quincke, *Trans.*, 1890, 749) must be ranked amongst the most important chemical discoveries of last year. Although the author never published any statement with reference to the compound recently described by Curtius, the possibility of its existence was nevertheless foreseen by him, in consequence of certain views he held regarding nitriles, these views having been advanced in a paper communicated to the first congress of Russian naturalists in 1867, and also in his *Principles of Chemistry* (1868—1870).

The publication of these views at the present time may, perhaps, help to explain the structure of nitrogen hydride, and to indicate its position among the other known compounds of nitrogen, possibly also to point out reactions and new methods by which this interesting acid may be prepared, and in this way throw some light on the nature of the metallic compounds of nitrogen.

When an element R combines with univalent elements X, to form a compound of the formula RX_n , the corresponding salt-forming hydrate has the composition $RO\frac{n}{2}(OH)_{4-n}$, in which, however, the total number of oxygen atoms is never more than four; this statement is based on conclusions drawn from a study of the periodic system, in accordance with which the relationship between the composition of the hydride and that of the higher salt-forming oxides on the one hand, and between the composition of the hydrates and that of the hydrogen compounds on the other, in the case of any element, may be expressed as follows:—(1) The sum of the valencies of the hydrogen and oxygen atoms (in the highest salt-forming oxides) which can combine with any element is equal to eight; (2) the number of oxygen atoms in the highest salt-forming hydrates is four; and as a consequence of the first two conclusions (3), the greatest quantity of hydrogen in the salt-forming hydroxides is not greater than that in the hydride of the element, when the hydride is a gaseous compound of the formula RH_n .

It is evident, therefore, firstly, that an element R, which, like nitrogen, for example, forms compounds of the composition RH_3 and R_2O_3 , or in general RX_3 and RX_5 , cannot form a salt-forming hydrate of the formula $R(OH)_3$, although the compound $R(OH)_3$ is capable of existence. Secondly, that even the highest hydrate RH_4O_4 may lose a part of its water, forming incomplete hydrates such as $H_3PO_4 = PO(OH)_3$, $H_2P_2O_7 = [PO(OH)_2]_2O$, and $PO_2(OH)$. Thirdly, that the forms of the normal ammonium salts of any element must

correspond with the hydrates of the element, and, consequently, may contain oxygen atoms other than those which unite the ammonium radicals to the element R; the compounds $\text{NO}_2(\text{ONH}_4)$, $\text{SO}_2(\text{OH})(\text{ONH}_4)$, $\text{CO}(\text{OH})(\text{ONH}_4)$, $\text{CO}(\text{ONH}_4)_2$, $\text{COH}(\text{ONH}_4)$, &c., may be quoted as examples of substances of this nature.

When such ammonium salts as these lose the elements of water, amides are formed in the first place by the elimination of water from the ONH_4 group; when the amides themselves lose the elements of water, a process which can only take place in the case of those derived from ammonium salts of the type given above, which contain excess of oxygen, nitriles are formed; ammonium hydrogen sulphate, for example, would first yield the amide $\text{SO}_2(\text{OH})\cdot\text{NH}_3$, and then the nitrile SO_2HN .

Now, since nitrogen and phosphorus form the compounds NH_3 and PH_3 respectively, their highest possible hydrates are the following:—

Meta-: $\text{N}_2\text{O}_5, \text{H}_2\text{O}$ and $\text{P}_2\text{O}_5, \text{H}_2\text{O} = 2\text{PO}(\text{OH})_2 - 2\text{H}_2\text{O}$.

Pyro-: $\text{N}_2\text{O}_5, 2\text{H}_2\text{O}$ „ $\text{P}_2\text{O}_5, 2\text{H}_2\text{O} = 2\text{PO}(\text{OH})_2 - \text{H}_2\text{O}$.

Ortho-: $\text{N}_2\text{O}_5, 3\text{H}_2\text{O}$ and $\text{P}_2\text{O}_5, 3\text{H}_2\text{O} = 2\text{PO}(\text{OH})_3$.

The complete hydrates, on the other hand, as, for example, $\text{N}_2\text{O}_5, 5\text{H}_2\text{O} = 2\text{N}(\text{OH})_5$, are unstable compounds, which are usually regarded simply as solutions; the ortho- and pyro-hydrates of nitric acid must also be regarded as unstable compounds, whereas the corresponding derivatives of phosphorus have long been looked on as distinct and definite hydrates, on account of the existence of the corresponding salts. As, on the other hand, in its basic mercury and lead salts, nitric acid shows a tendency to form ortho-salts, the fact that nitrogen compounds analogous to disodium hydrogen phosphate, $\text{PO}(\text{OH})(\text{ONa})_2$, cannot be easily produced, is simply one of the peculiarities which distinguish nitrogen from phosphorus, and which show the relative stability of phosphoric anhydride and ammonia compared with nitric anhydride and hydrogen phosphide, PH_3 . It may, therefore be considered as probable that, in addition to the meta-, or ordinary, ammonium nitrate, $\text{NO}_2\cdot\text{ONH}_4$, the pyro- and ortho-compounds, or the di- and tri-ammonium nitrate,

$\text{NO}(\text{OH})(\text{ONH}_4)_2$ and $\text{NO}(\text{ONH}_4)_3$,

and the corresponding amido- or anhydro-derivatives $\text{NO}_2(\text{ONH}_4)\text{NH}_2$ and $\text{NO}_2(\text{ONH}_4)_2\text{NH}_2$ are capable of existence. Both these anhydro-compounds have, in fact, been prepared by Divers (this Journal, 1873, 598), who considered them as solutions in which the tendency of ammonium nitrate to liquefy anhydrous ammonia is exhibited; but, in the following year, Raoult proved that the liquid produced in this way has a definite composition, $\text{NO}_2(\text{ONH}_4)_2\text{NH}_3$, and that between -10° and $+28^\circ$, it is decomposed into a definite solid compound of the composition $\text{NO}_2(\text{ONH}_4)\text{NH}_3$, which, in its turn, is readily dissociated on warming with liberation of ammonia.

These compounds, then, the existence of which was rendered probable from the conclusions arrived at above, correspond with the incomplete hydrates of (ortho-, meta-, and pyro-) nitric acid,

and must, therefore, to a certain extent, have an amide-like nature, in which case it is to be expected that they would be converted into nitriles by further loss of the elements of water. Assuming that the elimination of water takes place as completely as possible, then, just as ammonium nitrate is converted into the nitrile, nitrous oxide, the compound $\text{NH}_4\text{NO}_2\text{NH}_2$ would yield the nitrile N_2H_4 , and the compound $\text{NH}_4\text{NO}_3\cdot 2\text{NH}_3$ the nitrile N_4H_4 ; the second of these nitriles is Curtius' nitrogen hydride, the third is its ammonium salt N_4NH_4 .

As regards the properties of nitrogen hydride, which, at the first consideration, seem to be very unexpected, it can be shown that they are capable of easy explanation. The simplest, and at the same time the most plausible, view of the conversion of ammonium salts into amides and nitriles consecutively is, that, in the first place, the elements of water are eliminated solely at the expense of the ONH_4 group; it is in this way that all acid-amides are produced. When, however, the oxygen of the ONH_4 and OH groups has been taken away, any further loss of water can only take place by the combination of the hydrogen of the amido group with the oxygen of the acid radicle, as is the case, for example, in the formation of HCN from $\text{H}\cdot\text{CO}\cdot\text{NH}_2$.

If these arguments are borne in mind in considering the formation of hydrogen nitride, it is clear that it may be regarded as derived from the di-ammonium salt of orthonitric acid,

by the elimination of 4 mols. of water. The resulting compound NHNN contains two nitrogen atoms originally belonging to ammonium groups, and only one which belongs to the nitric acid molecule; whilst the hydrogen atom also belongs to the elements of nitric acid, and must, in consequence, possess the same character as in acids, not as in ammonia; considering also the energetic acid nature of nitric and nitrous acid, compared with carbonic acid, for example, and the position of nitrogen in the periodic system, which assigns to it more marked acid-forming properties than carbon, it follows that the nitrile, hydrogen nitride, must have a distinctly acid character. This conclusion is based on the fact that hydrogen cyanide, the nitrile of formic acid, has a distinctly acid character, notwithstanding that the hydrogen atom of the nitrile, when forming a component of the molecule of formic acid, is not replaceable by metals, and that it is subject to the influence of carbon, a feebler acid-forming element than nitrogen. The hydrogen atom in hydrogen cyanide must owe its acid character to the influence of the nitrogen and the carbon atom, and since the hydrogen atom in nitrogen hydride is in combination with nitrogen only, which is so decidedly an acid-forming element, it must have the properties of an acid.

Now, if nitrogen hydride is in reality a nitrile, it should, like the cyanogen compounds, have many peculiar properties; as, up to the present time, it has been but little investigated, it may be of interest to predict a few of the properties which, on further examination, nitrogen hydride may be found to show. It is probable, for example,

that the ammonium salt N_3NH_4 , which seems to be an asymmetrical compound, and, to a certain extent, analogous to ammonium cyanate, will undergo intramolecular change under suitable conditions, perhaps on warming its solution, and be converted into the symmetrical amide $N(NH_2)N(NH_2)$, the amido-nitrile of triammonium orthonitrate. Again, it is probable that if nitrogen hydride should form a double salt with iron and potassium, this compound will give rise to a series of characteristic, coloured salts, which would be analogous to the salts of hydroferrocyanic acid, and also to a series of compounds of the composition Fe_nN_{3n} , corresponding with Prussian blue, which, if capable of existence in the dry state, would, doubtless, be highly explosive. As regards the capability of forming polymerides, it may be assumed that the behaviour of hydrogen nitride and its derivatives is already indicated by the behaviour of the analogous phosphorus compounds, such as chlorophosphamide, $P_3N_3Cl_6$, and phospham; the latter is probably a polymeride of the composition $(PHN_2)_n$, and not the next analogue of nitrogen hydride, and it was, in fact, a consideration of this view of its nature which led the author to foresee the existence of nitrogen hydride. Preparation of Hydrogen Phosphide. By R. LÜPKE (*Chem. Centr.*, 1890, ii, 642—643; from *Zeit. f. physikal. und chem. Unterricht.*, 3, 280—289).—Tin and zinc phosphides are prepared by adding the equivalent quantity of amorphous phosphorus to the respective metals in the molten state covered with ammonium carbonate (?). Iron phosphide, FeP , by heating finely divided iron and amorphous phosphorus together; copper phosphide, by heating copper filings with amorphous phosphorus; magnesium phosphide, by adding the equivalent quantity of amorphous phosphorus to melted magnesium; sodium phosphide, by carefully adding yellow phosphorus to fused sodium under petroleum. The phosphides of tin, zinc, iron, and copper are not decomposed by water; whilst those of sodium and magnesium, like that of calcium, are decomposed by water. From magnesium phosphide, whether decomposed by water or by dilute hydrochloric acid, non-spontaneously inflammable hydrogen phosphide is obtained. From sodium phosphide, spontaneously inflammable hydrogen phosphide is obtained, which, in a great measure, readily changes to solid phosphide. The phosphides of tin and zinc are decomposed by cold dilute hydrochloric or sulphuric acid, but those of iron and copper are but slightly attacked even on boiling.

For the preparation of hydrogen phosphide from the phosphides of tin, zinc, or magnesium, an Erlenmeyer flask of 200–300 c.c. capacity is fitted with a stopper carrying three tubes; the one conducts carbonic anhydride gas to the bottom of the flask to displace the air, the second admits the dilute acid from a tap-funnel, the third is the delivery tube. To the latter is attached a tube, filled with glass wool, from which the gas passes out into nitric acid in a dish. In the case of tin phosphide, the flask is warmed gently on the water-bath at the commencement, after which the reaction proceeds regularly for thirty minutes to one hour, when, as the reaction becomes slower, the flask may be again warmed. In the case of zinc or magnesium phos-

phides, no external heating is requisite. The method is preferable to the preparation with potassium hydroxide and phosphorus or to that with calcium phosphide, and demonstrates the formation of the phosphide of hydrogen in analogous manner to the other compounds of hydrogen with the non-metals, ammonia excepted. The preparation of zinc phosphide is also especially recommended as being simple. The synthesis of hydrogen phosphide may be shown by putting sodium phosphite or hypophosphite into a hydrogen generator, when the phosphide is readily detected in the gas evolved. J. W. L.

Combination of Ammonia with Phosphorus Chlorides and Bromides. By A. BESSON (*Compt. rend.*, 111, 972—974).—Phosphorus trichloride combines with dry ammonia with development of heat and formation of a white solid to which Persoz gave the formula $\text{PCl}_3 \cdot 4\text{NH}_3$, and Rose the formula $\text{PCl}_3 \cdot 5\text{NH}_3$. The author's analyses confirm Rose's formula.

Ammonia acts very energetically on phosphorus pentachloride with formation of a considerable quantity of ammonium chloride, resulting most probably from the partial dissociation of the pentachloride in consequence of the great development of heat. If, however, the pentachloride is dissolved in carbon tetrachloride and dry ammonia is slowly passed into the solution, care being taken to avoid elevation of temperature, a white substance separates, which is somewhat stable in air and even when heated at 200° ; it has the composition $\text{PCl}_3 \cdot 8\text{NH}_3$. Phosphorus pentabromide, under the same conditions, yields a compound which is precisely similar in appearance, but has the composition $\text{PBr}_3 \cdot 9\text{NH}_3$.

The action of phosphorus trichloride on phosphine at the ordinary temperature produces the solid hydride P_2H_4 , and not phosphorus as Rose stated. This reaction, in fact, affords a convenient process for the preparation of this hydride in a pure state. The reaction does not take place at -20° , but the trichloride absorbs a considerable quantity of phosphine, and when the liquid returns to the ordinary temperature, the solid hydride is formed. Phosphorus tribromide behaves in a similar manner, but the reaction proceeds even at -20° . C. H. B.

Preparation of Pure Phosphoric Acid. By M. NICOLAS (*Compt. rend.*, 111, 974—975).—Powdered calcium phosphate is added gradually to a slight excess of commercial hydrofluoric acid diluted with an equal volume of water, and contained in a leaden or platinum vessel. There is considerable development of heat, and the liquid must be thoroughly agitated. When the action moderates, the liquid is gently heated, water being added to make up for loss by evaporation. When the liquid becomes viscous, the excess of hydrogen fluoride begins to escape, and the mixture is then heated until the expulsion of the acid is complete. The syrupy liquid thus obtained contains from 60 to 70 per cent. of phosphoric anhydride in the form of orthophosphoric acid. With pure materials, the phosphoric acid obtained is very pure; if bones and ordinary acid have been used, the product must be heated to carbonise the organic

matter, dissolved in water, filtered, and again evaporated. Pyrophosphoric and metaphosphoric acids can be obtained by evaporating at higher temperatures.

If hydrofluoric acid is added drop by drop to a large excess of powdered calcium phosphate, and the product is extracted with warm water, the solution, on evaporation, leaves a residue containing the various salts described by Erlenmeyer. C. H. B.

Redetermination of the Atomic Weight of Cadmium. By E. A. PARTRIDGE (*Amer. J. Sci.* [3], 40, 377—384).—The purification of the cadmium was effected by distillation in a vacuum in tube retorts of glass, about 300 mm. in length and 20—25 mm. in diameter. About 100 grams of cadmium was distilled until 60 grams had passed over, and the distillate was again distilled until about one-half had passed over. The residue in the first distillation when examined spectroscopically was found to contain lead, iron, thallium, a little copper, and traces of zinc; the residue from the second distillation was found to be entirely free from these impurities. All the cadmium used in the investigation was purified in this manner by double distillation.

Three methods were used for determining the atomic weight.

I. Cadmium oxalate was converted into the oxide by heating. Care must be taken that the temperature does not become too high, or reduction or volatilisation of the metal takes place.

II. Cadmium sulphate was converted into sulphide by heating in a current of hydrogen sulphide. The sulphate was weighed in stoppered glass tubes to prevent the absorption of water; the hydrogen sulphide was obtained from antimony sulphide, and was therefore free from hydrogen, and it was ascertained that cadmium sulphide is non-volatile when heated.

III. Cadmium oxalate was converted into sulphide by heating in a current of hydrogen sulphide. This change takes place at a temperature much below that which is required to convert the salt into oxide.

The results obtained were as follows:—

I.	Mean of 10 experiments,	111.8027.	Probable error,	0.010.
II.	"	111.7969.	"	0.008.
III.	"	111.8050.	"	0.009.

Regarding each series as of equal value, the mean of the three series gives 111.8015 as the atomic weight of cadmium, with $O = 16$. (Compare Clarke, this vol., p. 390). H. C.

Cuprammonium Bromides. By T. W. RICHARDS (*Ber.*, 23, 3790—3791).—By the action of dry ammonia on cupric bromide, a blue powder is obtained, which readily loses part of its ammonia in the air, and has the composition $\text{CuBr}_2 \cdot 6\text{NH}_3$, and not $\text{CuBr}_2 \cdot 5\text{NH}_3$, as given by Rammelsberg (*Ann. Phys. Chem.*, 55, 246). It corresponds therefore in composition with the chlorine compound, and may be termed *tetrammonocuprammonium bromide*. It is soluble in small quantities of water, but on dilution, cupric hydroxide separates.

On exposure to the air, it readily loses ammonia, forming an olive-green powder; this takes place even more easily on heating, the substance becoming quite green at 165° even in an atmosphere of ammonia. It then has the composition $\text{CuBr}_2 \cdot 2\text{NH}_3$, and corresponds with the "apple-green" chlorine compound. It readily absorbs ammonia, again becoming blue, and may be heated to 200° without alteration, but at higher temperatures it decomposes, forming copper and ammonium bromides, &c. It dissolves in aqueous ammonium bromide without decomposition, and may seemingly be recrystallised from this liquid. Similar crystals may be obtained by cautious addition of ammonia to a mixture of cupric and ammonium bromides.

H. G. C.

Mercury Arsenates and Phosphates. By K. HAACK (*Chem. Centr.*, 1890, ii, 736—737; from *Inaug. Diss. Halle*, 1890).—*Mercuric arsenate*, $\text{Hg}_3(\text{AsO}_4)_2$, is prepared by adding a solution of mercuric nitrate to one of disodium arsenate. It is a lemon-yellow powder, very slightly soluble in water, readily soluble in hydrochloric acid, sparingly soluble in nitric acid, insoluble in arsenic acid.

Mercuric phosphate, $\text{Hg}_3(\text{PO}_4)_2$, is prepared by adding a strongly acid solution of mercuric nitrate to one of disodium phosphate. It is a white salt, neutral to litmus, readily soluble in hydrochloric acid, but insoluble in phosphoric acid. From a neutral solution of mercuric nitrate, the salt is precipitated with admixture of normal or basic mercuric nitrate.

From solutions of mercuric chloride, disodium arsenate precipitates the mercuric arsenate mixed with oxychloride. From solution of mercuric chloride, disodium phosphate causes a reddish-brown precipitate of the composition $\text{HgCl}_2 + 2\text{Hg}_2\text{O}$, which contains a little disodium phosphate. By boiling basic mercuric sulphate with solution of disodium arsenate, a mixture of normal mercuric arsenate and mercuric oxide is formed, from which the latter may be removed by boiling acetic acid; an analogous reaction takes place with disodium phosphate. Mercuric iodide does not react with either of the sodium salts; mercuric oxide does not react either with the free acids or the salts. The double mercuric nitrate and sulphide does not react with the sodium salts in the cold, but on heating, mercuric sulphide is precipitated.

Mercurous nitrate (in excess) forms a double salt with disodium arsenate, of the formula $3\text{Hg}_2\text{A} \cdot \text{O}_4 + 2(\text{HgNO}_3 + \text{Hg}_2\text{O})$. If the arsenate is in excess, the normal mercurous arsenate, Hg_2AsO_4 , an orange-coloured amorphous powder, is formed. With disodium phosphate, analogous compounds are produced; the double salt contains, however, basic mercurous nitrate.

For the determination of nitric acid in the presence of arsenic and phosphoric acids and mercury, these were precipitated with excess of barium hydroxide, the excess of the precipitant was then separated with carbonic anhydride, and the nitric acid calculated from the amount of barium remaining in the solution.

J. W. L.

Ultramarine. By J. HEINTZE (*J. pr. Chem.* [2], 43, 98—105).—The claim of Kötting, the director of the laboratories of the Königl.

Porzellan-Manufactur in Meissen, as a discoverer of artificial ultramarine, has been overlooked, and mention of him is omitted from chemical literature; yet Köttig's discovery occurred in the spring of 1828, which was the very time when Gmelin and Guimet were disputing as to priority. The manufacture at Meissen is now abandoned, but, as the ultramarine emanating therefrom had a higher value, and was in greater demand than many other products, the author considers that an exact description of the process of manufacture adopted at these works will prove of value. As success depends on details, it is obvious that a short abstract of the process followed would be of little value.

A. G. B.

Removal of Gold from Suspension and Solution by Fungoid Growths. By A. LIVERSIDGE (*Chem. News*, 62, 277—279, 290—291).—In various bottles of distilled water holding in suspension gold reduced from the chloride by phosphorus in ether, and which had been in the dark for years, it was observed that the gold had only settled completely in those bottles in which fungoid growths had formed, and in such cases the metallic gold was easily detected in the growths. Various experiments were instituted to investigate the matter, and a solution of sodium aurochloride was exposed in the light to the action of various growths, such as those usually met with in solutions of potassium acetate, citric acid, oxalic acid, magnesium sulphate, and potassium tartrate, also cheese and banana moulds and bread, and other organic matter, all of which not alone removed gold in suspension but also from solution. The growths do not form in the presence of carbon bisulphide, chloroform, benzene, or turpentine, neither did the oxalic acid mould thrive or act.

D. A. L.

Ammoniacal Derivatives of Ruthenium Nitrosochloride. By A. JOLY (*Compt. rend.*, 111, 969—972; compare (*Abstr.*, 1889, 352, 678, 948).—When the chloride $\text{OH}\cdot\text{RuCl}_3\cdot\text{NO}\cdot 4\text{NH}_3$ is mixed with a large quantity of acid and evaporated by heat, it becomes turbid and deposits a red powder, only slightly soluble in water. The product can be dissolved in boiling water, and separates in small, very dense, orange-coloured crystals of the composition $\text{RuCl}_3\cdot\text{NO}\cdot 4\text{NH}_3$. The corresponding bromine and iodine derivatives are obtained in a similar manner. With platinum chloride, a solution of the trichloride yields a very dense, crystalline precipitate of the platinochloride, $\text{RuCl}_3\cdot\text{NO}\cdot 4\text{NH}_3\cdot\text{PtCl}_4$.

The strongly acid liquid from which the trichloride has separated has the colour of potassium dichromate, and when allowed to evaporate spontaneously deposits long, red or orange-red, monoclinic prisms of $105^\circ 54'$. They have the composition $\text{RuCl}_3\cdot\text{NO}\cdot 4\text{NH}_3\cdot 2\text{H}_2\text{O}$, are very soluble in cold water, and differ from the trichloride in being acid to methyl-orange. The compound is, therefore, most probably not merely a hydrate of the trichloride, but is a hydrochloride of a hydroxy-dichloride, $\text{OH}\cdot\text{RuCl}_2\cdot\text{NO}\cdot 4\text{NH}_3\cdot\text{HCl} + \text{H}_2\text{O}$. When heated, it loses water and hydrogen chloride, and is partially converted into the trichloride. If the solution is evaporated, some trichloride separates, and the conversion becomes complete on evaporation to

dryness. Platinum tetrachloride gives a yellow, crystalline precipitate of the platinumchloride, $\text{OH}\cdot\text{RuCl}_2\cdot\text{NO}\cdot 4\text{NH}_3\cdot\text{PtCl}_4$.

By double decomposition with silver nitrate, the salt $\text{RuCl}_2\cdot\text{NO}\cdot 4\text{NH}_3$ yields the nitrate $\text{Ru}(\text{NO}_3)_2\cdot\text{NO}\cdot 4\text{NH}_3$, more soluble than the nitrate $\text{OH}\cdot\text{Ru}(\text{NO}_3)_2\cdot\text{NO}\cdot 4\text{NH}_3$ previously described. The same product is obtained by evaporating either of the chlorides to complete dryness with excess of nitric acid. If the liquid is merely boiled with excess of the acid for some time, it becomes red, and deposits crystals of an acid salt $\text{OH}\cdot\text{Ru}(\text{NO}_3)_2\cdot\text{NO}\cdot 4\text{NH}_3 + \text{HNO}_3$.

The sulphates are more complex, and their number is greater in consequence of the formation of acid salts and of hydrates. They all crystallise well, but some decompose readily when redissolved in water. When the trichloride or hydroxy-dichloride is evaporated with a slight excess of sulphuric acid, and the product is allowed to crystallise from the acid liquid, the acid sulphate, $(\text{RuNO}_2\cdot 4\text{NH}_3)_2(\text{SO}_4)_6 + \text{H}_2\text{SO}_4 + \text{Aq.}$ is obtained in small yellow or orange-yellow needles. This salt decomposes in presence of a small quantity of cold water, leaving a pink residue, which dissolves with difficulty in boiling water, forming a solution which is neutral to methyl orange. When the solution cools, the salt $(\text{RuNO}_2\cdot 4\text{NH}_3)_2(\text{SO}_4)_3 + 10\text{H}_2\text{O}$ separates in slender, nacreous needles, but if the solution is boiled for a long time it deposits a sulphate corresponding with the hydroxy-dichloride. The sulphate, $\text{OH}\cdot\text{RuSO}_4\cdot\text{NO}\cdot 4\text{NH}_3 + \text{H}_2\text{O}$, has previously been described; when crystallised in presence of a slight excess of sulphuric acid, it is converted into orange-red crystals of the acid sulphate,

and this when heated is partially converted into the sulphate corresponding with the trichloride.

All these new compounds in ammoniacal solution yield the hydroxy-dichloride $(\text{Cl}_2\cdot\text{OH})$, or the corresponding sulphate or nitrate. When heated with aqueous potash, ammonia is evolved, and the nitroso-hydroxide, $\text{Ru}(\text{OH})_2\cdot\text{NO}$, forms and dissolves in excess of alkali. When this solution is saturated with hydrogen chloride, the salt $\text{RuCl}_2\cdot\text{NO}\cdot 2\text{KCl}$ separates. It is clear that the group NO is very intimately united to the ruthenium.

C. H. B.

Iridioammonium Compounds. By W. PALMAER (*Ber.*, 23, 3810—3819).—The author has previously shown (*Abstr.*, 1889, 352) that three different series of iridioammonium compounds may be obtained. The present paper gives a more detailed description of those compounds containing 5 molecules of ammonia to 1 atom of iridium, which correspond with the "purpureo-" compounds of cobalt, chromium, and rhodium. As, however, the iridium derivatives are pale-yellow, the name "purpureo-" is unsuitable for them, and the term pentamine-compounds is therefore employed.

Iridiumpentamine trichloride, $\text{Ir}(\text{NH}_3)_5\text{Cl}_3$, is obtained by the action of ammonia on iridium trichloride or tetrachloride or their double salts, in the form of wine-red crystals; if it is prepared from the chlorosulphate by the action of barium chloride, the crystals obtained are yellow, the red colour of the first being due to a slight admixture

of ammonium iridiochloride. Both varieties give exactly the same measurements. It crystallises in the rhombic system ($a : b : c = 0.9873 : 1 : 1.5527$), and is isomorphous with the corresponding cobalt and rhodium compounds. It has a sp. gr. of 2.68 at 15.3° , dissolves in 153.1 parts of water at 15.1° , and is not altered on heating at 275° . As with the other "purpureo-" salts, one atom of chlorine is more firmly combined than the other two, and is not removed by cold sulphuric acid or cold silver nitrate solution.

Iridiumpentamine chlorosulphate, $\text{Ir}(\text{NH}_3)_5\text{ClSO}_4 + 2\text{H}_2\text{O}$. The preparation of this salt has already been described (*loc. cit.*). If, after treating the chloride with sulphuric acid, water is added, a precipitate of slender, matted needles separates on cooling, which probably consists of the *acid sulphate*. These redissolve on warming, and the normal salt is then precipitated on the addition of alcohol. The latter forms small, strongly refractive, monosymmetric crystals ($a : b : c = 1.1984 : 1 : 0.74831$; $\beta = 84^\circ 48\frac{1}{2}'$), has a sp. gr. of 2.551 at 15.2° , and dissolves in 134.5 parts of water at 15° .

Iridiumpentamine chlorobromide, $\text{Ir}(\text{NH}_3)_5\text{ClBr}_2$, obtained by decomposing the chlorosulphate with the theoretical quantity of barium bromide, forms pale-yellow, rhombic crystals

$$(a : b : c = 0.98765 : 1 : 1.5236),$$

dissolves in 213.6 parts of water at 15° , and has a sp. gr. of 3.007 at 16° . The *chloriodide*, $\text{Ir}(\text{NH}_3)_5\text{ClI}_2$, obtained in a similar manner, forms brownish-yellow, rhombic crystals ($a : b : c = 0.9424 : 1 : 1.4220$), soluble in 104.5 parts of water at 15° , and having a sp. gr. of 3.118 at 15.6° . The *chloronitrate*, $\text{Ir}(\text{NH}_3)_5\text{Cl}(\text{NO}_3)_2$, dissolves in 51.54 parts of water at 15° , and has a sp. gr. of 2.404 at 15.4° . The *chloronitrite*, $\text{Ir}(\text{NH}_3)_5\text{Cl}(\text{NO}_2)_2$, obtained from the trichloride by treating it with the theoretical quantity of silver nitrite, crystallises in large, pale yellow, rhombic prisms ($a : b : c = 0.9651 : 1 : 0.5350$), is readily soluble and has a sp. gr. of 2.519 at 16.8° . The *chloroxalate*, $\text{Ir}(\text{NH}_3)_5\text{ClC}_2\text{O}_4$, forms slender, white, sparingly soluble needles, and the *platinochloride*, $\text{Ir}(\text{NH}_3)_5\text{ClPtCl}_6$, a heavy, orange-yellow precipitate, which is very sparingly soluble in water, and consists of microscopic, almost rectangular, tablets.

A solution of the chloronitrate gives precipitates with solutions of a large number of salts, amongst which may be mentioned potassium iodide, ferrocyanide, and dichromate, ammonium oxalate, barium dithionate, and mercuric chloride. Silver nitrate and sodium phosphate give no precipitate. The solution of the trichloride gives a precipitate of the platinochloride with platinic chloride and sulphuric acid, whilst gold chloride gives a precipitate of lustrous, garnet-red, rhomboidal prisms. Aqua regia resolves the trichloride into iridium tetrachloride and ammonium chloride, the latter being, for the most part, further decomposed; if chlorine gas be passed into the cold aqueous solution of the chloride, this assumes a colour similar to that of potassium permanganate, which disappears in daylight, the solution becoming brown. Further addition of chlorine, or shaking with alcohol and ether, renews the colour for a short time.

The above reactions agree closely with those of the corresponding

cobalt, chromium, and rhodium compounds, with the exception that rhodiumpentamine trichloride is not attacked by chlorine. A further difference in the compounds of these two metals is shown in the behaviour of the chlorine atom combined directly with the metal, which is much more readily displaced in the case of the rhodium salt.

To obtain *iridiumpentamine tribromide*, $\text{Ir}(\text{NH}_3)_5\text{Br}_3$, it is necessary to heat the chloride with water and soda or silver oxide for several hours, which probably yields a mixture of the roseochloride and roseohydroxide, and to treat the product with concentrated hydrobromic acid. It forms yellow, well-developed, rhombic crystals ($a : b : c = 1.0254 : 1.16086$), dissolves in 352 parts of water at 12.5° , and has a sp. gr. of 3.246 at 16.7° . The *bromonitrite*, $\text{Ir}(\text{NH}_3)_5\text{Br}(\text{NO}_2)_2$, crystallises in thick, pale-yellow prisms, soluble in 17.9 parts of water at 18° , the solution having an alkaline reaction. Its sp. gr. is 2.733 at 13.5° . The *bromosulphate*, $\text{Ir}(\text{NH}_3)_5\text{BrSO}_4 + \text{H}_2\text{O}$, is obtained by triturating the foregoing salt with an excess of sulphuric acid. On adding water and cooling, slender, matted needles separate, which probably consist of the acid sulphate, and are converted into the normal salt by redissolving and precipitating with alcohol. This forms small, lustrous, yellow tablets, which lose their water of crystallisation at 100° .
H. G. C.

Mineralogical Chemistry.

Pinakiolite and Trimerite, new Swedish Minerals. By G. FLINK (*Zeit. Kryst. Min.*, 18, 361—376).—1. *Pinakiolite*.—This mineral was found by the author at Långbanshyttan, in Wermland, with hausmannite in granular limestone. As it always occurs in small, tabular crystals, the name of pinakiolite is suggested, from *πίναξ* (small table) and *λίθος* (stone). The sp. gr. of the mineral is 3.681, and its hardness is 6. It is very brittle, and gave on analysis the following results:—

B_2O_3	MgO.	Mn_2O_3	Fe_2O_3	CaO.	PbO.	SiO_2	H_2O	Total.
15.65	28.58	49.39	2.07	1.09	0.76	1.21	0.47	99.22

The formula is $(\text{MgO})_3\text{B}_2\text{O}_3\text{MnO.Mn}_2\text{O}_3$. Pinakiolite belongs to the rhombic system. It is quite black in colour, and has a strong metallic lustre. In composition it resembles ludwigite.

2. *Trimerite*.—This mineral was found by the author in the Harstigs mine, in Wermland, and is named from *τριμής* (divided in three) in reference to the form of the crystals. It occurs in granular limestone, in crystals always surrounded by calcite. Its sp. gr. is 3.474, and its hardness is 6 to 7. On analysis, it yielded:—

SiO_2	BeO.	MnO.	FeO.	CaO.	MgO.	Total.
39.77	17.08	26.86	3.87	12.44	0.61	100.63

Its formula is $(\text{Mn}, \text{Be})\text{SiO}_4$. The mineral crystallises apparently in the hexagonal system. Its optical properties, however, prove that it must be regarded as being composed of asymmetric individuals grouped together in a mimetic manner. B. H. B.

Synthesis of Kainite and Tachhydrite. By A. DE SCHULTEN (*Compt. rend.*, 111, 928—930).—A solution of 500 grams of magnesium chloride, 40 grams of potassium sulphate, and 56 grams of crystallised magnesium sulphate is evaporated on a water-bath. When the solution is sufficiently concentrated, small crystals of kainite separate, and can be freed from magnesium chloride and from carnallite by washing with absolute alcohol. An excess of magnesium sulphate helps to prevent the formation of carnallite, but gives a product containing a slight excess of magnesium. One sample of crystals had the composition—

SO_3	MgO	Cl	K	H_2O	Total
33.80	17.17	14.03	15.09	20.50	100.09

which agrees closely with the formulæ $\text{KCl}, \text{MgSO}_4, 3\text{H}_2\text{O}$ or $\text{K}_2\text{SO}_4, \text{MgSO}_4, \text{MgCl}_2, 6\text{H}_2\text{O}$. Water decomposes the crystals rapidly, magnesium chloride passing into solution, whilst picromerite, $\text{K}_2\text{SO}_4, \text{MgSO}_4, 6\text{H}_2\text{O}$, separates in microscopic crystals. Artificial kainite forms tabular, monoclinic crystals with hexagonal or quadratic contours; sp. gr. 2.120 at 15° , that of the natural mineral being 2.151. Details of the measurements of the crystals are given.

Tachhydrite, $\text{CaCl}_2, 2\text{MgCl}_2, 12\text{H}_2\text{O}$, is obtained in large, but extremely deliquescent crystals, by the evaporation of a solution containing 200 grams of anhydrous calcium chloride and 150 grams of crystallised magnesium chloride. The crystals are rhombohedrons, and their composition agrees closely with that of the mineral; sp. gr. 1.666 at 15° , that of the mineral being 1.671. O. H. B.

Castanite. By L. DARAPSKY (*Jahrb. f. Min.*, 1890; ii, Ref. 267—269).—In a specimen of crystallised iron sulphates, from Sierra Gorda, in Chili, the author thought, at first, that he detected the mineral described by Frenzel as hohmannite (*Abstr.*, 1890, 456). Closer investigation proved, however, that this was a new ferric sulphate, which the author terms castanite. It crystallises in prismatic groups, probably of the monoclinic system. It is of a chestnut-brown colour, with an orange streak and a yellowish-orange powder. It is transparent, has a vitreous lustre, a hardness of 3, and a sp. gr. of 2.18. It is distinctly attacked by water, and is soluble with difficulty in hydrochloric acid. On analysis, it gave the following results:—

SO_3	Fe_2O_3	H_2O	Al_2O_3	BaO	Total
33.80	33.92	30.76	trace	1.15	99.63

Its formula is $\text{Fe}_2\text{O}_3, 2\text{SO}_3, 8\text{H}_2\text{O}$. The other known natural ferric sulphates are:—

Amarantite	$\text{Fe}_2\text{O}_3, 2\text{SO}_3, 7\text{H}_2\text{O}$.
Hohmannite	$2\text{Fe}_2\text{O}_3, 3\text{SO}_3, 13\text{H}_2\text{O}$.
Paposite	$2\text{Fe}_2\text{O}_3, 3\text{SO}_3, 10\text{H}_2\text{O}$.

B. H. B.

The Proportion of Molybdenum in Scheelite. By H. TRAUBE (*Jahrb. f. Min.*, Beilage 7, 232—245).—Scheelite has hitherto been considered to be a calcium tungstate, in which tin oxide, fluorine, chlorine, cupric oxide, the oxides of didymium, cerium, and lanthanum, and traces of magnesium, have at various times been observed as admixtures. On analysing with great care a specimen of scheelite from South-west Africa, the author detected a considerable proportion of molybdenum. Thinking that this metal might occur in scheelite from other localities, the author made a series of analyses, the results being that molybdenum was met with in every case in smaller or larger quantities. The method employed for the quantitative separation of molybdic acid from tungstic acid was essentially that given by H. Rose. The following are the analytical results given by the author:—

	WO_3 .	$\text{M}\text{o}\text{O}_3$.	CaO .	Total.	Sp. gr.
1a	71.08	8.23	20.33	99.64	5.88
1b	75.29	3.98	20.34	99.61	6.03
1c	76.78	3.69	19.86	100.33	6.01
1d	77.84	2.23	19.48	99.55	6.03
1e	78.04	1.92	19.57	99.53	6.06
2	77.54	2.03	19.91	99.48	6.07
3a	79.94	trace	19.57	99.51	6.12
3b	80.17	0.07	19.49	99.83	6.02
4	79.76	trace	19.67	99.43	6.13
5	80.16	trace	19.65	99.81	6.14
6a	78.57	1.62	19.37	99.56	6.03
6b	79.68	0.76	19.29	99.73	6.04
7	79.97	0.35	19.27	99.59	6.01
8a	70.56	8.09	20.05	98.70	5.96
8b	71.59	7.63	20.51	99.53	5.96
9	79.77	trace	19.65	99.42	6.09
10	80.29	trace	19.44	99.73	6.01

The localities from which the material was obtained were the following:—1. Zinnwald, Saxony (*a*, reddish-brown crystals; *b*, yellowish-brown, imperfect crystals; *c*, yellow, translucent crystals; *d*, yellow, imperfect crystals; *e*, greyish-white mass); 2. Altenberg; 3. Fürstenberg, Saxony (crystals consisting of white octahedral centre, *a*, and a yellow coating, *b*); 4. Schlackenwald, Bohemia; 5. Guttannen, Switzerland; 6. Traversella (*a*, large, yellow crystals; *b*, translucent, yellow crystals); 7. Carrock Fall, Cumberland; 8. Pot Mine, South-west Africa (specimens contain copper and lime); 9. Mount Ramsay, Tasmania; 10. New Zealand. Besides these, analyses were made of scheelite from Neudorf, in the Harz, and from the Riesengrund, in Bohemia, distinct traces of molybdenum being obtained in each case.

B. H. B.

Manganopectolite. By J. F. WILLIAMS (*Zeit. Kryst. Min.*, 18, 336—389).—This mineral occurs with thomsonite and other alteration products of elæolite-syenite at Magnet Cove, Arkansas. On the crystals, the planes observed were OP , $\infty P\infty$, $+2P\infty$, $\infty P\infty$. The hardness of the mineral is 5 and its sp. gr. is 2·845. Analysis gave the following results:—

SiO_2	Fe_2O_3	CaO	MnO	Na_2O	H_2O	CO_2	Total
53·03	0·10	30·28	4·25	8·99	2·43	0·82	99·90

Its formula is $(\frac{2}{10}Ca\frac{1}{10}Mn)_2NaHSi_3O_9$. These results, as well as those of the optical examination, show the close connection between this mineral and pectolite. As this new zeolite differs from pectolite chiefly in its percentage of manganese, the author suggests for it the name of manganopectolite. B. H. B.

Identity of Violan and Anthochroite. By L. J. IGELSTRÖM (*Jahrb. f. Min.*, 1890, ii, Ref. 270—271).—From the results of analyses of violan and anthochroite, the author concludes that these two minerals are identical, and proposes to include them both under the name of anthochroite. Analyses of violan by E. Schluttig (I), and of anthochroite by the author (II), gave the following results:—

	SiO_2	Al_2O_3	CaO	MgO	MnO	FeO	Na_2O	K_2O	Co Ni	Total
I. 51·81	2·59	22·62	14·16	2·58	0·79	5·00	0·25	0·37		100·17
II. 51·60	1·40	23·30	13·50	3·40	—	6·80	—	—		100·00

B. H. B.

Chrysotile from the Pyrenees. By H. GOGUEL (*Zeit. Kryst. Min.*, 18, 447; from *Bull. Soc. Chim.*, 11, 155).—The mineral occurs at Medoux, near Bagnères de Bigorre, in veins a few inches in thickness, in serpentine, which is enclosed in blocks in a limestone breccia. The mineral is apple-green in the interior of the serpentine, and golden-yellow in the vicinity of the surrounding limestone, and whilst the optical characteristics are those of a normal chrysotile, the analysis yielded—

SiO_2	Al_2O_3	FeO	MgO	CaO	H_2O
33·3	5·0	7·5	23·7	12·3	17·5

B. H. B.

Offrétite, a New Mineral. By F. GONNARD (*Compt. rend.*, 111, 1002—1003).—Offrétite is a zeolite which occurs in very small quantity, associated with christianite and chabasite, in the basalt of Mount Simionse, near Montbrison. It forms small, brilliant, limpid, colourless crystals with a hexagonal aspect, and without any modification of the edges of the base or the faces of the prism. It polarises light feebly; the sign of elongation is positive, and plates perpendicular to the axis show sections analogous to those given by herschelite. Offrétite is brittle, cleaves in a direction normal to the base, and has a vitreous fracture; sp. gr. 2·13. It has the composition—

SiO ₂	Al ₂ O ₃	CaO.	K ₂ O.	H ₂ O.	Total.
52.47	19.06	2.43	7.72	18.90	100.58

which may be represented by the formula $2(K, Ca)O, 3Al_2O_3, 14SiO_2 + 17H_2O$. Before the blow-pipe, it becomes white, and melts to a white enamel without intumescence; with microcosmic salt, it gives a skeleton of silica; heated in a closed tube, it evolves water. Offrétite is attacked with difficulty even by hot acids; when fused with pure calcium carbonate, it yields a very pale brown, homogeneous glass with a slightly greenish fracture.

C. H. B.

French Minerals. By A. LACROIX (*Zeit. Kryst. Min.*, 18, 439—440; from *Bull. Soc. Chim.*, 11, 70, 148).—*Albite*, from Pouzac (Haute-Pyrénées), occurs in yellow limestone. The crystals are white and opaque, or transparent, and filled with black pigment irregularly distributed. The black crystals (sp. gr. 2.563) gave, on analysis, the following results:—

SiO ₂	Al ₂ O ₃	Na ₂ O.	CaO.	Ignition.	Total.
67.04	20.45	10.57	0.65	1.30	100.01

The author also describes *orthoclase* from Matour (Saône-et-Loire), *rutile* from the slates of the Mont Cenis, and *manganese epidote* from the mica-schist of the Island of St. Groix.

B. H. B.

Kryokonite. By E. A. WÜLFING (*Jahrb. f. Min.*, Beilage 7, 152—174).—The material examined by the author was the cosmic dust collected by A. E. Nordenskiöld, in Greenland, in 1883. The author gives a summary of the literature relating to kryokonite. A new analysis of material from which all magnetic particles were removed by means of the magnet gave the following results:—

SiO ₂	Al ₂ O ₃	FeO.	CaO.	MgO.	K ₂ O.	Na ₂ O.	Ignition.	Total.
62.08	14.79	4.54	4.65	2.32	1.73	3.52	6.75	100.38

The dust appears to be fairly homogeneous. The author's experiments prove that the kryokonite of 1883 consists for the most part of feldspar, quartz, mica, and hornblende. Feldspar occurs in greatest quantity; quartz forms some 15 per cent. of the mass, whilst hornblende and mica are present to a less extent. The accessory minerals are pale-pink garnet rich in magnesia, rhombic pyroxene, zircon, and magnetite. In one case, monoclinic pyroxene and sillimanite were observed. The admixed organic matter forms one-twentieth of the powder. It contains nitrogen, and yields, on distillation, ammonia and organic bases. It further contains small quantities of humic acid. Small chondritic masses indicate a meteoric origin for the dust. Metallic iron could not be detected. The cosmic portion is, however, a very small one, and it is possible that a portion of the dust was an air sediment of the detritus of crystalline rocks.

B. H. B.

Organic Chemistry.

Allyl Fluoride. By H. MESLANS (*Compt. rend.*, 111, 882—883).—Allyl iodide is allowed to fall drop by drop on silver fluoride contained in a copper flask heated to 35° and fitted with a serpentine condenser cooled to $2-3^{\circ}$. The gas is passed through a tube containing silver fluoride heated to 60° , and is collected over mercury.

Allyl fluoride, C_3H_5F , is a colourless gas with an alliaceous odour and a burning taste; sp. gr. at $16^{\circ} = 2.11$ (calc. 2.10). It ignites readily, and burns with a smoky flame which evolves large volumes of hydrogen fluoride. It liquefies at about 1° under normal pressure. Water dissolves 2.5 vols. of the gas at 15° ; alcohol dissolves 60 vols. at 16° , and ether more than 100 vols. Induction sparks decompose the gas readily with formation of a large proportion of acetylene and a considerable increase in volume; carbon is deposited round the electrodes and on the walls of the apparatus, and the glass of the latter is strongly attacked. When the gas is heated below dull redness in a glass vessel, there is an abundant deposit of carbon, a small quantity of silicon fluoride is formed, and the residual gas contains a large proportion of methane, but no acetylene. When sodium is heated in the gas, the metal is quickly covered with a thick deposit of carbon, and the gas increases in volume, and contains a considerable quantity of methane. Crystallised silicon behaves practically in the same way as glass, and phosphorus has no action even at its boiling point.

Allyl fluoride is not affected by hot aqueous potash, and is only slowly decomposed by alcoholic potash; lime-water and baryta-water act but slowly on it. Aqueous ammonia does not dissolve the gas, but ammoniacal cuprous chloride absorbs a considerable quantity with formation of a yellowish-white precipitate and separation of a very volatile liquid which seems to be allyl chloride. C. H. B.

Action of Nitriles on Organic Acids. By C. E. COLBY and F. D. DODGE (*Amer. Chem. J.*, 13, 1—12).—The authors have determined the behaviour of acetonitrile, propionitrile, benzonitrile, and phenylacetoneitrile when heated with the common organic acids in sealed tubes, at temperatures between 230° and 280° , to be as follows:—(1.) Fatty nitriles and fatty acids give secondary amides. (2.) Fatty nitriles and aromatic acids exchange their cyanogen and carboxyl groups, giving fatty acids and aromatic nitriles. (3.) Aromatic nitriles and fatty acids give mixed secondary amides. (4.) Aromatic nitriles and aromatic acids, as a rule, give rise to secondary amides, although at high temperatures the nitrile of a higher radicle may be formed.

The secondary amides probably have the unsymmetrical formula $R'CO \cdot O \cdot RC \cdot NH$, since they are produced by a change analogous to that of the spontaneous conversion of orthocyanobenzoic acid into phthalimide (compare Liebermann, *Abstr.*, 1887, 45).

G. T. M.

Reactions of Potassium Ferricyanide. By PRUD'HOMME (*Chem. Centr.*, 1890, ii, 783—784; from *Mon. Sci.* [4], 4, ii, 899—902).—*Action of Metals and Metallic Oxides.*—As a rule, metals do not exert any deoxidising action on potassium ferricyanide. With copper, copper potassium ferrocyanide, $K_2CuFeCy_6$, and potassium ferrocyanide are formed. With cupric hydroxide, it becomes oxidised; with lead hydroxide, potassium lead ferrocyanide, potassium ferrocyanide, lead dioxide, and water are formed; lead carbonate reacts similarly.

In addition to the salts obtained by Wronboff and Rammelsberg, the author finds that lead nitrate reacts but slowly in the cold with potassium ferricyanide; a greenish precipitate is formed which decolorises indigo at ordinary temperatures.

With potassium chlorate, potassium ferricyanide reacts, as already intimated by Jeanmaire, with formation of ferrocyanide, chloric acid, oxygen, and potassium chloride, but the author considers that all three compounds are formed at the same time, and not in stages. Indigo is decolorised at the ordinary temperature.

With potassium dichromate, potassium ferricyanide does not react; but with the chromate, potassium ferrocyanide and potassium dichromate are formed.

A concentrated solution of nitroprusside is prepared by adding to a solution of 34.5 grams of sodium nitrite in 150 grams of water and 120 grams of a solution of sodium hydrogen sulphite of 37° B. to 82 grams of potassium ferricyanide in 250 grams of water. The mixture is heated until oxygen ceases to be disengaged, and a further 120 grams of the sulphite solution added, when, on cooling the dark red solution, a crystalline salt separates which in boiling water decomposes into Prussian blue and sulphuric acid, and is probably the same compound as that formed by dissolving Prussian blue in concentrated sulphuric acid. A still better yield of nitroprusside is obtained by boiling a solution of 34.5 grams of sodium nitrite, 15 grams of sodium thiosulphate, and 41 grams of potassium ferricyanide in 400 grams of water, and, after cooling, adding 120 grams of sodium hydrogen sulphite solution of 37° B. A brown precipitate also forms, which is soluble in concentrated hydrochloric acid. Sodium polysulphide gives a beautiful dichroic solution with the nitroprusside; in transmitted light, it appears a purple-red; in reflected light, it appears blue.

J. W. L.

Constitution of Fulminic Acid. By A. F. HOLLEMAN (*Ber.*, 23, 3742—3744).—See p. 446.

Behaviour of Ethyl Ether with Sulphuric Acid: Separation of Ethyl Ether from Ethyl Bromide. By L. SCHOLVIEN (*Chem. Centr.*, 1890, ii, 782—783; from *Apoth. Zeit.*, 5, 607—608).—Owing to the contradictory statements regarding the behaviour of ethyl ether with sulphuric acid to be found in text books, the author was led to determine exactly under what conditions the two react together.

On mixing them much heat is developed, but at ordinary temperatures there is neither at once nor after a time any chemical

combination of the two, and dilution with water causes their separation unchanged.

If the mixture is heated at 100° for some time (30 hours), much ethyl hydrogen sulphate is formed, together with a little diethyl sulphate; by heating strongly, sulphurous anhydride, ethylene, and water are formed.

The separation of ethyl ether from ethyl bromide, in which it usually is present when first prepared, may be readily effected by a patented process of Riedel and Co., which consists in slowly adding an equal weight of sulphuric acid to the impure ethyl bromide contained in a reflux apparatus.

J. W. L.

Production of Higher Alcohols in Fermentation. By L. LINDET (*Compt. rend.*, 112, 102—104).—The production of higher alcohols is very slow at first, but increases as fermentation progresses, and continues with still greater rapidity after fermentation proper has ceased. In one case, the quantities of higher alcohols per litre at various times after the commencement of fermentation were as follows:—14 hours, 3.64 c.c.; 20 hours, 4.45 c.c.; 38 hours (fermentation complete), 6.44 c.c.; 24 hours later, 9.2 c.c. It follows that the higher alcohols are not simply products of the normal fermentation of sugar. Their formation seems to take place chiefly under those abnormal conditions of yeast life consequent on the disappearance of the sugar; they may also be produced by some special micro-organism which at first is almost inactive in presence of the rapidly developing and vigorous yeast, but becomes active when the work of the yeast is finished. It is clear that the longer the time between fermentation and distillation, the greater the proportion of higher alcohols in the product.

C. H. B.

The Pentaglucooses (Pentoses). By W. E. STONE (*Ber.*, 23, 3791—3798).—It has been shown by Tollens and his pupils, in the course of their researches on this group of sugars, that both arabinose and xylose are readily acted on by strong acids with formation of furfuraldehyde, the quantity of which may be approximately determined by conversion into furfuralamide. Further, they have shown that when any quantity of furfuraldehyde is obtained by distilling vegetable products with strong acids, it may be regarded as showing the presence of pentoses or pentose-forming compounds in those products. The author has, therefore, investigated the action of acids on 37 different products, and in the following 29 cases obtained quantities of furfuralamide varying from 0.4 per cent. in the first case to 8.16 per cent. in the last:—Clover ensilage, oatmeal, maize and cob meal, orange peel, maize ensilage, white lupine seeds, timothy hay, linseed meal, clover hay, yellow lupine seeds, maize bran, malt sprouts, coats of orange seeds, strawberry pulp, oat straw, water melon seeds, maize straw, Hungarian grass, beet pulp, cotton seed hulls, cowdung, wheat straw, peach gum, gum arabic, gum tragacanth, cherry gum, brewers' grains, maize cobs. The following eight substances did not yield appreciable quantities of furfuraldehyde, but all gave the qualitative

reaction with paper soaked in aniline acetate:—Cotton-seed cake, ground maize, sweet potatoes, linseed cake, orange pips, coffee beans, buckwheat, and common beans.

Quantitative estimations have also been made of the reducing power of the pentoses on Fehling's solution. It was found that in solutions containing 1 per cent. or less of arabinose 1.9—2.0 milligrams of copper were precipitated by 1 milligram of arabinose, whilst 1 milligram of xylose under similar conditions precipitates 1.86—1.96 milligrams of copper. Both compounds, therefore, have a stronger reducing action than glucose, which precipitates 1.8—1.9 milligrams of copper.

Numerous attempts were also made to bring about the fermentation of xylose under conditions similar to those which cause the fermentation of the less readily attacked hexoses, such as galactose, but in every case without success.
H. G. C.

Pine Tree Honey-dew and Pine Tree Honey. By H. W. WILEY (*Amer. Chem. J.*, 13, 24—29).—The honey-dew was collected drop by drop from the pine leaves. It contained 54.41 per cent. of water and 45.59 per cent. of solid matters. Calculated as dextrose, it contained 17.44 per cent. of reducing sugar, and after inversion the increase in reducing power was equivalent to 8.16 per cent. of sucrose. The calculated specific rotatory power of the solid, other than dextrose and sucrose, was $[\alpha]_D = 105$, the substance possibly consisting of arabinose or perhaps a mixture of sugars.

Pine tree honey is made by the bees from the pine leaves during the winter. The sample examined differed from the honey-dew in being levorotatory, even to a greater extent than usually exhibited by honeys. It must consequently be inferred that the bees in gathering the honey exercised an inverting effect on it, or that the sample was not authentic (compare Amthor and Stern, *Zeit. ang. Chem.*, 1889, 575).
G. T. M.

Reduction of Fruit Sugar. By E. FISCHER (*Ber.*, 23, 3684—3687).—When an ice-cold solution (10 per cent.) of fruit sugar is reduced with sodium amalgam (2.5 per cent.), a mixture is obtained consisting of 30—40 per cent. of mannitol and 50 per cent. of crude, syrupy sorbitol, which can be separated by crystallisation, and yields 15 per cent. of pure, crystalline sorbitol. The latter crystallises in aggregates of slender, colourless needles; when air-dried, it melts at 55°, and at 75° when dried in a vacuum over sulphuric acid (compare Boussingault, who gives the melting points 60° and 100°, *Ann. Chim. Phys.* [4], 26, 376). The author points out that on reduction of fruit sugar the carbonyl carbon atom becomes asymmetrical; hence stereoisomerides are probable, and that this is the second reaction resulting in the formation of an asymmetrical carbon atom amongst compounds of the sugar group in which two stereoisomerides which do not combine together are formed.
E. C. R.

Synthesis of a New Glucobiose. By E. FISCHER (*Ber.*, 23, 3687—3691).—The author has obtained from glucose a new glucobiose,

which from its properties is doubtless constituted like maltose, and is hence called isomaltose. *Isomaltose* is obtained when pure glucose (100 grams) is dissolved in hydrochloric acid (400 grams) of sp. gr. 1.19 at the ordinary temperature, and the mixture allowed to remain for 15 hours at 15° — 10° . The product obtained after precipitation with alcohol and ether, is a mixture of grape-sugar, isomaltose, and other substances, from which the isomaltose is separated by means of its osazone. *Isomaltosazone*, which is only obtained at the rate of 2.5 per cent. of the glucose employed, crystallises from water in minute needles, which congregate together in yellow flocks, begins to soften at 140° , and melts between 150° — 153° . By rubbing it with strong hydrochloric acid, it is converted into isomaltosone, and this, on hydrolysis with 4 per cent. acid, yields glucose. E. C. R.

A Sugar from the Pectin of Plums. By R. W. BAUER (*J. pr. Chem.* [2], 43, 112).—The 40 grams of pectin obtained from 20 kilos. of plums in 1885 was heated for four hours with 400 grams of 5 per cent. sulphuric acid, and the still uninverted residue again heated for four hours with 300 grams of the same sulphuric acid; these inversions were mixed together, neutralised with chalk, and the evaporated syrup extracted with 90 per cent alcohol. After five years, the still uncrystallised liquid was warmed with phenylhydrazine acetate, whereby a yellow phenylglucosazone, optically inactive in water and in alcohol, and melting at 156° , was obtained. Arabinosazone and xylosazone both have this melting point, but behave differently towards polarised light. A. G. B.

Action of Aqueous Ammonia on Isopropyl Iodide and Chloride. By H. MALBOT and A. MALBOT (*Bull. Soc. Chim.* [3], 4, 340, 632, 634).—Isopropyl iodide and saturated aqueous ammonia are placed in sealed tubes; at the ordinary temperature, after some months, the reaction is complete, monisopropylamine iodide alone being formed.

When a similar mixture is heated in sealed tubes at 100° , the reaction is complete after four days; some propylene is formed, but the monisopropylamine iodide contains but traces of diisopropylamine iodide.

When isopropyl chloride is heated with strong aqueous ammonia in sealed tubes at 140° , much propylene is formed, and the resulting liquid separates into two layers. The supernatant fluid contains monisopropylamine, diisopropylamine, and some isopropyl chloride, whilst the aqueous layer contains monisopropylamine and diisopropylamine chlorides, the isopropyl chloride differing thus from the isopropyl iodide in furnishing free amines, and in the reaction not being complete. T. G. N.

Preparation of Lecithin from Plant Seeds. By E. SCHULZE and A. LUKIERNIK (*Ber.*, 24, 71—74).—Lecithin is always considered as being widely distributed in the vegetable kingdom, from the fact that the ethereal extract of many parts of plants contains phosphorus, and on hydrolysis yields choline and other decomposition products of lecithin. Hitherto, however, it has not been isolated

from plants, the difficulty being that the ethereal extract contains glycerides, waxes, cholesterin, &c., which are not readily separated. It was observed some time since (Abstr., 1889, 645) that finely powdered plant seeds only yield a portion of their lecithin on extraction with ether, the remainder being then obtained from the residue by treatment with hot alcohol. It is probable that the second portion of lecithin forms, with another substance present, an unstable compound which is decomposed by the hot alcohol. If the alcoholic solution be evaporated and treated with ether, the lecithin is taken up by the latter, and impurities may be removed by shaking the ethereal solution with water; an emulsion is first obtained, but on addition of sodium chloride this separates into two layers.

Lecithin solutions were obtained in this manner from vetch and lupine seeds; they were evaporated by gently warming, and the residue treated with absolute alcohol at 50°. The solution is cooled in a freezing mixture, and the precipitate obtained is washed with cold alcohol and dried over sulphuric acid. The product has a yellowish colour, and shows all the properties of lecithin. Its alcoholic ethereal solution gave with alcoholic platinic chloride a yellowish-white precipitate, and on hydrolysis gave the same products as animal lecithin, namely choline, glycerol, phosphoric acid, fatty acids, and also oleic acids, showing that the product is a mixture of several lecithins.

In the quantitative estimation of the fatty constituents of seeds, a correction must be made for the quantity of lecithin taken up by the ether, which is readily done by estimating the phosphorus in the extract, and subtracting the corresponding quantity of lecithin.

H. G. C.

Ethylene Bases. By A. W. v. HOFMANN (*Ber.*, 23, 3711—3718).—The author has shown in a former paper on the preparation of ethylene bases (this vol., p. 169), that on hydrolysis of the product formed by the action of ammonia on bromethylene, basic oils are obtained, and these on distillation show a continuously rising boiling point, which exceeds finally the limit of the mercurial thermometer. These oils contain diethylenediamine and higher members of the ethylene bases. The fraction from 117° to 121° yields ethylenediamine on redistillation; the fraction from 200° to 225°, on the addition of hydrogen chloride, gives a crystalline salt, which consists for the most part of diethylenetriamine hydrochloride (*Proc. Roy. Soc.*, 11, 420). The fraction from 250° to 300° gives, on addition of hydrogen bromide, triethylenetetramine hydrobromide, $C_6H_{14}N_4 \cdot 4HBr$. The same compound, together with diethylenediamine and other products, is also formed by digesting ethylene chloride (1 mol.) with ethylenediamine (3 mols.) on the water-bath, and subsequent treatment of the product with potash and fractionation of the oil so obtained. The fraction from 200° to 300° is converted into the hydrochloride, decomposed with silver hydroxide, and saturated with hydrogen bromide.

Triethylenetetramine, obtained from the hydrobromide by hydrolysis with potash, boils at 266—267°, is a colourless, viscous liquid, but becomes limpid on gentle warming, and dissolves in water with

development of much heat; the solution gives a strongly alkaline reaction, and absorbs carbonic anhydride with avidity. Sp. gr. = 0.9817 at 15°. At -18°, it solidifies to a radiated crystalline mass, which melts at +12°. The *hydrobromide*, $C_6H_{18}N_4 \cdot 4HBr$, crystallises from dilute alcohol with 1 mol. H_2O in hemimorphic prisms belonging to the rhombic system, $a : b : c = 0.5654 : 1 : 0.5014$. It is extremely soluble in water, slightly soluble in alcohol, and must be crystallised from a solution containing an excess of hydrogen bromide. A hydrobromide of the formula $C_6H_{18}N_4 \cdot 3HBr$ crystallises from neutral solutions. The *hydrochloride*, $C_6H_{18}N_4 \cdot 4HCl$, resembles the hydrobromide, and is best purified by solution in water and precipitation with alcohol. The *platinochloride*, $C_6H_{18}N_4 \cdot 2H_2PtCl_6$, is obtained in thin plates, and dissolves sparingly in water. The *aurochloride*, $C_6H_{18}N_4 \cdot 4HAuCl_4$, obtained in concentrated solutions, crystallises from hot water in beautiful, glistening plates. A second salt of the formula $C_6H_{18}N_4 \cdot 4HCl \cdot 8AuCl_3$ is obtained on boiling a dilute solution of the hydrochloride with excess of gold chloride, and is insoluble in water. A corresponding platinum salt could not be obtained.

Other salts of the tetramine were prepared, but not examined in detail; they are all, except the oxalate, easily soluble in water, and are precipitated from their solutions on the addition of alcohol. Methyl iodide acts on the tetramine with great violence. The *benzoyl compound*, $C_6H_4N_4Bz_4$, is easily prepared in alkaline solution, melts at 228—229°, crystallises from amyl alcohol in small needles, and is sparingly soluble in ethyl alcohol.

E. C. R.

Piperazine. By W. MAJERT and A. SCHMIDT (*Ber.*, 23, 3718—3723).—The authors come to the conclusion that Hofmann's diethylenediamine, Schreiner's spermine, Ladenburg's ethylenimine, and piperazine are identical.

Ladenburg gives the melting point of the base as 159—163°. Piperazine melts at 104—107°; it, however, eagerly absorbs carbonic anhydride with formation of the carbonate, which melts at 162—165°, and Ladenburg was no doubt dealing with the carbonate. Piperazine forms with uric acid the neutral and easily soluble salt of the formula $C_4N_2H_{10} \cdot C_5N_4H_4O_6$, which dissolves in 50 parts of water at 17°. The base has neither caustic nor toxic properties.

E. C. R.

Action of Heat on the Hydrochlorides of Ethylene Bases. By A. W. v. HOFMANN (*Ber.*, 23, 3723—3726).—Diethylenetriamine hydrochloride melts when cautiously heated; if, however, the temperature be raised, carbonisation takes place, and empyreumatic vapours and a crystalline sublimate are obtained. Diethylenediamine is obtained by extraction of the carbonised mass with water, and is recognised by converting it into the benzoyl compound, which melts at 191°. Triethylenetetramine hydrochloride, when treated in the same way, also yields diethylenediamine. Ethylenediamine hydrochloride yields diethylenediamine, but not with the same ease as the above compounds. Diethylenediamine hydrochloride gives on distillation the free base, but the greater part is decomposed. Amongst the products of the action of ammonia on ethylene chloride, bases of

high boiling point (above 300°) are formed, which have not been examined; they give, however, on distillation, diethylenediamine. The author prefers the name diethylenediamine to piperazine (*Ber.*, 23, 3718—3723). E. C. R.

Diethylenediimine (Piperazine). By A. LADENBURG (*Ber.*, 23, 3740—3741).—The product obtained by the distillation of ethylenediamine hydrochloride is probably diethylenediamine, and not diethylenediimine as previously stated, since it yields a benzoyl derivative which melts at 191° , and the free diamine has been shown by Hofmann to be capable of crystallisation (compare this vol., p. 169). J. B. T.

Guanamines. By C. HAAF (*J. pr. Chem.* [2], 43, 75—85).—*Propionoguanamine* is prepared by heating guanidine propionate (obtained by decomposing guanidine carbonate with propionic acid) in a flask on the sand-bath at 220 — 230° for some hours, dissolving the melt in water, filtering hot, and adding strong soda solution, which precipitates the base. It is best purified by conversion into the hydrochloride and subsequent decomposition with sodium hydroxide. It crystallises from water in anhydrous, quadratic pyramids; in a capillary tube, it blackens at 300° without melting; it dissolves freely in hot water and in alcohol. The *hydrochloride* is anhydrous.

Ceanthoguanamine is similarly obtained, but the white precipitate at first formed on addition of strong soda solution rapidly collects as an oily layer. It crystallises in tables and prisms, melts in a capillary tube at 130° , and is sparingly soluble in water, but freely in alcohol.

Attempts to prepare capryloguanamine and capriguanamine by this method have failed.

The guanamines of the volatile fatty acids afford excellent means for the identification of these acids; the first seven of the series are now known (see also this Journal, 1874, 1089; 1875, 754; 1876, ii, 187, 190); and in this paper the author gives figures of the crystalline forms of these seven. A. G. B.

Action of Hydroxylamine on Acetoacetaldehyde. By L. CLAISSEY and E. HURI (*Ber.*, 24, 139—140).—A compound of the formula $C_4H_{13}N_3O_2$ is obtained when sodium acetoacetaldehyde (40 grams) dissolved in water (60 c.c.) at 0° is mixed with hydroxylamine hydrochloride (26 grams) dissolved in water (20 c.c.), and the pale-yellow solution allowed to crystallise over sulphuric acid. It crystallises from hot alcohol in small, white needles, melts at 174° , and is sparingly soluble in water, ether, benzene, chloroform, and light petroleum. The oxime, cyanacetone, and methylisoxazole, which are probable products in this reaction (see p. 451), have not yet been obtained. E. C. R.

Glyoxylpropionic Acid and its Derivatives. By L. WOLFF (*Annalen*, 260, 79—136).—When levulinic acid is treated with bromine, it is converted into a dibromo-acid identical with that obtained by brominating β -bromolevulinic acid (*Abstr.*, 1885, 1123).

This compound melts at 114–115°, and is isomeric, but not identical, with the $\alpha\beta$ -dibromo-acid, which is formed by the addition of bromine to acetylacrylic acid; it must, therefore, have the constitution represented by one of the following formulæ:—

When it is boiled with water (10 parts) for 5 to 6 hours, it is completely decomposed, yielding, as principal product, an acid which is very probably glyoxylpropionic acid, and hydrogen bromide, together with small quantities of diacetyl (m. p. 87–88°) and carbonic anhydride. This decomposition can only be explained by assuming that the dibromolevulinic acid is first converted into a kind of trimethylene derivative of the constitution $\begin{matrix} \text{CO} \\ | \\ \text{CH} \end{matrix} \gg \text{C}\cdot\text{CH}_2\cdot\text{COOH}$, by

elimination of 2 mols. of hydrogen bromide, and that this intermediate product then combines with water in two ways to form both glyoxylpropionic acid and diacetylcarboxylic acid, the last-named compound being decomposed into diacetyl and carbonic anhydride.

Glyoxylpropionic acid, $\text{COH}\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, can be isolated from the brown aqueous solution obtained by the decomposition of dibromolevulinic acid in the following manner:—The diacetyl is separated by distillation, the hydrobromic acid in solution precipitated with silver carbonate, the filtrate treated with hydrogen sulphide, filtered, and evaporated; the acid is then obtained as a brown oil, which shows no signs of crystallising, but gradually changes into a resinous mass. It is readily soluble in water and alcohol, but only sparingly in the other ordinary solvents; it reduces Fehling's solution and ammoniacal silver nitrate, and it precipitates mercurous chloride from a solution of the mercuric salt. The barium, calcium, and zinc salts are readily soluble in water, and are obtained as dark, amorphous residues on evaporating their solutions. When the acid is oxidised with potassium permanganate in the cold, it is converted into succinic acid and carbonic anhydride.

$\gamma\delta$ -*Diisonitrosovaleric acid*, $\text{NOH}\cdot\text{CH}\cdot\text{C}(\text{NOH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, is formed when glyoxylpropionic acid is treated with hydroxylamine at the ordinary temperature. It crystallises from hot water in well-defined colourless plates, melts at 136°, and is very readily soluble in alcohol and hot water, but less readily in ether and cold water, and only sparingly in chloroform and carbon bisulphide; it dissolves in boiling acetic anhydride, yielding a deep-red solution, and, in its aqueous solution, ferric chloride produces a cherry-red coloration, which changes to yellow on the addition of hydrochloric acid. The barium salt, $(\text{C}_5\text{H}_7\text{N}_2\text{O}_4)_2\text{Ba} + 3\text{H}_2\text{O}$, prepared by saturating an aqueous solution of the acid with barium carbonate, crystallises from hot water, in which it is readily soluble, in slender needles, and loses the whole of its water at 110°; in its aqueous solution, ferric chloride produces a brownish-red precipitate which is soluble in excess, yielding a red solution. On oxidation with potassium permanganate in the cold, diisonitrosovaleric acid yields succinic acid, hydrocyanic acid, and nitric acid.

Furazanpropionic acid, $\begin{array}{c} \text{O}-\text{N} \\ \text{N}:\text{CH} \end{array} \gg \text{C}-\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, is produced,

together with small quantities of a bluish-black substance, described below, and resinous products, when finely-divided diisonitrosovaleric acid is dissolved in concentrated sulphuric acid (4 parts), the temperature being kept below 70° , the solution then heated for 20 minutes at 100° , and finally poured into cold water (3 vols.); the product is extracted with ether, and recrystallised from hot water with the addition of animal charcoal. It crystallises in lustrous plates, sinters together at about 84° , melts at 86° , and is readily soluble in ether, alcohol, chloroform, and hot water, but rather sparingly in cold water, carbon bisulphide, and light petroleum; it is not volatile with steam. Molecular weight determinations by Raoult's method in glacial acetic acid solution gave results in accordance with the molecular formula $\text{C}_6\text{H}_8\text{N}_2\text{O}_4$. The *calcium* salt, $(\text{C}_6\text{H}_8\text{N}_2\text{O}_4)_2\text{Ca} + 2\text{H}_2\text{O}$, crystallises from cold water, in which it is readily soluble, in lustrous needles, melts at 100° , and decomposes at 110° without becoming perfectly anhydrous. The *silver* salt crystallises from boiling water in needles, and explodes when heated.

Furazanpropionic acid is very stable, except towards alkalis, and can be heated with concentrated sulphuric acid or nitric acid at 100° , or with concentrated hydrochloric acid at 130° , without any appreciable decomposition taking place; hydroxylamine has no action on it in cold aqueous solution, but on heating at 50 – 60° , it undergoes intramolecular change into cyanonitrosobutyric acid, which is then converted into the amidoxime described below. It does not combine with bromine in chloroform solution at the ordinary temperature, and tin and hydrochloric acid have no action on it, even at moderately high temperatures. The *anhydride*, $(\text{C}_6\text{H}_8\text{N}_2\text{O}_4)_2\text{O}$, is formed when furazanpropionic acid is heated with acetic anhydride; it crystallises from chloroform in colourless plates, melts at 67° , and is readily soluble in hot benzene and chloroform, but rather sparingly in water, ether, alcohol, and carbon bisulphide. The freshly prepared aqueous solution of the anhydride has a neutral reaction, but soon becomes acid; when boiled with water or treated with cold sodium carbonate, the anhydride is completely reconverted into furazanpropionic acid.

Cyanonitrosobutyric acid, $\text{NOH}\cdot\text{C}(\text{CN})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, is quickly formed, with slight development of heat, when furazanpropionic acid is treated with excess of soda or ammonia at the ordinary temperature; on acidifying and extracting with ether, the cyano-derivative is obtained as a colourless oil which gradually solidifies. It separates from a mixture of benzene and ether in large, lustrous prisms containing benzene, which escapes on exposure to the air, the crystalline powder then melting at 87° , although it sinters together at 85° . It is not acted on by bromine at the ordinary temperature, and, in its aqueous solution, ferric chloride produces a yellowish-red coloration which disappears on the addition of hydrochloric acid. The *calcium* salt, $(\text{C}_6\text{H}_8\text{N}_2\text{O}_4)_2\text{Ca} + 2\text{H}_2\text{O}$, crystallises from hot water in microscopic needles, does not lose its water at 110° , and begins to decompose at

120°. The *silver* salt is a colourless, flocculent compound which melts and turns black when boiled with water.

When furazanpropionic acid is heated at 100° with aniline for several hours, it is partially converted into a compound which crystallises from boiling alcohol in needles, and is insoluble in water and alkalis. This substance, which is very probably the anilide of the acid, melts at 137° without any appreciable decomposition, but when heated at its melting point for some minutes, it solidifies again, having been converted into another crystalline substance which melts at about 184° with decomposition; the latter substance is also produced in very small quantities when furazanpropionic acid is boiled with aniline.

Cyanonitrosobutyric acid gives a very characteristic reaction with concentrated sulphuric acid, and also, but not so well, with concentrated hydrochloric acid; when warmed at about 60° for 1 to 2 minutes with a few drops of the concentrated acid, it yields a yellow solution which, on the addition of a small quantity of water, turns blue at the surface of contact of the two liquids; on agitating, a clear, cherry-red solution is obtained, but if the addition of water is continued, the colour finally changes to blue, and a substance is precipitated in bluish-black needles which dissolve in alkalis and ammonia with a deep-blue coloration, the solution turning red on boiling or on adding a mineral acid.

The *amidoxime*, $\text{NH}_2\cdot\text{C}(\text{NOH})\cdot\text{C}(\text{NOH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, is precipitated in slender needles when a concentrated aqueous solution of sodium nitro-cyanobutyrate is digested with hydroxylamine (1 mol.) at about 50° for some hours, and then acidified with acetic acid; it melts at 158° with decomposition, and is only sparingly soluble in water, alcohol, ether, and chloroform, but readily in dilute hydrochloric acid and sodium carbonate. Its aqueous solution gives, with ferric chloride, a red coloration, and with copper acetate, a dirty-green precipitate which is only sparingly soluble in water: when the amidoxime is boiled with water, it is converted into a crystalline compound which is insoluble in hydrochloric acid. It dissolves in boiling dilute hydrochloric acid, yielding a red solution, which turns blue on the addition of alkalis; these colour reactions are due to the formation of a dark-blue compound which is identical with that produced by the action of concentrated sulphuric acid on nitroso-cyanobutyric acid, and also with the dark bye-product obtained in the preparation of furazanpropionic acid.

α-Nitrosoglutaric acid, $\text{COOH}\cdot\text{C}(\text{NOH})\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{COOH}$, is obtained when cyanonitrosobutyric acid is boiled with potash or barium hydroxide, and when furazanpropionic acid (1 part) is heated with potassium hydroxide (2 parts) and water (6 parts) until the evolution of ammonia is at an end. It crystallises from warm water in ill-defined, colourless prisms, melts at 152° with evolution of carbonic anhydride, and is readily soluble in warm water, but only moderately easily in ether, chloroform, benzene, and cold water; it is decomposed by boiling water with liberation of carbonic anhydride, and, in its aqueous solution, ferric chloride produces a reddish-brown coloration. The normal salts of the alkalis are readily

soluble in water, but those of the alkaline earths and the heavy metals are only sparingly soluble; the *potassium* salt is crystalline. The *barium* salt, $C_4H_5NO_3Ba + 1\frac{1}{2}H_2O$, crystallises in lustrous needles, loses about $\frac{1}{2}$ mol. H_2O at 100° , and gradually decomposes at a higher temperature. The *calcium* salt crystallises in broad needles or plates; the *silver* salt is amorphous, and explodes when heated.

Succinamic acid, $C_4H_5NO_3$, is formed when nitrosoglutaric acid is warmed with acetic anhydride until the evolution of carbonic anhydride is at an end; on evaporating the red solution over calcium oxide, there remains a thick syrup, probably acetylsuccinamic acid, from which, on the addition of a little water, succinamic acid is deposited in crystals. It separates from warm water in colourless needles, melts at 157° (not above 300° , as stated by Tenchert, *Annalen*, 134, 146), and is moderately easily soluble in cold water, but only sparingly in ether, alcohol, chloroform, and benzene; when boiled with water, it is gradually converted into ammonium succinate.

Inactive *glutamic acid* (*amidoglutaric acid*),

is obtained when concentrated hydrochloric acid is poured over finely-divided nitrosoglutaric acid and a slight excess of the theoretical quantity of tin added in small portions at a time; the clear, yellow solution is treated with hydrogen sulphide to precipitate the tin, and the filtrate evaporated, when glutamic acid hydrochloride remains as a syrup which gradually solidifies. This salt crystallises from hot hydrochloric acid in needles, melts at about 193° with decomposition, and is very readily soluble in water, to which it imparts an acid reaction; it has all the properties of the hydrochloride of the glutamic acid obtained from albuminoids, and described by Hlasiwetz and Habermann (*Annalen*, 169, 157), but unlike the latter, which is dextro-rotatory, it is optically inactive. The two salts are nevertheless identical crystallographically, and form long, colourless plates, $a:b:c = 0.8873:1:0.3865$, belonging to the rhombic system. Inactive glutamic acid, prepared by decomposing the hydrochloride with silver carbonate, crystallises from hot water in small, rhombic plates, $a:b:c = 0.7454:1:1.2367$, melts at 198° with decomposition (see below), and is readily soluble in boiling water, but only sparingly (1 in 66.7 parts) in water at 20° , and in alcohol, ether, carbon bisulphide, and light petroleum. It differs from the active acid in crystalline form; in its aqueous solution, ferric chloride produces a red coloration. The *copper* salt,

is obtained in blue needles when the acid is boiled with copper carbonate and the deep-blue solution allowed to cool; it loses the whole of its water at 135° , and is not soluble in less than 1000 parts of boiling water, whereas the copper salt of the active acid is soluble in about 400 parts. When the acid is heated at its melting point, it is decomposed into pyrrolidonecarboxylic acid,

this compound melts at 182—183°, and is identical with the pyroglutamic acid obtained by Haitinger (*Monatsh.*, 3, 228) by heating active glutamic acid, and also with the glutimic acid prepared by Schützenberger (*Ann. Chim. Phys.* [5], 16, 372) by decomposing albumin with barium hydroxide at 180°.

Zinc hydroxyglutarate, $C_5H_6O_5Zn + 3H_2O$, is obtained in crystals when glutamic acid hydrochloride (1 part) is dissolved in ice-cold, very dilute hydrochloric acid, an aqueous solution of potassium nitrite (1 part) added to the solution in the course of a few hours, the mixture kept at the ordinary temperature until gas ceases to be evolved, then diluted, boiled with excess of zinc carbonate, filtered, and evaporated. It crystallises from boiling water in slender needles, and is decomposed by hydrogen sulphide in aqueous solution, yielding γ -hydroxyglutaric acid. Careful experiments showed that this acid is stable in a crystalline condition, but it cannot be isolated; on evaporating its solution at 100°, there remains a thick syrup which gradually solidifies over sulphuric acid to a mass of slender, hygroscopic crystals of butyrolactone- γ -carboxylic acid, $C_5H_6O_4$. The γ -hydroxyglutaric acid (m. p. 72—73°) described by Markovnikoff (*Annalen*, 182, 347), and also by Ritthausen (*J. pr. Chem.*, 99, 461) and Dittmar (*ibid.* [2], 5, 338), as a thick syrup, is doubtless a mixture of the γ -hydroxy-acid and butyrolactone- γ -carboxylic acid.

Butyrolactone- γ -carboxylic acid, $\begin{array}{c} CH_2 \cdot CH_2 \\ | \quad \quad | \\ CO \quad \quad O \end{array} > CH \cdot COOH$, melts at 49—50°, and is very readily soluble in water and alcohol, but only sparingly in ether, chloroform, benzene, and carbon bisulphide; when the lactone is treated with cold water, a solution containing 18 per cent. of the hydroxy-acid is obtained, but, on boiling, the quantity of this acid produced amounts to 47 per cent. A salt of the composition $(C_5H_6O_4)_2Ca + 2H_2O$ is obtained in crystals when a freshly-prepared aqueous solution of the lactone-acid is neutralised with calcium carbonate in the cold, quickly filtered, and evaporated over sulphuric acid. It is very readily soluble in water, to which it imparts a slight acid reaction; when dried, it loses 2 mols. H_2O . The zinc salt, $(C_5H_6O_4)_2Zn + 2H_2O$, prepared in like manner, is amorphous, and very readily soluble in water; it melts at 100°, loses the whole of its water at 100—115°, and, in aqueous solution, is slowly converted into the neutral salt of hydroxyglutaric acid. Barium butyrolactonecarboxylate, $(C_5H_6O_4)_2Ba$, is obtained as a colourless, vitreous mass when a concentrated solution of the lactone-acid is treated with excess of barium carbonate at the ordinary temperature, and the filtrate evaporated under reduced pressure; it is readily soluble in water, to which it imparts a slight acid reaction, but is reprecipitated on adding alcohol. The silver salt, $C_5H_6O_4Ag_2$, is precipitated, but only in very small quantities, when a concentrated solution of any one of the three salts just described is mixed with silver nitrate, and on boiling the mother liquors, a further separation of the salt takes place; it crystallises from boiling water in colourless needles.

F. S. K.

Action of Ammonia, Isobutylamine, and Aniline on Ethyl Acetonedicarboxylate. By W. O. EMERY (*Ber.*, 23, 3761—3765).—By the action of aqueous ammonia on ethyl acetonedicarboxylate, v. Pechmann and Stokes (*Abstr.*, 1885, 1202; 1887, 155) obtained the ethyl salt of β -hydroxyamidoglutamic acid,

which undergoes condensation forming the glutazine,

or $\text{NH} \cdot \text{C} \begin{array}{c} \text{CH}_2 \cdot \text{CO} \\ \text{CH} \cdot \text{CO} \end{array} > \text{NH}$ (*Annalen*, 260, 160). If the ethyl salt be allowed to remain in the cold with alcoholic ammonia, a different reaction takes place, *ethyl- β -amidoglutaconate*,

being formed. This is a thick, pale-yellow oil, which boils at 157—158° under 12—13 mm. pressure, and has a sp. gr. of 1.11169 at 20°/4°.

Isobutylamine acts even more readily than ammonia, with formation of *ethyl- β -isobutylamidoglutaconate*,

which is also a slightly yellow oil boiling at 181—182° under 17 mm. pressure, and having a sp. gr. of 1.02725 at 20°/4°. Aniline acts in rather a different manner, 1 mol. of water and 2 mols. of alcohol being eliminated. The product is sparingly soluble in alcohol, and crystallises from the solution in slightly yellow plates which melt at 275° with decomposition, and have the composition $\text{C}_{17}\text{H}_{14}\text{N}_2\text{O}_3$. It is probably a glutazine derivative of the constitution

The *oxime* of acetonedicarboxylic acid, $\text{HO} \cdot \text{N} \cdot \text{C}(\text{CH}_2 \cdot \text{COOH})_2$, already shortly mentioned by Pechmann and Wehsarg (*Abstr.*, 1887, 28), is readily prepared by allowing aqueous solutions of the acid and of hydroxylamine to remain together for 24 hours. It is extracted by agitation with ether, and separates on the evaporation of the latter in large, transparent crystals melting at 53—54°. After drying in the exsiccator, a product remains which melts at 89°, and has the composition $\text{C}_5\text{H}_5\text{NO}_4$, and therefore consists of the anhydride. The *silver* salt has the composition $\text{C}_5\text{H}_4\text{NO}_5\text{Ag}$, and explodes on heating.
H. G. C.

Coloured Compounds derived from Ethyl Acetonoxalate. By L. CLAISEN (*Ber.*, 24, 128—130).—When the colourless sodium salt of ethyl acetonoxalate is heated with glacial acetic acid, the solution becomes of an intense reddish-violet colour (*Abstr.*, 1888, 676). This is due to the formation of characteristically coloured metallic derivatives of the composition $\text{C}_6\text{H}_3\text{O}_4\text{M}'$, derived from the substance $\text{C}_6\text{H}_4\text{O}_5$, which contains 1 mol. of water less than acetonoxalic acid, $\text{COMe} \cdot \text{CH}_2 \cdot \text{CO} \cdot \text{COOH} - \text{H}_2\text{O} = \text{C}_6\text{H}_4\text{O}_5$. These salts are best pre-

pared by allowing acetonoxalic acid to stand at the ordinary temperature with anhydrous sodium or potassium acetate and acetic anhydride. The alkali salt is formed with the production of an intense violet colour. By adding barium chloride, silver nitrate, &c., to the alkaline derivatives, other metallic derivatives are obtained, which are mostly well crystallised. The potassium and sodium salts are easily soluble in water; the barium, strontium, calcium, and silver salts are sparingly soluble. In aqueous solution they are dark reddish-violet, in solid condition deep bluish-violet, and in compact crystals quite black. These compounds are in some degree like the phthaleins; excess of alkali turns them bright-yellow; the addition of mineral acids restores the colour, which is again weakened by excess of acid. They are decolorised by sulphurous acid. The author believes the compound to be a diacetylated dihydroxyquinone of the formula $\text{COMe}\cdot\text{C}\begin{smallmatrix} \text{C}(\text{OH})\cdot\text{CO} \\ \text{CO}\cdot\text{C}(\text{OH}) \end{smallmatrix}\text{C}\cdot\text{COMe}$.

Ethyl oxalacetate on similar treatment gives blue salts, which, however, are less stable than the above. E. C. R.

Ethyl β -Acetyltricarballoylate. By W. O. EMERY (*Ber.*, 23, 3755—3756).—In the preparation of ethyl acetosuccinate from ethyl acetoacetate and ethyl bromacetate on the large scale, considerable quantities of *ethyl β -acetyltricarballoylate* are formed, and may be readily separated by fractionating the product under reduced pressure. It boils at 190° under 16 mm. pressure, and has a sp. gr. of 1.12141 at $20^\circ/4^\circ$. The compound has previously been obtained in an impure condition by Michle (*Abstr.*, 1878, 490); it combines with phenylhydrazine at the temperature of the water-bath, forming the *hydrazone*, $\text{C}_{20}\text{H}_{18}\text{N}_2\text{O}_6$, which, after recrystallisation first from carbon bisulphide and then from ethyl acetate, forms small prisms melting at $100\text{--}101^\circ$. H. G. C.

A New Synthesis of Tricarballoylic Acid and of Certain Ethereal Salts. By W. O. EMERY (*Ber.*, 23, 3756—3761).—The ethyl salt of chlorosuccinic acid readily acts on the sodium compounds of ethyl acetoacetate and of ethyl malonate, with formation of derivatives of tricarballoylic acid. Ethyl chlorosuccinate is prepared by saturating an alcoholic solution of the acid with hydrogen chloride; it boils at 122° under 15 mm. pressure, and has a sp. gr. of 1.14557 at $20^\circ/4^\circ$. When it is added to an alcoholic solution of ethyl sodacetate, separation of sodium chloride takes place almost immediately, and the reaction is complete in a few minutes. The product is a thick oil, which distils at 175° under 9 mm. pressure, has a sp. gr. of 1.12577 at $20^\circ/4^\circ$, and the composition $\text{C}_{14}\text{H}_{14}\text{O}_7$. From its mode of preparation, it must be *ethyl α -acetyltricarballoylate*,

It unites with phenylhydrazine, forming an oily compound, which appears to be *ethyl 1-phenyl-3-methylpyrazolone-4-succinate*, $(\text{C}_{18}\text{H}_{18}\text{N}_2\text{O}_5)$. On hydrolysis, it yields the corresponding acid $\text{C}_{14}\text{H}_{14}\text{N}_2$, which crystallises from water containing sulphuric acid in needles having

a reddish lustre, and melting at 210—212°. Ethyl α -acetyltricarballoylate also reacts with alcoholic ammonia, with formation of a well crystallised compound, which is being further investigated.

By the action of ethyl chlorosuccinate on ethyl sodiomalonate, the ethyl salt of *propanetetra-carboxylic acid*,

is obtained. It is an oil which distils at 203—204° under 18 mm. pressure, has a sp. gr. of 1.11841 at 20°/4°, and cannot be distilled under atmospheric pressure without decomposition. It forms a sodium compound, and also combines with chlorine and bromine forming a monochloro- and monobromo-substitution product; by the action of alcoholic potash, it is converted into tricarballoylic acid.

Ethyl butanepentacarboxylate,

is prepared by acting on the sodium compound of ethyl ethenyltricarboxylate with ethyl chlorosuccinate, and forms a thick, colourless oil, which boils at 216—218° under 16 mm. pressure, and has a sp. gr. of 1.14088 at 20°/4°. H. G. C.

Synthesis of Aconitic Acid. By L. CLAISEN and E. HORT (*Ber.*, 24, 120—127).—Ethyl acetate and ethyl oxalate combine in the presence of sodium ethoxide to form ethyl oxalacetate,

and this, on remaining with a concentrated solution of potassium acetate, dissolves after a time with the formation of the potassium salt of a monobasic acid of the composition $\text{C}_{14}\text{H}_{18}\text{O}_9$, which was identified as the triethyl salt of aconitoxalic acid. It is best prepared as follows:—Ethyl oxalacetate (37 grams) is mixed with a solution of potassium acetate (20 grams) in 20 c.c. of water, with constant shaking; after some time the mixture becomes clear and slightly warm, and, in consequence of the formation of bye-products, is blue to bluish-green. On acidifying with hydrochloric or sulphuric acid, the product is precipitated as an oil, and can be extracted with ether. It is a colourless liquid of the consistence of glycerol, easily soluble in alcohol and ether, sparingly in water; the alcoholic solution gives an intense red coloration with ferric chloride. The *barium salt*, $(\text{C}_{14}\text{H}_{17}\text{O}_9)_2\text{Ba} + 2\text{H}_2\text{O}$, obtained as a white precipitate on adding barium chloride to a solution of the potassium salt, is very sparingly soluble in water, and crystallises in slender, felted needles which lose their water of crystallisation at 100°, or on remaining over sulphuric acid in a vacuum. The *lead salt*, $(\text{C}_{14}\text{H}_{17}\text{O}_9)_2\text{Pb}$, is more insoluble than the barium salt, and is obtained as a crystalline precipitate on adding lead nitrate to the boiling solution of the barium salt. It is somewhat easily soluble in hot alcohol, and, on the addition of water, crystallises in beautiful, short needles.

The conversion of the above acid into aconitic acid is rather a difficult operation, as excess of alkali produces a partial decomposition into acetic and oxalic acids. It is best carried out as follows:—The

acid (1 mol.) dissolved in alcohol is mixed with 3 per cent. alcoholic potash (6 mols.), and heated for three hours on the water-bath; one-third of the alcohol is then distilled off, and the product dissolved in water and heated until the solution, on acidification with acetic acid, no longer turns red with ferric chloride. The solution is acidified with acetic acid, calcium acetate added, filtered, the filtrate containing the calcium salt acidified with sulphuric acid, and the aconitic acid extracted with ether. The aconitic acid so obtained melts after recrystallisation at 191° .

The authors point out that this synthesis is of importance in relation to the presence of aconitic and citric acids in nature.

E. C. R.

Hydrolysis of Ethereal Salts of Organic Acids by Potassium Acetate. By L. CLAISEN (*Ber.*, 24, 127—128).—By the action of potassium acetate on ethyl oxalacetate, the triethyl salt of aconit-oxalic acid is formed, and not the tetrethyl salt (see preceding abstract). Similarly, from ethyl acetonoxalate, the monethyl salt of diacetonedioxylic acid is formed instead of the diethyl salt. Hence potassium acetate, besides acting as a condensing agent, must also act as a hydrolysing agent. Ethyl oxalate (1 mol.), when warmed with a solution of potassium acetate (1 mol.) in an equal weight of water on the water-bath with constant shaking, is easily converted into potassium ethyl oxalate. Potassium oxalate is not formed in this reaction.

E. C. R.

Synthesis of Chelidonic Acid. By L. CLAISEN (*Ber.*, 24, 111—120).—When an excess of ethyl oxalate reacts with acetone in the presence of sodium ethoxide, the sodium derivative of ethyl acetonoxalate, $\text{CH}_3\text{CO}\cdot\text{CH}_2\text{CO}\cdot\text{COOEt}$, is first formed, and this, by the further action of ethyl oxalate and sodium ethoxide, is converted into the disodium salt of ethyl acetonedioxylic acid, $\text{CO}\cdot(\text{CH}_2\text{CO}\cdot\text{COOEt})_2$. The latter is identical with ethyl xanthochelidonate, and is more stable than the acid, but is easily converted into ethyl chelidonate, or chelidonic acid, $\text{CO}\cdot\begin{matrix} \text{CH}_2\text{C}(\text{COOEt}) \\ \text{CH}_2\text{C}(\text{COOEt}) \end{matrix}\text{CO}\cdot$.

It is to be noted that on treating ethyl acetonoxalate with ethyl oxalate, the ethyl oxalate residue enters the methyl group, and not the group $-\text{CO}\cdot\text{CH}_2\text{CO}\cdot$. Probably other ethereal salts would give, with acetone, similar pyrone and xanthopyrone derivatives, and on treating these with ammonia, many new pyridine derivatives would be obtained. Ethyl acetonoxalate and ethyl acetonedioxylic acid correspond with the mono- and di-aldehyde derivatives of acetone. Compounds are easily prepared containing both an aldehyde and ethyl oxalate residue. Kerstiens has prepared such a compound by acting on acetone, first with an aldehyde then with ethyl oxalate. By heating, they are converted into derivatives of dihydropyrone. If, however, acetone be treated first with ethyl oxalate and then with an aldehyde, both the ethyl oxalate and aldehyde residues enter the same methyl group of the acetone, and a lactone is formed. The author restricts his attention to ethyl acetonedioxylic acid and its reactions, and reserves the last-named compounds for a later communication.

Ethyl acetonedioxalate (ethyl xanthochelidonate) is prepared by dissolving ethyl sodacetonoalate (5 grams) in hot ethyl oxalate (8 grams), and adding to the hot mixture a solution of sodium ethoxide (2 grams) in alcohol (10 c.c.).

The product is washed with hydrochloric acid and water, and purified by crystallisation from alcohol. 350 grams of ethyl sodacetonoalate yields about 320 grams of crude ethyl acetonedioxalate: this crystallises in slender prisms, melts at $103-104^{\circ}$, is somewhat easily soluble in hot alcohol, methyl alcohol, and benzene, and gives an intensely yellow solution with dilute alkalis. By prolonged boiling, it is partially converted into ethyl chelidonate. The alcoholic solution gives with ferric chloride an intense brown coloration, with ferrous sulphate a dark green; a greenish-yellow copper salt is precipitated by copper acetate, and a golden-yellow lead salt by lead acetate.

Chelidonic acid is obtained by heating the above compound with fuming hydrochloric acid, in a sealed tube, for one hour at 100° , or more easily by simply evaporating it a few times with fuming hydrochloric acid on the water-bath. It forms colourless needles, and gives all the reactions of natural chelidonic acid, but melts at 262° with charring and evolution of gas. The natural acid obtained from the celandine melts at 220° .

Ethyl chelidonate is obtained by saturating an alcoholic solution of ethyl xanthochelidonate with hydrogen chloride, and extracting the product with ether. It crystallises from alcohol in short, lustrous prisms, melts at 63° , and is crystallographically identical with ethyl chelidonate prepared from the natural chelidonic acid. E. C. R.

Oxidation of Gluconic Acid with Fehling's Solution. By W. TIEMANN (*Chem. Centr.*, 1890, ii, 742—743; from *Zrit. Vereins Rübenzuckerind.*, 1890, 787—789).—The author's investigation was made with a view to determine whether gluconic acid is oxidised to glyconic acid by Fehling's solution, such reactions being objectionable in the determination of sugar volumetrically. The author believes that the glyconic acid is formed, although no very definite result was obtained. J. W. L.

Action of Nitric Acid on Ethyl Methenyltricarboxylate. By A. P. N. FRANCHIMONT and E. A. KLOBBE (*Rec. Trav. Chim.*, 9, 220—222).—Ethyl methenyltricarboxylate is prepared by the action of ethyl chloroformate on ethyl sodiomalonate; it boils at $149-150^{\circ}$ under a pressure of 27 mm., and melts at 29° . It dissolves in nitric acid without development of heat, and on pouring the product into water an oily liquid separates of the composition $\text{NO}_2\cdot\text{C}(\text{COOEt})_3$; this is decomposed by warming with barium hydroxide solution, yielding 3 mols. of carbonic anhydride. T. G. N.

Action of Nitric Acid on Methane Di- and Trisulphonic Acids. By A. P. N. FRANCHIMONT and E. A. KLOBBE (*Rec. Trav. Chim.*, 9, 223—224).—Although a nitro-derivative of methane-

disulphonic acid is known to exist, the authors were unable to prepare nitro-derivatives by the action of absolute nitric acid on potassium methanedisulphonate and trisulphonate. T. G. N.

Preparation of Ethereal Salts of Furfuracrylic Acid. By L. CLAISEN (*Ber.*, 24, 143—144).—Ethyl furfuracrylate is easily prepared by a method similar to that which has been employed by the author for the preparation of ethyl cinnamate (*Abstr.*, 1890, 891). Sodium wire (1 mol.) is added to pure ethyl acetate (about 6 mols.), and furfuraldehyde (1 mol.) is gradually added to the well cooled mixture. When all the sodium has dissolved, acetic acid (1 mol.) is added, and then water. The salt is washed with soda, dried with calcium chloride, and distilled. It is a pale-yellow oil, and distils at 233—235° without decomposition. The acid prepared from it melts at 139—140° (compare Marckwald, *Abstr.*, 1883, 135). By this method 25 grams of ethereal salt are obtained from 40 grams of furfuraldehyde.

This condensation takes place easily only in the case of acetic acid; when homologues of acetic acid are employed, the yield is less the greater the molecular weight of the acid. E. C. R.

Oxidation Products of Brominated Thiophens. By A. ANGELI and G. CIAMICIAN (*Ber.*, 24, 74—78).—It has been shown by Ciamician and Zanetti (*Abstr.*, 1890, 264, 1155) that whereas by the action of an alkaline solution of hydroxylamine, the pyrrolines are converted, with varying difficulty, into the dioximes of the corresponding γ -diketones, the same reaction does not take place with the thiophens. The authors find, however, that brominated thiophens are converted by concentrated nitric acid into open chain derivatives, a reaction corresponding with the conversion of brominated pyrrolines into dibromomaleïnimide (*Abstr.*, 1887, 597; 1888, 61).

Tetrabromothiophen, when treated with nitric acid of sp. gr. 1.52, loses its sulphur and a portion of the bromine, and is converted into dibromomaleic acid, $\text{COOH}\cdot\text{CBr}\cdot\text{CBr}\cdot\text{COOH}$. Tribromo- β -thiotolen, under similar conditions, yields the anhydride of bromocitraconic acid, $\text{COOH}\cdot\text{CBr}\cdot\text{CMe}\cdot\text{COOH}$, identical with the compound obtained by Fittig and Krusemark (*Abstr.*, 1881, 416). α -Tribromothiotoleol yields a compound having the composition $\text{C}_8\text{H}_4\text{Br}_3\text{O}_3$, which crystallises in small, colourless needles melting at 78—79°, and is probably dibromacetylacrylic acid, $\text{C}(\text{AcBr})\cdot\text{CBr}\cdot\text{COOH}$. It is sparingly soluble in cold, readily in hot water, and in alcohol, ether, and benzene, the latter solution being precipitated by light petroleum. It gives a yellowish precipitate with phenylhydrazine consisting of fine, matted needles which appear to be a mixture, as the melting point lies between 84° and 100°. H. G. C.

Trithiënyl. By A. RENARD (*Compt. rend.*, 112, 49—50).—Sulphur vapour and benzene do not react at a dull-red heat, but if the mixture is passed through a tube heated to bright redness, there is obtained, together with carbon bisulphide, hydrogen sulphide, and

unaltered sulphur, a brownish liquid which, when distilled, yields unaltered benzene, and a yellow substance which soon solidifies. This last product is *trithienyl*, $C_6SH_3(C_6SH_3)_2$, and after purification by repeated crystallisation from boiling alcohol, it forms yellowish needles melting at 147° to a yellow liquid which boils at 357° ; vapour density 8.6. It is somewhat soluble in benzene, ether, and chloroform, but less soluble in alcohol, acetic acid, and light petroleum. When mixed with cold sulphuric acid, it becomes rose coloured, and on heating forms a violet solution which changes to blue. Water decolorises this solution, and precipitates unaltered trithienyl.

Trithienyl is not affected by boiling alkaline potassium permanganate, nor by ordinary nitric acid. The direct action of bromine in presence of carbon bisulphide yields *trithienyl hexabromide*, $C_{12}S_3H_3Br_6$, as an unstable, black, amorphous powder which loses all its bromine when exposed to the air, and is instantly decolorised by cold alcohol, ether, and benzene. *Tribromtrithienyl*, $C_{12}S_3H_3Br_3$, is obtained by the prolonged action of bromine at 100° in presence of acetic acid, and crystallises from benzene in slender, confused needles which melt at 282° , and are somewhat soluble in benzene, carbon bisulphide, and chloroform, especially when heated, but dissolve only slightly in acetic acid, and are insoluble in alcohol and ether. *Trithienyl isulphonic acid*, $C_{14}S_4H_5(HSO_3)_3$, is obtained by the action of fuming sulphuric acid at 115 – 120° ; its calcium salt is not crystallisable, and forms a very soluble, brown powder.

A compound, $C_{12}H_3S_3O_4$, is obtained by the action of fuming nitric acid in sealed tubes at 150 – 160° , or by the prolonged action of chromic acid in a boiling acetic acid solution. In both cases the product is precipitated by water and crystallised from acetic acid. It forms white plates which melt at 312 – 313° , but do not boil even at 400° ; it is insoluble in ether, carbon bisulphide, and light petroleum, very slightly soluble in benzene and chloroform, and slightly in acetic acid and in alcohol, especially on heating. Aqueous solutions of alkalis have no action on the compound, but it dissolves in nitric acid, and also in sulphuric acid at 100° , forming a colourless solution. It gives no characteristic coloration with sulphuric acid and isatin, or with phenanthraquinone.

O. H. B.

Direct Substitution in the Aromatic Series. By C. A. LOBBY DE BRUYN (*Rec. Trav. Chim.*, 9, 210–219).—The author takes exception to the statement of Laubenheimer that, when the two nitro-groups of a dinitro-derivative have the meta- or para-position, one cannot be displaced by a hydroxyl- or amido-group, and suggests the following empirical law in reference to dinitro-derivatives:—When either the nitro-group or the chlorine or bromine atom occupies the ortho- or the para-position in reference to a second nitro-group, the former group or atom can be replaced by a hydroxyl-, alkoxyl-, or amido-group, whereas this substitution does not occur when the first nitro-group occupies the meta-position in reference to the second nitro-group. Numerous examples are adduced which confirm the above general conclusions

T. G. N.

Conversion of Orthochloronitrobenzene and of Orthobromonitrobenzene into Orthonitranisole and Orthonitrophenetole. By C. A. LOBBY DE BRUYN (*Rec. Trav. Chim.* [3], 197—207).—Sodium alkyl oxides react with some halogen derivatives of benzene, substituting the alkoxide group for the halogen of the nucleus, and the author finds this reaction obtains in the cases of orthochloronitrobenzene and orthobromonitrobenzene.

To a solution of 1 : 2-orthochloronitrobenzene (3 grams) in methyl alcohol (15 c.c.) sodium methoxide (4 c.c. of a solution containing 0.0607 gram of sodium per c.c.) is added, and the mixture is heated in a sealed tube at 100° for six hours. After evaporation of the alcohol, the residue is treated with water, and the oily, yellow drops which separate are subjected to steam distillation, when nitranisole (2 grams) is obtained. The estimation of the chlorine in the residues proves the reaction to be quantitative.

1 : 2-Orthobromonitrobenzene when similarly treated, yields nitroanisole containing 4 per cent. of orthobromonitrobenzene.

When to a boiling mixture of orthochloronitrobenzene (2 grams) dissolved in alcohol (250 c.c.), sodium ethoxide (25 c.c. of a solution containing 0.0174 gram of sodium per c.c.) is added in successive portions of 15 c.c. and 10 c.c., an interval of 40 hours elapsing between the additions, there is obtained from the product of the reaction by treatment with weak aqueous soda and subsequent steam distillation, a yellowish-red liquid, which contains dinitrophenetole (80 per cent.) and unaltered orthochloronitrobenzene.

Orthobromonitrobenzene, when treated in like manner, yields a product which contains about 66 per cent. of phenetole.

From the above instances, the linkage of the chlorine atom to the benzene nucleus appears to be less strong than that of the bromine atom, which is a condition the reverse of that obtaining in the fatty series.

T. G. N.

Unsymmetrical Trinitrobenzene (1:2:4). By C. A. LOBBY DE BRUYN (*Rec. Trav. Chim.* [3], 184—196).—Paranitrobenzene (40 grams) is heated with a mixture of nitric acid (sp. gr. 1.52) and sulphuric anhydride for six days, at a temperature which is gradually increased from 50—155°; the contents of the flask are then poured into cold water, and the mass, after washing, is treated with chloroform, and the yellow substance which this solvent extracts, is washed with weak sodium carbonate solution, dried, and distilled in a current of carbonic anhydride at 150°. By this means, any excess of paranitrobenzene is removed from the trinitrobenzene remaining in the retort, and it is purified by boiling with nitric acid (sp. gr. 1.4), from which it crystallises on cooling, and then recrystallising from ether, or from methyl or ethyl alcohol acidified with hydrochloric acid.

As thus obtained, trinitrobenzene (1 : 2 : 4) forms transparent, yellow crystals melting at 57.5°, and of sp. gr. 1.725—1.73 at 15.5°. It is very soluble in benzene, less so in chloroform, ether, methyl and ethyl alcohols, and but sparingly in carbon bisulphide (tables of solubility are given). The crystals enter into a condition of super-

fusion, and on evaporation of the chloroform or benzene solution it remains liquid for months, unless rubbed, when it solidifies.

By the action of a dilute solution of sodium methoxide in methyl alcohol, it is converted into dinitranisöl (1 : 2 : 4), an almost quantitative yield being obtained, and a similar reaction obtains with sodium ethoxide; in this case some dinitrophenol is also formed, the yield depending directly on the concentration of the sodium ethoxide solution and on the temperature; thus, at the ordinary temperature with dilute sodium ethoxide solution, the yields corresponded with respective conversions of 74 per cent. and 62 per cent. of the tri-derivative into dinitrophenetöl, and 4 per cent. and 6 per cent. into dinitrophenol; in the case of strong solutions at a higher temperature, 11 per cent. was converted into dinitrophenetöl, and 60 per cent. into dinitrophenol.

Sodium hydroxide acts in a complex manner on the substance, but when it is heated with sodium carbonate solution, or with very dilute soda, dinitrophenol (1 : 2 : 4) is formed to the extent of 90 per cent. and 55 per cent. respectively of the trinitrophenol used.

Potassium cyanide and trinitrobenzene (1 : 2 : 4), dissolved in methyl alcohol, react at 25° to form dinitranisöl.

When trinitrobenzene is heated in sealed tubes with methyl alcohol at 150° it yields dinitranisöl, and similar treatment with water affords dinitrophenol (1 : 2 : 4). T. G. N.

Symmetrical Dinitrophenol. By C. A. LOBBY DE BRUYN (*Rec. Trav. Chim.*, 9, 208).—Dinitranisöl is prepared by heating solutions of trinitrobenzene (1 : 3 : 5), and of sodium methoxide in methyl alcohol at 80° for 30 minutes. The dinitranisöl thus obtained as long, white needles melting at 105°, is heated with concentrated hydrochloric acid in sealed tubes at 170—180° for 5—6 hours, and the crystalline, reddish product is purified by pouring its solution in concentrated hydrochloric acid into water.

As thus obtained, *o*-dinitrophenol forms silky needles, melts at 122°, is not attacked by dilute nitric acid, but dissolves in it, and crystallises out again in clear needles, whereas concentrated nitric acid (sp. gr. 1.4) forms with the substance a compound which melts at 173°. The author is continuing the research. T. G. N.

Metanitroparamidophenol and its Derivatives. By H. HÄHLI (*J. pr. Chem.* [2], 43, 62—75).—Diacetylparamidophenol is best prepared by adding paramidophenol which has been dried quickly in a stream of hydrogen at 130—140° to double its weight of acetic anhydride, heating in a reflux apparatus for half an hour, distilling, and recrystallising the residue from water.

Nitrodiacetylparamidophenol is obtained by adding diacetylparamidophenol (1 part) by degrees to red fuming nitric acid (1½ parts) cooled by ice, and, when the liquid has become syrupy, pouring it into ice-cold water, and recrystallising the precipitate from alcohol. It forms brilliant, sulphur-yellow prisms which melt at 146—147°, and are decomposed at 260°; it is sparingly soluble in water, but more freely in glacial acetic acid, alcohol, and ether.

Metanitroparamidophenol (compare Hübner, *Abstr.*, 1882, 506) is

easily obtained by heating the diacetyl derivative with sodium hydroxide, and then precipitating with an acid. From ether it crystallises in dark-red prisms with a green lustre, melting at 148° , and from water in the same form with 1 mol. H_2O ; it also dissolves in alcohol and chloroform. The *hydrochloride* and *sulphate* are described; also the *potassium* and the *tetramethylammonium* compounds. When the latter is heated, a small quantity of *nitroparanisidine* is formed; this crystallises in dark-red prisms, melts at 123° , dissolves in water, alcohol, and ether, sparingly in benzene, and volatilises with steam; its *acetyl* derivative melts at 115° ; its *hydrochloride* is described.

Metanitroparadiazophenol chloride is obtained by passing nitrous acid through a cooled solution of metanitroparamidophenol, in alcohol containing some strong hydrochloric acid; it crystallises in colourless, microscopic prisms, explodes in a closed tube at 126 – 129° , and is sparingly soluble in water and alcohol, but insoluble in ether; the *perbromide* is described. When heated with absolute alcohol under pressure (790–800 mm.) it is converted into metanitrophenol; this settles the constitution of the above nitroamidophenol.

Metaparamidophenol (Köhler, Abstr., 1884, 1159), obtained by the usual reducing process, crystallises in colourless, microscopic prisms, and melts with decomposition at 167 – 168° ; its hydrochloride is oxidised by ferric chloride to a red substance, probably a derivative of the red substance obtained by Griess, and others (Abstr., 1884, 1322; 1889, 500); its *sulphate* and *triacetyl*-derivative (melting at 135 – 136°) are described.

Metaparamidoanisole hydrochloride, obtained by reducing metanitroparanisidine, forms colourless, lustrous leaflets, dissolves in water with a brown colour, and yields a red colouring matter when oxidised.

Metanitropariodophenol is produced by the action of hydriodic acid on metanitroparadiazophenol chloride; it crystallises in yellow needles melting at 156° , dissolves in most solvents, and is not volatile with steam; the *potassium* and *silver* compounds are described; the *acetyl*-derivative melts at 107.5° , and begins to boil with decomposition at 260° . *Metanitropariodophenetol* forms microscopic, yellow needles, melts at 63.5° , and distils with decomposition at 320° . A. G. B.

Quantitative Investigation of Reduction Processes. By K. ELBS (*J. pr. Chem.* [2], 43, 39–46).—An electric current was passed through a galvanometer, and then through a decomposing cell containing either an acid or alkaline solution of the substance to be reduced. The anode was separated from the cathode by a porous plate, and a tube was provided whereby the evolved hydrogen could be collected and measured. The electrodes were platinum foil of 15.6 sq.c. surface; the current was generated by 2–4 Bunsen's cells; the readings were taken every five minutes, and averaged on one hour.

The amount of hydrogen consumed in reducing the substance present is the difference between the amount actually evolved and the amount which should theoretically be evolved, as calculated from the intensity of the current shown by the galvanometer. The strength of

the solution, the intensity of the current, the hydrogen liberated thereby, the hydrogen evolved, the hydrogen used in reduction, and the temperature are given in each experiment.

The substances experimented on were orthonitrophenol, paranitrophenol, orthoparadinitrophenol, and picric acid; they were dissolved in water or alcohol of different strengths, generally to the extent of 0.01 or 0.1 gram-molecule per litre; the quantity of sulphuric acid added was generally 2, but sometimes 4 gram-molecules; where sodium hydroxide was used, 2 gram molecules were added.

The author has not classified his results, and, inasmuch as nearly every condition varies in every experiment, it is difficult to see any relation between them. A stronger current does not bring about a proportionally greater reduction, a less percentage of hydrogen being consumed. Greater reduction occurs in alkaline than in acid solution. The order of reducibility of the substances experimented on is the same as that in which they are quoted above, the position of the nitro-group seemingly influencing it; for a general conclusion, however, the author requires a more extensive series of experiments.

A. G. B.

Phenol of Birchwood Tar. By M. PFRENGER (*Arch. Pharm.*, 1228, 713—719).—*Oleum betulini ætherium rectificatum* was the raw material employed; it is a brownish-yellow refracting liquid with acid reaction and sp. gr. 0.956 at 15°. The liquid was freed from acid by means of sodium carbonate, washed with water, and treated repeatedly with aqueous potash to obtain the phenoxide. From the latter, the phenol was separated by sulphuric acid, taken up with ether, well washed, and finally dried with sodium sulphate. The purified phenol was fractionated. After numerous operations, a fraction, 181° to 191, probably cresol with a small amount of phenol, was obtained. The fraction 191° to 200°, when heated with zinc-dust, yielded mainly toluene and a little anisole. The same fraction, when heated at 150° with methyl iodide and some methyl alcohol, yielded methyl cresyl ether and a little catechol dimethyl ether. The fraction 200° to 205° was dissolved in ether and heated at 80° with alcoholic potash; on cooling, the long needles of the potassium salt were collected, dissolved in water, and decomposed by hydrochloric acid, after which the separated compound was purified, and found to be guaiacol. The same fraction heated at 150° with methyl iodide yielded mainly catechol dimethyl ether and a little methyl cresyl ether.

The fraction 206° to 211°, when fused with potassium hydroxide, yielded, as the only definite product, hydroxyisophthalic acid. The fraction 218° to 224° gives the reactions of monomethyl homoxycatechol (creosol). The constituents of birchwood tar creosote are traces of phenol, cresol, guaiacol, 1.3.4-xyleneol and 1.3.4-creosol, the third and last compounds forming the bulk.

J. T.

Constitution of Quinone. By F. KEHRMANN (*J. pr. Chem.* [2], 43, 106—110).—It was a work of supererogation on the part of Nef to prove that the anilic acids contain two hydroxyl groups (*Abstr.*, 1890, 1271), as this has already been generally accepted.

The tendency of quinone to form additive products with 2 and 4 atoms of bromine (*loc. cit.*), which enter in pairs into the ortho-position, is no better evidence for Fittig's than for Claus's formula for quinone. Analogy cannot be drawn between Baeyer's additive products of terephthalic acid and additive products of quinone, for the latter is an oxygen additive product, whilst hydroterephthalic acids are hydrogen additive products. The possibility that bromine may attach itself to the oxygen atom in quinone, and not to the carbon atom, must not be overlooked.

Colour Reactions of Aromatic Amines. By C. LAUTH (*Compt. rend.*, 111, 975—977).—The author has extended the reaction with lead peroxide to a large number of amines. One drop of a liquid amine, or an equivalent quantity of a solid, is mixed in a watch glass with 10 drops of a mixture of 3 vols. of acetic acid of 8° and 7 vols. of water. Fragments of lead peroxide are placed near the edge of the watch glass, and by inclining the latter the liquid is made to touch the peroxide. A similar experiment should be made with an alcoholic solution of acetic acid of similar dilution, since some of the bases are not soluble in aqueous acetic acid. The colour reactions in the second case are sometimes different, in consequence of the presence of oxidation products of the alcohol. The following results were obtained, the second series of colours being those obtained with the alcoholic solution:—

Aniline, very fugitive violet-red, changing to red-brown; with alcohol the same. *Methylaniline*, blue-green, violet, blue, olive; violet, red-violet, olive. *Dimethylaniline*, orange, grass-green, olive-green, grey; orange-green. *Ethylaniline*, blue-green, blue, violet, olive; violet, violet-black, olive. *Diethylaniline*, bright orange, yellow; greenish-yellow. *Benzylaniline*, red-brown, reddish-violet, grey; yellowish-grey, green. *Methylbenzylaniline*, orange, greenish-yellow, grey-green; bright green, blue-green, violet. *Ethylbenzylaniline*, orange; olive, bright green, olive. *Diphenylamine*, very faint violet-grey; bright green, olive. *Methyldiphenylamine*, magenta-red, violet, brown; violet-brown. *Paratoluidine*, bright blood-red, brown-red; bright blood-red. *Orthotoluidine*, dragon-green, violet; red-violet, brown-violet, orchil-colour. *Dimethylparatoluidine*, green-brown, dull yellow; green-brown, dull yellow. *Dimethylorthotoluidine*, bright orange-red, orange-brown; green-brown, olive. *Xylidine* (meta- α -, meta- β -, and a mixture of ortho- and para-), blue-violet, dark-grey; violet-red, orchil-colour. *Paraphenylenediamine*, bright blue-green, brown; bright blue-green, brown. *Metaphenylenediamine*, brown; brown. *Dimethylparaphenylenediamine*, magenta-red, blue-violet, violet-black; magenta-red, blue-violet, blue-black. *Dimethylmetaphenylenediamine*, faint yellow-brown; yellow-brown. *Toluylenediamine*, bright brown-red; bright brown-red. *α -Naphthylamine*, very faint blue-violet; very faint blue-violet. *β -Naphthylamine*, very faint brown-yellow; very faint reddish-brown. *Dinaphthylamine*, bright madder-red, opaque-white; madder-red, only slightly soluble. *Benzidine*, intense pure blue, violet, red; yellow solution and blue precipitate. *Tetramethylbenzidine*, grass-green,

orange in presence of excess of acid; grass-green. *Dimethylortho-anisidine*, magenta-violet, dull violet; grey-green, olive. *Dimethyl-metanisidine*, yellow-brown; yellow-brown. C. H. B.

Orthamidoparaditolylamine. By O. FISCHER and L. SIEDER (*Ber.*, 23. 3798—3802).—*Orthamidoparaditolylamine*,

is prepared by reducing orthonitroditolylamine (Abstr., 1882, 1059) with tin and hydrochloric acid, removing the tin with hydrogen sulphide, and precipitating the base with alkali. It crystallises from light petroleum in beautiful, colourless prisms, which quickly assume a brownish-red colour in the air; it melts at 109°, and dissolves in concentrated sulphuric acid with a beautiful, blue coloration, which changes to green on boiling or remaining for some time. The *hydrochloride* and *oxalate* crystallise in beautiful, colourless needles, the latter being almost insoluble in cold water. The *picrate*, $\text{C}_{11}\text{H}_{18}\text{N}_2 \cdot \text{C}_6\text{H}_3\text{N}_3\text{O}_7$, forms brownish-red crystals. On long-continued boiling with an excess of acetic anhydride, the diamine is converted into the *acetyl* compound, $\text{C}_{11}\text{H}_8\text{N}_2\text{Ac}$, which crystallises from alcohol in white prisms melting at 126°.

When an alcoholic solution of the diamine is boiled with carbon bisulphide for 8—10 hours, it is converted into the corresponding *thiocarbamide*, $\text{C}_6\text{H}_3\text{Me} \cdot \text{N}(\text{C}_7\text{H}_7) > \text{CS}$, which is separated from a little adhering yellow colouring matter by repeated crystallisation from alcohol, and then forms colourless prisms melting at 270°. It is insoluble in water, sparingly soluble in light petroleum, readily in hot alcohol and benzene, and also soluble in concentrated sulphuric acid with a green colour.

The diamine condenses with aldehydes like other orthodiamines, forming anhydro-bases which may be regarded as derivatives of dihydroamidines. Benzaldehyde yields a compound having the constitution $\text{C}_6\text{H}_3\text{Me} \cdot \text{N}(\text{C}_7\text{H}_7) > \text{CHPh}$; the crude, reddish-yellow, crystalline compound is purified by frequent crystallisation from alcohol with addition of animal charcoal, and then forms stellate groups of colourless needles, and melts at 156°. The *hydrochloride* forms long, colourless prisms; the *platinochloride*, $(\text{C}_{21}\text{H}_{20}\text{N}_2)_2 \cdot \text{H}_2\text{PtCl}_6$, orange crystals melting at 271°; and the *aurochloride*,

golden-yellow needles. The anhydro-compound obtained from salicylaldehyde separates from alcohol in yellow crystals; it melts at 160°, and is sparingly soluble in water, alcohol, and hydrochloric acid, readily in benzene and hot dilute sulphuric acid. The orthonitro-benzaldehyde-derivative forms radiating, yellow crystals, and melts at 113°.

On addition of ferric chloride to a solution of the base in alcoholic hydrochloric acid, a blood-red solution is obtained, from which almost black crystals with a steel-blue lustre separate. These contain

iron, and on treatment with ammonia assume a beautiful, red colour. The separated red flakes are carefully washed, dried, and extracted with benzene, which leaves hydrated ferric oxide as a residue. On concentrating the extract, or adding a little light petroleum, garnet-red, spear-shaped needles or narrow plates separate. This substance melts at 188° , decomposes on more strongly heating, and is fairly soluble in benzene, toluene, and boiling alcohol, sparingly in light petroleum. It is a feeble base, the salts of which are decomposed by water. Its formation is represented by the following equation:— $2C_{14}H_{16}N_2 + 2O = C_{28}H_{27}N_3O + NH_3 + H_2O$. Unlike the oxidation product of orthodiamidobenzene, its solutions show no fluorescence, and it appears to belong to a new class of compounds, of which the oxidation product of metaparatoluylenediamine is also a member. This has the composition $C_{14}H_{15}N_3O$, and crystallises from methyl alcohol in brownish-red crystals melting at $246-247^{\circ}$.

H. G. C.

Action of Phosphorus Chloride on Aromatic Tertiary Amines. By A. MICHAELIS and A. SCHENK (*Annalen*, 260, 1-39; compare Abstr., 1888, 834).—*Paraphenylenedimethylaminedimethylphosphine*, $PMe_2 \cdot C_6H_4 \cdot NMe_2$, is obtained by gradually adding the theoretical quantity of dimethylamidophosphoryl chloride to zinc methyl, both compounds being previously dissolved in benzene, and the reaction being carried out in the cold and in an atmosphere of dry carbonic anhydride; the benzene is then distilled off in an atmosphere of carbonic anhydride, the residual zinc compound treated with excess of dilute soda, and the phosphine extracted with ether. It is a colourless, highly refractive liquid, boils at 265° , is lighter than water, and very readily oxidises on exposure to the air; it solidifies, when cooled, to a transparent, crystalline mass which melts at 10° .

Paraphenylenedimethylaminedimethylphosphine oxide,

is formed when the phosphine is exposed to the air, or, more quickly, when it is heated with finely divided mercuric oxide; it crystallises from hot ether in slender, colourless needles, melts at 62° , and is very readily soluble in alcohol and chloroform.

The *sulphide*, $PSMe_2 \cdot C_6H_4 \cdot NMe_2$, is best prepared by treating the phosphine with the theoretical quantity of sulphur in chloroform solution; it crystallises from hot alcohol, in which it is very readily soluble, in colourless needles, melts at 155° , and turns yellow on exposure to light.

The compound $PMe_2 \cdot C_6H_4 \cdot NMe_2 \cdot CS_2$ is produced by the direct combination of its constituents, the reaction being very energetic; it is a red powder, melts at 162° , and is sparingly soluble in alcohol.

Paraphenylenedimethylaminetrimethylphosphonium iodide,

prepared by treating the phosphine with methyl iodide in well-cooled ethereal solution, crystallises from alcohol in colourless needles, melts at $26\frac{1}{2}^{\circ}$, and turns yellowish on exposure to light.

The compound $PIMe_2Et \cdot C_6H_4 \cdot NMe_2$, obtained by treating the base

with ethyl iodide under the same conditions, crystallises in colourless needles, melts at 199° , and turns yellowish on exposure to light.

Paraphenylenedimethylaminediethylphosphine, $\text{PEt}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2$, is formed when dimethylamidophosphenyl chloride is treated with zinc ethyl as described in the case of the corresponding dimethyl derivative. It is a colourless liquid, boils at 298° , and solidifies when cooled, melting again at 12.5° ; it oxidises on exposure to the air, combines readily with bromine, and dissolves freely in hydrochloric acid, sulphuric acid, &c. The *oxide*, $\text{POEt}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2 + \text{H}_2\text{O}$, prepared by heating the phosphine with mercuric oxide, crystallises from ether in thick, transparent needles, melts at 65° , and is very readily soluble in alcohol and chloroform. The *sulphide*, $\text{PSEt}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2$, is a colourless, crystalline compound melting at 148° . The compound $\text{PEt}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2\cdot\text{CS}_2$ crystallises in small, red plates, melts at 107° , and is insoluble in ether, but soluble in alcohol and hydrochloric acid.

Paraphenylenedimethylaminediethylmethylphosphonium iodide,

formed by the combination of the phosphine with methyl iodide, separates from alcohol in colourless crystals, melts at 186° , and is readily soluble in chloroform, but insoluble in ether. The corresponding *triethyl* derivative, $\text{PIEt}_3\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2$, is formed when the phosphine is warmed with ethyl iodide; it crystallises from alcohol in thick, colourless needles, melts at 180° , and is insoluble in ether, but readily soluble in chloroform.

Paraphenylenedimethylaminediphenylphosphine oxide,

is obtained when the corresponding phosphine (*loc. cit.*) is boiled with excess of ferric chloride; it separates from hot dilute alcohol in colourless, moss-like crystals, melts at 183.5° , and is readily soluble in alcohol, chloroform, and concentrated hydrochloric acid, but insoluble in water. The *sulphide*, $\text{PSPPh}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2$, prepared by boiling the phosphine with a carbon bisulphide solution of the theoretical quantity of sulphur, crystallises in slender, colourless needles, melts at 183° , and is readily soluble in alcohol and chloroform.

Paraphenylenedimethylaminediphenylmethylphosphonium iodide,

is a thick, yellowish oil; when treated with silver oxide in hot alcoholic solution, it is converted into a deliquescent, crystalline, strongly alkaline hydroxide, the *platinochloride* $(\text{PPh}_2\cdot\text{C}_6\text{H}_4\cdot\text{NMe}_2)_2\cdot\text{H}_2\text{PtCl}_6$, of which separates from alcohol in orange plates.

Phenylenedimethylaminephenylmethylphosphine oxide,

is formed when a solution of the hydroxide just referred to, or of the corresponding iodide, is boiled with potash; it separates from a mixture of chloroform and light petroleum in compact crystals, melts at 146° , and is very readily soluble in most ordinary solvents.

Diethylamidophosphenyl chloride, $\text{POCl}_2\cdot\text{C}_6\text{H}_4\cdot\text{NEt}_2$, prepared as described in the case of the corresponding dimethyl compound (*loc. cit.*), is a thick, reddish oil, readily soluble in benzene, ether, and alcohol.

Methylbenzylamidophosphenyl chloride, $\text{PCl}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NMe} \cdot \text{C}_7\text{H}_7$, obtained in a similar manner, is a reddish oil, and resembles the diethyl-derivative in its properties.

Methylbenzylamidophosphinic acid, $\text{P}(\text{OH}_2) \cdot \text{C}_6\text{H}_4 \cdot \text{NMe} \cdot \text{C}_7\text{H}_7$, obtained by decomposing the sodium salt (see below) with dilute hydrochloric acid, crystallises from water or very dilute alcohol in small, slender needles, melts at 96° , turns greenish on exposure to the air, and is soluble in acids and alkalis. The sodium salt,

is deposited in colourless needles or plates when methylbenzylamidophosphenyl chloride is decomposed with water, the solution neutralised with sodium carbonate, evaporated to dryness, and the residue extracted with hot alcohol; it melts at 233° .

Ethylbenzylamidophosphenyl chloride, $\text{PCl}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NEt} \cdot \text{C}_7\text{H}_7$, prepared from ethylbenzylamine, is an oil.

Methylphenylamidophosphenyl chloride, $\text{PCl}_2 \cdot \text{C}_6\text{H}_4 \cdot \text{NMePh}$, is also an oil; when treated with concentrated soda, it solidifies to a mass of crystals of sodium methylphenylamidophosphinate,

This salt crystallises from alcohol in colourless, lustrous plates, melts at 265° , and is very readily soluble in water, but almost insoluble in benzene and chloroform. The corresponding acid,

crystallises from hot water in small needles and from alcohol in nacreous plates, and melts at 150.5° . F. S. K.

New Synthesis by means of Diazo-compounds. By R. HIRSCH (*Ber.*, 23, 3705—3710).—The author, when preparing phenol by a synthetical method which has lately been used commercially, namely the decomposition of diazobenzene salts by boiling, has never obtained anything like a theoretical yield, and an examination of the bye-products led to the following results:—

If aniline hydrochloride is diazotised and the solution warmed until all the diazo-compound is destroyed, and then distilled as long as any trace of phenol comes over, the residue consists of a brownish liquid and a small quantity of resin, and deposits crystals after a time. These crystals were identified as parahydroxydiphenyl, $\text{C}_{12}\text{H}_{10}\text{O}$. Nitrohydroxydiphenyl is also formed in the reaction when an excess of nitrite is used, or when the diazo-solution is not allowed to remain long enough for the complete absorption of the nitrite. As it is probable that the hydroxydiphenyl is formed from phenol and diazobenzene, a solution of diazobenzene was shaken with phenol with the following results:—500 c.c. of diazobenzene solution, corresponding with 50 grams of aniline, was shaken with 500 grams of phenol containing 10 per cent. of water; the phenol solution increased in weight to 615 grams, and the aqueous solution contained only hydrochloric acid, sodium chloride, and phenol. The author supposes this phenol solution to contain oxyazobenzene, $\text{C}_6\text{H}_5 \cdot \text{N} \cdot \text{OC}_6\text{H}_5$.

It evolves gas after a time in the cold, and decomposes violently on heating. It was cautiously decomposed in a reflux apparatus, and the phenol solution washed with strong salt solution and distilled. The portion boiling above 200° was mixed with twice its weight of toluene and extracted with 10 per cent. aqueous soda. The soda solution is coloured intensely blue and absorbs considerable quantities of oxygen. The product insoluble in soda, on distillation, gave, between 260° and 290° , diphenyl ether, OPh_2 , to the extent of about 50 per cent. on the aniline used, and between 320° and 350° a neutral oil which is believed to be the ether, $\text{C}_{12}\text{H}_9\text{OPh}$.

The soda solution was covered with half its volume of toluene and acidified with constant shaking. On distillation of the toluene, a small quantity of phenol was obtained, and, between 260° and 300° , a mixture of parahydroxydiphenyl and orthohydroxydiphenyl to the extent of more than half the weight of aniline employed.

The blue compound, owing to the small yield, could not be isolated. It, however, forms an easily oxidisable leuco-compound, and behaves like a solution of paradihydroxydiphenylamine.

The author has obtained similar results with the homologues of aniline, and with benzidine and naphthylamine; and also when ortho-, meta-, or para-cresol is substituted for phenol. The phenols obtained give excellent yields of the corresponding hydrocarbons when heated with zinc-dust. On nitration in acetic acid solution, well crystallised nitro-compounds are formed. The description of the new compounds is reserved for a later communication.

E. C. R.

Action of Phenylhydrazine on α -Hydroxy-acids and their Ethereal Salts, II. By A. REINERT and W. KAYSER (*Ber.*, 23, 3701—3705).—The authors have already studied the action of phenylhydrazine on α -hydroxybutyric acid and mandelic acid (*Abstr.*, 1896, 155); the present paper deals with the further study of the action of phenylhydrazine on mandelic acid and its ethereal salts.

When the reaction between mandelic acid and phenylhydrazine is brought about quickly (within an hour), pseudophenylhydrazidomandelic acid is formed; if, however, the mixture is heated for a day at 150° , a mixture of pseudophenylhydrazidomandelic acid and mandelic anilide is obtained, which cannot be separated by crystallisation.

Mandelic anilide, $\text{OH}\cdot\text{CHPh}\cdot\text{CO}\cdot\text{NHPh}$, obtained from the above mixture by extraction with acetic anhydride, melts at 146° , crystallises from water in beautiful, iridescent plates and dissolves easily in alcohol, ether, benzene, chloroform, and acetic acid, sparingly in light petroleum; this solvent precipitates it from its solution in benzene or chloroform. The ethyl salt of mandelic acid yields with phenylhydrazine the anhydride of phenylhydrazidophenylacetic acid, $\text{CO}\cdot\text{CHPh}\cdot\text{N}_2\text{HPh}$ (which melts at $165\text{--}166^{\circ}$), together with varying quantities of pseudophenylhydrazidomandelic acid and benzylidene-phenylhydrazine (m. p. 153°).

Dibenzylpseudophenylhydrazidomandelic acid, $\text{C}_{22}\text{H}_{22}\text{N}_2\text{O}_4$, obtained by the action of benzoic chloride on pseudophenylhydrazidomandelic

acid, crystallises from alcohol in colourless needles, melts at 208° , and is easily decomposed into benzoic and mandelic acids and phenylhydrazine. *Nitrosopseudophenylhydrazidomandelic acid*, $C_{14}H_{13}N_3O_3$, obtained by the action of nitrous acid on pseudophenylhydrazidomandelic acid, is very unstable, decomposes at about 70° , and is an acid whose salts with the heavy metals are extremely unstable. E. C. R.

Determination of the Spacial Configuration of Stereoisomeric Oximes. By A. HANTZSCH (*Ber.*, 24, 13—31; see also *Abstr.*, 1890, 348, 970, 1263, 1273).—I. *The Configuration of Stereoisomeric Aldoximes.*—In their first paper on the “asymmetrical nitrogen atom,” Hantzsch and Werner, in agreement with the results of Goldschmidt, adopted the view that the two benzaldoximes are structurally identical, and that their isomerism is due to stereo-
metrical causes, as represented by the formulæ, $\begin{array}{c} \text{Ph} \cdot \text{C} \cdot \text{H} \\ | \\ \text{HO} \cdot \text{N} \end{array}$ and $\begin{array}{c} \text{Ph} \cdot \text{C} \cdot \text{H} \\ | \\ \text{N} \cdot \text{OH} \end{array}$.

The structural identity of these and similar oximes, which has been disputed by many chemists (*Abstr.*, 1890, 1121, 1412), follows from the fact that the acetyl derivatives of the β -oximes are converted by traces of hydrogen chloride or of acetic chloride at the ordinary temperature into the acetyl derivatives of the α -oximes, whereas, as already frequently shown, hydrogen chloride has the reverse action on the oximes themselves, converting the α - into the β -compound. This is in full agreement with Hantzsch and Werner's formulæ, whereas, to explain it according to the formulæ given by Beckmann, namely,

it is necessary to assume that a far reaching intramolecular change takes place, including a migration of the acetyl group from the nitrogen atom to the oxygen atom. Further, both α - and β -acetyl compounds are equally readily converted by soda or ammonia at the ordinary temperature into the original oximes, whilst, if in the one case the acetyl group were combined with oxygen, and in the other with nitrogen, some difference would almost certainly be noticed in their stability towards alkalis.

Hantzsch and Werner assigned to β -benzaldoxime the second of the formulæ given above, as it readily yields benzonitrile by loss of the elements of water. The validity of this argument was, however, disputed by Beckmann (*Abstr.*, 1890, 1121), who maintained that benzamide is the first product of the reaction, and that this then loses water, forming the nitrile. The author, as is shown in detail in a subsequent abstract, finds that, in reality, benzonitrile is obtained directly, and that the benzamide found is really formed from the latter by the assumption of the elements of water. Moreover, not only β -benzaldoxime, but all β -aldoximes under certain conditions, readily yield nitriles at the ordinary temperature, whilst under the same circumstances the α -oximes yield no trace of nitrile. This reaction, therefore,

affords a ready means of ascertaining to which group any particular oxime belongs, it being assumed in this, as in the case of maleic acid, &c., that the groups between which the reaction takes place occupy an adjacent position in the molecule. The conversion of the β -aldoximes into nitriles is represented as follows:—

The β -oximes themselves do not usually pass directly into the nitriles, but their acetyl derivatives, which, as above stated, are reconverted by soda or ammonia into the original compound, are reolved by the alkaline carbonates into the nitrile and acetic acid:—

The isolation of the β -acetyl derivatives is a matter of considerable difficulty, although when once obtained in a condition of purity, they are fairly stable, and may be recrystallised from most indifferent solvents. As, however, the mere blowing of a little hydrogen chloride or acetic chloride vapour on to them is sufficient to convert them into the α -compounds it is necessary to use acetic anhydride in their preparation, and to avoid all traces of mineral acids. For the simple determination of the configuration of an oxime, it is, however, unnecessary to isolate the acetyl derivative, the oxime being simply boiled with acetic anhydride, poured into iced water, filtered if necessary, and treated with solid sodium carbonate. The oil which separates is the acetyl derivative if the oxime is an α -compound, and the nitrile if it is a β -compound. The latter is detected by the odour and also by the fact that it does not dissolve in soda in the cold or on gentle warming.

II. *Configuration of Stereo-isomeric Ketoximes.*—Hitherto the only ketoximes concerning which any conclusion as to their configuration could be drawn, were those of the benzile group, no facts having been discovered which throw light upon the configuration of the stereo-isomeric asymmetrical monoximes. The author now finds that this may be ascertained by a reaction which has long been known, namely, the conversion of the aromatic ketoximes into the isomeric acid anilides. Thus Beckmann found that benzophenoxime may be converted into benzanilide:—

With asymmetrical ketoximes, this reaction might take place in two different ways, as shown by the equation

In all the cases investigated by Beckmann and his pupils, the reaction proceeds in one and the same manner. As stereo-isomeric oximes were then unknown, the author has re-investigated this

isomeric change with such isomerides, and finds that, in fact, the change takes place in a different manner in the two cases. Although the nature of this reaction is not yet fully understood, it appears probable that the hydroxyl combined with the nitrogen atom changes places with one of the groups combined with the neighbouring carbon atom, the tautomeric form of the acid amide containing the group $C(OH).N$ being first formed. In the case of stereo-isomeric oximes, that radicle will change places with the hydroxyl which is nearest to it in space. With the formulæ employed by Hantzsch and Werner for the oximes, this intramolecular change is represented in the following manner:—

The behaviour of the benziledioximes likewise confirms this supposition, for β -benziledioxime, to which Hantzsch and Werner for other reasons assigned the constitution $\begin{array}{c} Ph \cdot C \cdot C \cdot OPh \\ | \quad | \\ H \cdot ON \quad N \cdot OH \end{array}$, is readily converted into oxanilide, whilst α -benziledioxime, which received the asymmetrical formula $\begin{array}{c} Ph \cdot C \text{---} C \cdot Ph \\ | \quad | \\ N \cdot OH \quad N \cdot OH \end{array}$, behaves in reality as an asymmetrical compound in Beckmann's reaction.

In the case of stereo-isomeric asymmetrical ketoximes, it is, therefore, possible to determine the configuration by means of the acid amide which it forms in Beckmann's reaction, the hydroxyl group being closer to that radicle which is found combined with the nitrogen in the amide. Thus, the two isomeric oximes of paramethoxybenzophenone, $NOH \cdot CPh \cdot C_6H_4 \cdot OMe$, yield respectively anisanilide, $MeO \cdot C_6H_4 \cdot CO \cdot NHPh$, and benzaniside, $COPh \cdot NH \cdot C_6H_4 \cdot OMe$, in a pure condition. In most cases, however, it happens that only one of the oximes yields a pure product, the second giving a mixture of the two acid amides, owing to the fact that the labile oxime has in the reaction undergone a partial transformation into the more stable derivative. Thus, for example, the higher melting oxime of phenyl tolyl ketone yields pure paratoluylanilide, whilst the lower melting isomeride gives a mixture of the same compound with benzoparatoluidide, the latter being formed in larger quantity. The same holds good for the oximes of meta- and para-chlorobenzophenone. This reaction, therefore, also renders it possible to determine which is the stable, and which the labile, form. In most cases, the stable form is that in which the hydroxyl is nearest to the unsubstituted radicle, but in certain cases, such as paramethoxybenzophenone, the reverse is the case.

The nature of the acetyl derivatives of these oximes also corresponds exactly with the behaviour of the latter in the above intramolecular change, the stable forms yielding the stable acetyl

compounds, whilst those giving a mixture of amides form acetyl derivatives which readily pass into the stereo-isomeride.

Hitherto it has not been possible to use any systematic nomenclature for the stereo-isomeric ketoximes, but in view of the above results, the author proposes to use the prefix α - for those in which the hydroxyl occupies the adjacent position to the unsubstituted phenyl or other radicle, and the prefix β - for those in which the hydroxyl and substituted radicle are adjacent, as shown in the formulæ:—

The benzilemonoximes and phenyltolylloximes then retain their present names; the three benziledioximes, however, which have the formulæ—

become $\alpha\beta$ -, $\alpha\alpha$ -, and $\beta\beta$ -benziledioxime respectively.

In all the reactions mentioned in this paper, it appears that the hydroxyl group of the oxime takes part as a whole, and not simply the hydrogen atom of the group. This forms a strong argument against the proposals of Auwers and V. Meyer (Abstr., 1890, 1263).

H. G. C.

Configuration of Asymmetrical Oximes which do not form Stereometric Isomerides. By A. HANTZSCH (*Ber.*, 24, 31—36).—Hitherto stereometric isomerides have not been found in the case of the greater number of asymmetrical oximes; this may be due either to the fact that the “labile” form is too unstable to be isolated by any method as yet discovered, or to the fact that the hydroxyl group occupies a neutral position with respect to the groups X and Y, as in the formula $\begin{array}{c} \text{X} \\ \diagup \\ \text{Y} > \text{C} : \text{N} \cdot \text{OH} \end{array}$. Further, the known oxime might in reality be a mixture of the two isomerides in equal molecular proportions, similar to the optically inactive substances containing an asymmetric carbon atom.

The author has subjected a number of these oximes to the reactions discussed in the previous abstract, and finds that all asymmetrical oximes correspond with one or other of the possible stereometrical formulæ, and that, therefore, the non-discovery of the second isomeride is due to the fact that it is so extremely unstable. The mixed aromatic ketoximes all have the α -constitution $\begin{array}{c} \text{Ph} \cdot \text{C} \cdot \text{C}_n\text{H}_{2n+1} \\ \parallel \\ \text{HO} \cdot \text{N} \end{array}$, for in

Beckmann's reaction, it is always the aromatic group which migrates from the carbon to the nitrogen atom, as shown with acetophenone, deoxybenzoin, and phenylacetic acid. The aliphatic ketoximes, on the other hand, are, as shown by Meyer (Abstr., 1886, 783), readily converted into nitriles by the action of acetic chloride, and must, there-

fore, be the β -isomerides. In the case of the ortho-substituted aromatic aldoximes, for which, at first, the β -constitution was considered most probable, it was found that their acetyl compounds may be reconverted into the oximes quite readily, and that they must, therefore, be α -derivatives.

Of very great interest is the behaviour of the thiophen-derivatives. The only known thiophenaldoxime corresponds very closely with β -benzaloxime; it yields a nitrile by the action of acetic chloride, and is, therefore, really a β -compound. Thiénylglyoxylic acid also forms only a β -oxime, whilst it is found that phenylglyoxylic acid yields two, of which the β -compound is by far the more stable. It appears, therefore, that the α -configuration is stable with the aromatic aldoximes, but already labile with their carboxylic acids; it is rarely obtained in the thiophen-derivatives, and has not been found at all among the fatty compounds.

In all cases where a methyl group is present in the oxime, it appears to exert a repellent influence on the hydroxyl group, which then takes up a position adjacent to the second radicle.

H. G. C.

The Oximes of Aldehydes and α -Ketonic Acids. By A. HANZSCH (*Ber.*, 24, 36—51).—The results given in this and the following paper form the experimental portion of the research of which the theoretical results have been discussed in the two preceding abstracts.

α -Acetylbenzaloxime, $\text{Ph} \cdot \overset{\text{H}}{\underset{\text{N} \cdot \text{OAc}}{\overset{\text{O}}{\text{C}}}} \cdot \text{H}$, is formed by the action of acetic anhydride on the oxime, and is an oil which is insoluble in solutions of alkaline carbonates, but is converted by ammonia and alkalis into the original oxime without forming a trace of nitrile. The action of acetic chloride on the oxime is less satisfactory, as the hydrogen chloride formed partially converts it into the β -oxime. β -Acetylbenzaloxime, $\text{Ph} \cdot \overset{\text{H}}{\underset{\text{N} \cdot \text{OAc}}{\overset{\text{O}}{\text{C}}}} \cdot \text{H}$, is only formed by very carefully adding a slight excess of acetic anhydride, gently warming, and pouring into iced water. The solution, on immediate evaporation in a vacuum, yields the acetyl compound in six-sided prisms; it melts at 55—56°, and is soluble in alcohol and benzene, sparingly in ether. When pure, it is fairly stable, but with cold soda or warm ammonia, it is reconverted into the β -oxime; with solutions of potassium or sodium carbonate, it yields benzonitrile, but, contrary to the observations of Beckmann (*Abstr.*, 1890, 1121), the author has never been able to find any benzamide with the benzonitrile. It is converted into the α -acetyl compound by mineral acids, acetic chloride, bromine, iodine, &c., the change being instantly brought about by gaseous halogen hydro-acids, acetic chloride, and bromine:—By the action of acetic chloride on the β -oxime itself, one-half of the latter is converted into the α -acetyl compound, and the other into β -benzaloxime hydrochloride.

The acetyl derivatives of α - and β -anisaldoxime are prepared in exactly the same manner. The former crystallises in oblique prisms melting at 48°, and the latter in four-sided prisms melting at 64°.

In their chemical behaviour also, they closely correspond with the acetylbenzaldoximes.

The oxime of phenylglyoxylic acid already prepared by Müller (Abstr., 1883, 1129) is not the primary product of the action of hydroxylamine. To obtain the latter, the action of hydroxylamine must be allowed to take place in the cold, and the solution then be extracted with ether. It separates from the latter in large, transparent, thick prisms, melts with complete decomposition at 127° , and is very soluble in water, alcohol, and ether. Its aqueous solution gives a characteristic, dark-green, voluminous precipitate with cupric acetate. It is converted by acetic anhydride into the *acetyl* derivative, $\text{OAc}\cdot\text{N}\cdot\text{CPh}\cdot\text{COOH}$, which crystallises in oblique prisms, is soluble in alcohol, ether, and acetic anhydride, and decomposes at $118\text{--}119^{\circ}$; with alkalis and alkaline carbonates, it yields the original oxime, which has, therefore, the α -configuration. The β -phenyloximidoacetic acid, already obtained by Müller, is prepared by heating the acid with hydroxylamine in neutral, acid, or alkaline solution, or even by allowing them to remain together in the cold for several days. It crystallises in small, white needles, or four-sided, oblique prisms, melting when quite pure at 145° with evolution of gas, is less soluble than the α -compound in water, chloroform, and ether, and is very stable towards mineral acids, and even concentrated sulphuric acid; on long continued boiling with hydrochloric acid, or more readily with hydroxylamine hydrochloride, it is converted into benzonitrile. The β -acetyl compound is obtained with difficulty in six-sided tablets; it melts at $124\text{--}125^{\circ}$ with decomposition, and passes very readily into benzonitrile and carbonic anhydride, thus confirming the supposition that the compound has really the β -configuration.

Like α -benzaldoxime, α -phenyloximidoacetic acid is converted into the β -compound by the action of hydrogen chloride on its dry ethereal solution, a very unstable hydrochloride of the latter being first formed. On the other hand, whereas β -benzaldoxime is reconverted into the α -compound by dilute aqueous hydrochloric acid, the reverse reaction takes place with the phenyloximidoacetic acid, the α - passing into the β -derivative. The latter may, however, be indirectly converted into the α -compound by the action of acetic chloride, which yields α -acetylphenyloximidoacetic acid.

The only known oxime of thiophenylaldehyde melts at 128° , and corresponds in its physical properties with β -benzaldoxime, and would, therefore, appear also to have the β -configuration. This is confirmed by the fact that not only the acetyl compound, but the oxime itself, readily passes into thiophen-nitrile on treatment with sodium carbonate solution. The *acetyl* compound, $\text{C}_6\text{H}_5\text{S}\cdot\text{CH}\cdot\text{NOAc}$, crystallises in oblique prisms melting at $75\text{--}80^{\circ}$ with decomposition.

The oxime of thiénylglyoxylic acid has been prepared by Peter (Abstr., 1885, 765), and Bradley (Abstr., 1886, 1014), who describe it as crystallising in slender needles, and melting at 137° . After recrystallisation from dilute alcohol, the author found the melting point $145\text{--}146^{\circ}$, decomposition also taking place. It has also the β -configuration, and like β -phenyloximidoacetic acid is sparingly soluble in water; it passes even more readily than the latter compound into the

nitrile when warmed with acidified water, or better with hydroxylamine hydrochloride. Its *acetyl* compound, which is best obtained by the action of acetic chloride, forms small prisms, melts at 85–87° with evolution of gas, and is converted into the nitrile not only by alkaline carbonates, but also by acetic acid, water, and alcohol.

The oxime of pyruvic acid, or methyloximidoacetic acid, has also the β -configuration. Its *acetyl* derivative, $\text{CH}_3\text{C}(\text{NOAc})\cdot\text{COOH}$, crystallises in a similar manner to the oxime, melts at 60° with decomposition, and is converted by potassium carbonate at 0° into acetonitrile, carbonic anhydride, and water. H. G. C.

Stereo-isomeric Ketoximes. By A. HANTZSCH (*Ber.*, 24, 51–61). As already explained, the configuration of the stereo-isomerides of asymmetrical ketoximes may be ascertained by their behaviour in Beckmann's reaction. The reagent employed was phosphorus pentachloride in absolute ethereal solution; the hydrolysis of the acid anilide formed was carried out by heating with concentrated hydrochloric acid at 160°.

Methoxybenzophenone, $\text{COPh}\cdot\text{C}_6\text{H}_4\cdot\text{OMe}$, is readily obtained by the action of benzoic chloride on anisole in presence of aluminium chloride, according to Gattermann's description (*Abstr.*, 1890, 962). The action of hydroxylamine was carried out in alkaline solution, and the oximes separated by fractionally precipitating the acetic acid solution with water. The α -oxime, $\text{Ph}\cdot\text{C}(\text{N}(\text{HO})\text{Me})\cdot\text{C}_6\text{H}_4\cdot\text{OMe}$, separates

generally as an oil, and crystallises from alcohol in four-sided, seemingly rhombic tablets melting at 137–138°. Its *hydrochloride* forms small needles melting at 123–124°, and its *acetyl* compound melts at 100°. Acetic chloride yields a mixture of the α - and β -acetyl compounds. In Beckmann's reaction, below -10° an anilide is formed which on hydrolysis yields aniline, methyl chloride, and phenol. Above -10° , some of the isomeric anilide of benzoic acid is also formed. The β -oxime, $\text{Ph}\cdot\text{C}(\text{N}(\text{HO})\text{Me})\cdot\text{C}_6\text{H}_4\cdot\text{OMe}$, is more readily

soluble in organic solvents than the α -compound, and crystallises seemingly in rhombohedra. It forms a hygroscopic *hydrochloride* melting at 110°, and an *acetyl*-derivative melting at 52–53°. In Beckmann's reaction it is converted at all temperatures into the anilide of benzoic acid, which, on heating with hydrochloric acid, yields methyl chloride, paramidophenol, and benzoic acid. The β -configuration is, therefore, the more stable.

The oximes of parachlorobenzophenone were prepared and separated by the method given by V. Meyer. The α -oxime, $\text{Ph}\cdot\text{C}(\text{N}(\text{HO})\text{Cl})\cdot\text{C}_6\text{H}_4\cdot\text{Cl}$, gave the anilide of parachlorobenzoic acid, whilst the β -acid, even at -10° , formed the parachloranilide of benzoic acid, mixed with parachlorobenzanilide. The α -compound is, therefore, here the stable modification.

The oximes of metachlorobenzophenone and the chloroketone itself have not hitherto been prepared. The latter is obtained by convert-

ing metamidobenzoic acid successively into metachlorobenzoic acid and its chloride, and acting with the latter on benzene in presence of aluminium chloride. It forms a crystalline powder sparingly soluble in alcohol and melts at 82—83°. The oximes were prepared in the usual manner and separated by fractional precipitation with water from acetic acid solution; the α -oxime is a crystalline powder which melts at 132—133°, and in Beckmann's reaction yields metachlorobenzanilide. The β -oxime melts at 105—106° and gives in Beckmann's reaction at -20°, a mixture of the metachloranilide of benzoic acid and of metachlorobenzanilide. Here again, therefore, the α -derivative is the stable modification.

The oximes of paratolyl phenyl ketone have already been fully described. The α -oxime readily yields the anilide of paratoluic acid, and the β -oxime a mixture of two-thirds of the paratoluidide of benzoic acid and one-third of the anilide of paratoluic acid. β -Tolylphenylketoxime is, therefore, the most labile of the hitherto discovered labile modifications, which is probably due to the presence of the methyl group. It has also been found that the β -modification of parethylbenzophenonoxime is much more stable, and under suitable conditions may be converted solely into parethylbenzanilide.

In addition to the thiénylphenylketoxime, $C_6SH_3 \cdot CPh \cdot NOH$, discovered by Comey (Abstr., 1884, 1168), an isomeric compound is formed in the preparation of the oximes by Auwers' method, which is less readily soluble in the usual solvents and melts at 113—114°, the first compound melting at 91—92°. Both are readily converted into *acetyl* compounds, that obtained from the less fusible oxime melting at 88—89°, and that from the more readily fusible oxime at 80—84°.

The Beckmann intramolecular change does not proceed smoothly with either compound, probably owing to the presence of the thiényl group, and it has not, therefore, been found possible to determine which has the α -, and which the β -configuration.

The formation of two different hydrochlorides of stereo-isomeric methoxybenzophenonoximes mentioned above is of importance, inasmuch as it shows the existence of stereo-isomeric ammonium com-

pounds of the general formula $R' - N \begin{array}{c} H \\ \diagup \quad \diagdown \\ \quad \quad Cl \end{array} OH$, which probably stands

in close relation to the observation of Le Bel on certain differences in simpler structurally identical ammonium salts. H. G. C.

Constitution of Fulminic Acid: Dibenzoylcarbamide. By A. F. HOLLEMAN (*Ber.*, 23, 3742—3744).—When the dibenzoylcarbamide recently described (this vol., p. 64) is heated with 4 parts of aniline at 180—190°, it yields ammonia, benzamide, bezanilide, and symmetrical diphenylcarbamide; the relatively small quantity of ammonia and bezanilide is due to the fact that they are produced by the interaction of part of the benzamide with aniline.

The dibenzoylcarbamide from guanidine carbonate and benzoic anhydride melts at 197°, instead of 210°, as stated in text books, and is consequently identical with the symmetrical carbamide obtained from silver or sodium cyanamide.

The author considers fulminic acid to be a tautomeric compound represented by the following three formulæ, which readily serve to explain its reactions:—

J. B. T.

Hydroxyketones from Fatty Acids and Phenols. By A. GOLDZWEIG and A. KAISER (*J. pr. Chem.* [2], 43, 86—98; compare Perkin, *Trans.*, 1880, 546—549; Nencki, *Abstr.*, 1890, 488).—*Propionylphenol*, $\text{OH}\cdot\text{C}_6\text{H}_4\cdot\text{COEt}$, is obtained by dissolving zinc chloride (2 parts) in propionic acid (1 part), adding phenol (1·5 parts), and heating until the liquid begins to boil (155°); the cooled mass is shaken with water and the undissolved portion recrystallised from hot water. It forms colourless needles or short, rhombic prisms; it is anhydrous and gradually becomes pale-yellow on exposure to light; it melts at 148° and dissolves in water (2896 parts at 15° and 30 parts at 100°), alcohol, and ether; its solutions are not coloured by ferric chloride, but they reduce ammoniacal silver solution in the cold. When melted with alkalis, it yields parahydroxybenzoic acid (m. p. 210°) and phenol. The *dibromo-derivative*, $\text{C}_6\text{H}_3\text{Br}_2\text{O}_2$, crystallises in leaflets which melt in a capillary tube at 100°, and are sparingly soluble in water, but freely so in alcohol and ether. *Propionylidinitrophenol* forms lustrous, yellow, anhydrous crystals which melt at 180°, and dissolve in hot water, alcohol, ether, and alkalis. *Propionylphenol hydrazone* forms yellow leaflets which melt at 80°; it is insoluble in water and is unstable therein; it dissolves in alcohol, ether, and benzene, and the solutions give precipitates with the salts of the heavy metals.

Propionylresorcinol, $\text{C}_6\text{H}_3(\text{OH})_2\cdot\text{COEt}$ [$(\text{OH})_2:\text{COEt} = 1:3:4$], is similarly prepared; it crystallises in lustrous, pale ruddy-yellow, slender needles, and melts in a capillary tube at 95°; it dissolves in alcohol, ether, benzene, and alkalis, but very little in water; it is coloured dark-red by ferric chloride but not by bleaching powder; its solution in water is precipitated by silver nitrate, lead acetate, and barium hydroxide; bromine precipitates it in weak alcoholic solution; its orientation is deduced from its analogy to orthoparadihydroxyacetophenone (resacetophenone). The *hydrazone* melts at 115° and is very unstable; it is similar in properties to propionylphenolhydrazone.

Propionylquinol, $\text{C}_6\text{H}_3(\text{OH})_2\cdot\text{COEt}$, is prepared like propionylphenol; it crystallises in long, slender, lustrous, white needles, melts at 92° and is soluble in the same solvents as the above compounds; with ferric chloride, it gives a yellowish-red coloration; its solutions are precipitated by lead acetate and bromine-water, and reduce silver and copper solutions. The *hydrazone* melts at 100° and resembles the above hydrazones in properties.

Catechol does not form such ketones as the above, either with propionic or acetic acid; pyrogallol, on the other hand, yields them very easily.

Aceto- α -naphthol (α -hydroxynaphthyl methyl ketone) has been described by Witt (*Abstr.*, 1888, 486). *Propionyl- α -naphthol*,

obtained by heating propionic acid (75 grams) with zinc chloride (100 grams) and α -naphthol (145 grams) and extracting with water and then with ether, forms yellow crystals which melt at 81° ; it dissolves in sulphuric acid with an orange colour, and in alkalis with a yellowish-brown colour; it also dissolves in hot alcohol and ether, the solution in alcohol being coloured violet by ferric chloride. The *hydrazone* forms lemon-yellow crystals which are stable in air, melt at 128° , and dissolve in alcohol and ether. With diazobenzene chloride, propionyl- α -naphthol yields *propionyl- α -naphtholazobenzene*; this forms yellowish-red crystals which melt in a capillary tube at 110° .

Butyryl- α -naphthol crystallises in slender, grey, silky needles, melts at 78° , and is more soluble in water than the propionyl-derivative. *Isobutyryl- α -naphthol* melts at 79° . A. G. B.

Chloro-derivatives of Benzaldehyde. By H. ERDMANN and E. SCHWECHLEN (*Annalen*, 260, 53—78).—As the chloro-derivatives of benzaldehyde, some of which have recently been employed by Erdmann and Kirchhoff for the synthesis of naphthalene derivatives (*Abstr.*, 1880, 150), have as yet been but little investigated, and as many contradictory statements appear in the literature of these compounds, the authors have made them the subject of a more complete investigation.

The monochlorobenzaldehydes have, when pure, a pleasant odour, like that of oil of bitter almonds, but when boiled with water they give off irritating vapours.

Orthochlorobenzaldehyde (compare Erdmann and Kirchhoff, *loc. cit.*) is best obtained in a pure condition by means of its oxime; it melts at -4.5 to -3° , boils at 213 — 214° , and gives orthochlorobenzoic acid on oxidation. The *oxime*, C_7H_5ClNO , is formed when the chloraldehyde is warmed with hydroxylamine hydrochloride and sodium carbonate in aqueous solution; it crystallises from alcohol in compact prisms, $a:b:c = 0.49926:1:0.48256$; $\beta = 85^{\circ} 10'$, melts at 75 — 76° , and is reconverted into the aldehyde by boiling, dilute (1:1) sulphuric acid. The *hydrochloride* is gradually precipitated in large crystals when hydrogen chloride is passed into an ethereal solution of the oxime; it is soluble in ether and is reconverted into the oxime by cold sodium carbonate. The *acetal* is formed when chlorobenzaldehyde is boiled with acetic anhydride and sodium acetate; it crystallises from alcohol and chloroform, in which it is only sparingly soluble, in colourless needles, melts at 205 — 206° , and is reconverted into the aldehyde by boiling sodium carbonate.

Metachlorobenzaldehyde is best prepared by reducing metanitrobenzaldehyde (50 parts) with stannous chloride (225 parts) and concentrated hydrochloric acid (300 parts), gradually treating the ice-cold and diluted solution of the amido-compound with a solution of sodium nitrite (23 parts) in water (90 parts), and then decomposing the diazo-compound with a hydrochloric acid solution of cuprous chloride; when benzaldehyde is treated with chlorine in presence of zinc chloride as recommended by Müller (*D.R.-P.* 30329, 1883), both the meta- and the para-chloraldehyde are formed. Metachlorobenzaldehyde melts at 17 — 18° and boils at 213 — 214° . The α -oxime,

C_7H_5ClNO , obtained in the same way as the corresponding ortho-compound, crystallises from alcohol in large, pointed prisms, and melts at $70-71^\circ$.

Metachloro- β -benzaldoxime hydrochloride is gradually deposited in small, colourless crystals when hydrogen chloride is passed into an ethereal solution of the α -oxime; it melts between 130° and 140° with slight decomposition, and has a strong acid reaction. The β -oxime, prepared by decomposing the hydrochloride with sodium carbonate, crystallises from dilute alcohol in long prisms and melts at $115-116^\circ$ when quickly heated, being converted into the α -oxime, a change which is analogous to that observed by Beckmann (Abstr., 1889, 607) in the case of β -benzaldoxime. Both the α - and the β -oxime of metachlorobenzaldehyde are decomposed by dilute sulphuric acid into the aldehyde and hydroxylamine.

Pure parachlorobenzaldehyde (compare Erdmann and Kirchoff, *loc. cit.*) melts at 47.5° and boils at $213-214^\circ$. The α -oxime, C_7H_5ClNO , is formed when the aldehyde is treated with hydroxylamine hydrochloride and sodium carbonate as described in the case of the ortho-compound; it separates from alcohol in colourless crystals, melts at $106-107^\circ$, and is very readily soluble in ether.

The *hydrochloride* of the β -oxime is obtained when the α -compound is treated with hydrogen chloride in ethereal solution; it crystallises in prisms, melts at $100-110^\circ$ with slight decomposition, and has a strongly acid reaction. The β -oxime, prepared by decomposing the salt with cold sodium carbonate solution, crystallises from dilute alcohol in flat prisms, and melts at 140° when quickly heated, being at the same time converted into the α -oxime. The α - and the β -oxime are both readily decomposed by dilute sulphuric acid yielding hydroxylamine and parachlorobenzaldehyde.

Parachlorophenylisocrotonic acid, $C_6H_4Cl \cdot CH \cdot CH \cdot CH_2 \cdot COOH$, is formed as an intermediate product in the conversion of parachlorophenylparaconic acid (*loc. cit.*) into 2-chloro-1'-naphthol, and is best prepared by carefully heating the paraconic acid in an oil-bath until the evolution of carbonic anhydride is at an end. It separates from carbon bisulphide in colourless crystals, melts at $108-109^\circ$, and when heated for some time at its boiling point is converted into the chloronaphthol mentioned above. The *sodium salt*,

crystallises from hot water, in which it is rather sparingly soluble, in colourless prisms.

The dichloro-derivatives of benzaldehyde can be prepared by chlorinating the corresponding dichlorotoluenes at their boiling points and then shaking the dichlorobenzal chloride (1 part), obtained in this way, with a mixture of concentrated sulphuric acid (2 parts) and fuming sulphuric acid (2 parts), containing 10 per cent. of sulphuric anhydride, until the evolution of hydrogen chloride is at an end; in the case of the compound of the constitution

the temperature must be raised to $30-40^\circ$, and in the case of the

1:2:3-compound to 40—50° in order to complete the reaction. The acid solution is finally separated from any undecomposed, insoluble chloride, poured on to ice, the crystalline aldehyde treated with sodium carbonate to free it from chlorinated derivatives of benzoic acid, and purified by distillation.

Dichlorobenzaldehyde [$\text{CHO}:\text{Cl}_2 = 1:2:4$], prepared from the corresponding dichlorotoluene, crystallises in colourless prisms, melts at 70—71°, boils at 231—245°, and has an odour like that of oil of bitter almonds. The *oxime* crystallises in long, silky needles, melts at 136—137°, and combines with hydrogen chloride in ethereal solution yielding a crystalline hydrochloride melting at 133.5°, which is reconverted into the oxime on treatment with sodium carbonate. The *acetal* crystallises in plates, melts at 221—222°, is only very sparingly soluble in the ordinary solvents, and is decomposed by soda.

The dichlorobenzaldehyde (m. p. 57—58°), described by Gnehm, (*Ber.*, 17. 752), has the constitution [$\text{CHO}:\text{Cl}_2 = 1:2:5$]. It is volatile with steam, very readily soluble in most ordinary solvents, and dissolves in concentrated sulphuric acid with an olive-green coloration: on oxidation with potassium permanganate, it is converted into paradichlorobenzoic acid (m. p. 152—153°), from which paradichlorobenzene (m. p. 53—54°) can be easily obtained. The *oxime* crystallises from dilute alcohol in colourless needles, melts at 124—125°, and forms a crystalline hydrochloride which is very readily soluble in ether.

Dichlorobenzaldehyde [$\text{COH}:\text{Cl}_2 = 1:3:4$], prepared from the corresponding dichlorotoluene, melts at 43—44°, not at 68° as stated by Beilstein (*Annalen*, 152, 229); it boils at 247—248°, is readily volatile with steam, and on oxidation it yields orthodichlorobenzoic acid (m. p. 201—202°). The α -*oxime*, $\text{C}_7\text{H}_4\text{Cl}_2\text{N}\cdot\text{OH}$, crystallises from hot water in microscopic prisms and melts at 114—115°. The *hydrochloride* of the β -*oxime* is precipitated in crystals when hydrogen chloride is passed into an ethereal solution of the α -compound; it melts at 150° with decomposition, and is decomposed by sodium carbonate yielding the β -*oxime*. This compound crystallises from dilute alcohol in moss-like needles, and melts at 120° when quickly heated, being reconverted into the α -*oxime*.

2:4-*Dichlorophenylparaconic acid*, $\text{C}_{11}\text{H}_5\text{Cl}_2\text{O}_4$, can be obtained by heating the corresponding dichlorobenzaldehyde with succinic anhydride and anhydrous potassium acetate at 130—140° for 4—5 hours, as described in the preparation of chlorophenylparaconic acid (*loc. cit.*). It crystallises from hot water, in which it is only sparingly soluble (1 in about 140), in colourless plates, melts at 164.5—165.5°, and has a very bitter taste; the barium salt crystallises from hot water in prisms. The corresponding 2:5-*dichloro-acid*, $\text{C}_{11}\text{H}_5\text{Cl}_2\text{O}_4$, prepared in like manner, crystallises in colourless plates with 1 mol. H_2O , melts at 197—198°, and decomposes at 212° with evolution of carbonic anhydride. The 3:4-*dichloro-acid*, $\text{C}_{11}\text{H}_5\text{Cl}_2\text{O}_4$, crystallises from water in needles, melts at 136—137°, and decomposes at about 170° with evolution of carbonic anhydride.

2:4-*Dichlorophenylisocrotonic acid*, $\text{C}_{10}\text{H}_5\text{Cl}_2\text{O}_3$, can be obtained by

heating the corresponding paraconic acid in an oil-bath until the evolution of carbonic anhydride is at an end; it crystallises from carbon bisulphide in colourless prisms, melts at $120-121^{\circ}$, and on further heating is converted into 2:4-dichloro-1'-naphthol melting at 132° (compare Erdmann, Abstr., 1889, 265).

2:5-Dichlorophenylisocrotonic acid, prepared in like manner, crystallises from carbon bisulphide in colourless prisms, melts at $148-149^{\circ}$, and gives 1:4-dichloro-1'-naphthol when heated more strongly.

3:4-Dichlorophenylisocrotonic acid is formed in small quantities when the corresponding paraconic acid is heated carefully, but the principal products are 1:2-dichloro-1'-naphthol and 1:3-dichloro-1'-naphthol; it crystallises in colourless needles, melts at $63-64^{\circ}$, and is only sparingly soluble in water. F. S. K.

Action of Hydroxylamine on Benzoylacetaldehyde. By L. CLAISEN and R. STOCK (*Ber.*, 24, 130-138).—The action of hydroxylamine on benzoylacetaldehyde differs in some respects from its action on 1:3-diketones, $R \cdot CO \cdot CH_2 \cdot CO \cdot R$. The first product of the reaction is the monoxime, $CO \cdot Ph \cdot CH_2 \cdot CH \cdot NOH$, whilst in the case of the diketones the reaction goes a step further; the elements of two molecules of water are eliminated, and an isoxazole is formed. The elimination of the elements of water from the monoxime of benzoylacetaldehyde takes place in two ways, according to the conditions; either cyanacetophenone or phenylisoxazole being formed. The latter is less stable than the isoxazole obtained from the diketone, and is slowly converted by aqueous alkali, instantly by sodium ethoxide, into the sodium salt of cyanacetophenone.

Benzoylacetaldoxime, $COPh \cdot CH_2 \cdot CH \cdot NOH$, is obtained by adding a concentrated aqueous solution of hydroxylamine hydrochloride to the sodium salt of benzoylacetaldehyde, dissolved in seven times the weight of water and cooled to 0° . It crystallises in colourless prisms, melts at $86-87^{\circ}$, and is easily soluble in benzene, hot water, alcohol, methyl alcohol, ether, and chloroform, sparingly so in light petroleum and carbon bisulphide. It gives a bright yellow solution with alkalis, and is precipitated with carbonic anhydride; on the other hand, it dissolves to a noticeable extent in alkaline carbonate. Ferric chloride turns the alcoholic solution dark green, which is converted to a deep blue on the addition of sodium acetate; excess of sodium acetate precipitates a black iron salt.

Cyanacetophenone, $COPh \cdot CH_2 \cdot CN$, is prepared by mixing sodium benzoylacetalddehyde (17 grams) dissolved in water (100 c.c.) with aqueous soda (4 grams in 20 c.c.) and hydroxylamine hydrochloride (7 grams), and heating the mixture for a day on the water-bath. The oxime is also converted into cyanacetophenone by warming with acetic anhydride, and treating the product with soda. It crystallises from water in colourless, flat prisms and plates, resembling benzoic acid, melts at $80-81^{\circ}$, and is easily soluble in alcohol, but gives no coloration with ferric chloride. It dissolves in dilute alkalis and alkaline carbonates, and is reprecipitated by carbonic anhydride.

Phenylisoxazole, $CPh \cdot \begin{array}{c} O-N \\ \parallel \\ CH \cdot CH \end{array}$, is obtained when the above

Artificial Salicylic Acid. By W. R. DUNSTAN and O. F. C. BLOCH (*Pharm. J. Trans.* [3], 21, 429—436).—Artificial salicylic acid has been observed to differ in its therapeutic action from the pure "natural" acid obtained from the oil of winter-green. Although much work has already been done on the subject with the view of ascertaining the cause of this difference, the exact nature of the impurities contained in the artificial acid of commerce has not been experimentally established. The authors have examined two foreign acids, isolated by Williams in 1878 from commercial salicylic acid, but not then identified. These acids are now shown by their physical and chemical properties, as well as by the analyses of their silver and lead salts, to be orthocresotic or orthohomosalicylic acid [$\text{CH}_3 : \text{OH} : \text{COOH} = 1 : 2 : 3$], and metacresotic or metahomosalicylic acid [$\text{CH}_3 : \text{OH} : \text{COOH} = 1 : 3 : 4$] respectively. The ortho-acid melts at 163° (corr.), the meta-acid at 174.5° (corr.). They have been formed from the corresponding cresols contained in the crude phenol from which the salicylic acid had been prepared.

The melting point of pure salicylic acid has been variously stated, the highest recorded temperature being 159° and the lowest 155° . The authors find that "natural" salicylic acid, after recrystallisation from alcohol, melts at 156.75° (corr.), and that if the acid melting at this temperature be converted into the sodium salt, and fractionally precipitated with silver nitrate, the acid recovered from each fraction of silver salt also melts at 156.75° , which may therefore be accepted as the melting point of the pure substance. By very slowly cooling a 1 per cent. solution in hot water, the pure acid may readily be obtained in large, distinct, prismatic crystals, but in presence of about 5 per cent. of one of the cresotic acids, the salicylic acid no longer furnishes large crystals, and the impure acid melts at a lower temperature.

A specimen of the artificial salicylic acid of commerce (m. p. 154.5°) was examined by Williams' method. It was converted into a calcium salt by boiling with water and calcium carbonate, and crystallised many times from water. From the residue of soluble salt from which most of the calcium salicylate had crystallised, there was obtained a small quantity of an acid, which after further purification melted constantly at 151° (corr.). Analysis of the silver and lead salts, as well as its physical and chemical properties, proved it to be paracresotic or parahomosalicylic acid

For the purposes of preparing pure salicylic acid from the impure acid of commerce, the method depending on the different solubilities of the calcium salts was not found satisfactory, being extremely tedious, owing to the number of recrystallisations that are necessary. A better plan consists in preparing the lead salts by the action of lead carbonate, and crystallising these from dilute alcohol; lead salicylate being much less soluble than the lead cresotates. By this means 70—80 per cent. of the original acid may be recovered in the form of pure salicylic acid from the first fraction of crystals deposited from the alcoholic solution.

At the request of the authors, Professor Charteris ascertained whether the three cresotic acids described above were poisonous. When administered in alcoholic solution to animals by injection, the ortho-acid was observed to be markedly toxic, the para-acid less so, whilst the meta-acid proved to be innocuous. W. R. D.

Coumarone. By A. R. L. DOHME (*Amer. Chem. J.*, 13, 29—34; compare Fittig and Ebert, *Abstr.*, 1883, 474; Rössing, *Abstr.*, 1885, 388; and Kraemer and Spilker, *Abstr.*, 1890, 496).—Aniline and concentrated ammonia are without action on coumarone even when heated with it in sealed tubes at 280°. Bromocoumarone, obtained by heating the dibromo-additive product with alcoholic potash, is also unaffected by these reagents. When coumarone and phosphorus pentachloride in molecular proportion are heated in sealed tubes at 175°, a mixture of coumarone dichloride and chlorocoumarone is obtained, and the latter, when heated at 275° with excess of pentachloride in a sealed tube for five hours, gives a compound which melts at 57·5—58°, crystallises in long, thin, white, satiny needles, and appears to have the constitution $C_8H_4 \begin{smallmatrix} O \\ \diagup \diagdown \\ CCl \end{smallmatrix} CCl$. The remarkable stability of the coumarone molecule, and the difficulty with which the oxygen contained in it is replaced, both point to the conclusion that the closed-ring formula suggested by Fittig and Hantzsch correctly represents its constitution. G. T. M.

Quinonecarboxylic Acids. By J. STIEGLITZ (*Amer. Chem. J.*, 13, 38—42).—*Tetretethyl parachloroquinonedimalonate*,

is prepared by treating tetrachloroquinone (1 mol.) in dry benzene or acetone with ethyl sodiomalonate (4 mols.) dissolved in absolute alcohol. The reaction is complete after heating the mixture in a water-bath for a few minutes, and on acidifying, washing, drying, and evaporating the benzene solution, a dark oil is formed, which, when mixed with a little cold alcohol, deposits yellow needles. On recrystallisation from hot alcohol, pale yellow needles are obtained; these are only slightly soluble in ether or benzene, dissolve readily in chloroform and in hot alcohol, and with the alkaline hydroxides give deep violet-coloured solutions, due to the formation of compounds in which sodium or potassium is substituted for the remaining hydrogen atom in the malonic groups. Reducing agents, such as sulphurous anhydride or zinc-dust and glacial acetic acid, convert the compound into *tetretethyl paradichloroquinonedimalonate*,

This substance crystallises in white needles, melts at 160—161°, dissolves readily in ordinary solvents, gives a violet coloration with alkaline hydroxides, and is converted by oxidising agents, such as ferric chloride, into the quinone.

Tetretethyl paramidoquinonedimalonate, $C_8(NH_2)_2O_2[CH(COOEt)_2]_2$, crystallises in long, flat prisms, melts at 159—160°, and is formed when *tetretethyl paradichloroquinonedimalonate* is treated in the cold with alcoholic ammonia. It may be precipitated from its solution by

means of water, and purified either by precipitation from its solution in chloroform by light petroleum or by simply washing it with ether.

Tetraphenyl paradichloroquinonedimalonate is readily dissolved by a dilute solution of sodium hydroxide, the odour of alcohol being immediately perceptible. If, after remaining a few minutes, the solution be poured into cold sulphuric acid, a brown precipitate is formed, and this, on recrystallisation from acetone or alcohol, forms dark-red plates of *parachlorohydroxyquinone*, $\text{OH}\cdot\text{C}_6\text{H}_2\text{ClO}_2$; it sublimes with slight decomposition and without having previously melted, and is easily soluble in alcohol, in acetone, and in the alkaline hydroxides. If the solution of tetraphenyl paradichloroquinonedimalonate and sodium hydroxide be allowed to remain for an hour, and then warmed on a water-bath, both chlorine atoms are displaced by hydroxyl, the resulting compound agreeing in its properties with those ascribed to *paradihydroxyquinone* by Nietzki (Abstr., 1888, 1181) and Loewy (Abstr., 1886, 1028). The reaction by which the last-mentioned compounds are obtained consists in the substitution of hydrogen for the malonic groups; the author has consequently thought it of interest to commence the investigation of the action of ethyl sodio-malonate on ethyl dibromoquinoneterephthalate. The latter compound may be readily obtained from ethyl succinosuccinate by a simplification of the process used by Herrmann (Abstr., 1886, 1028) and Böniger (Abstr., 1888, 954). The succinosuccinate (1 mol.) is dissolved in dry chloroform, and bromine (1 mol.) gradually added; the chloroform solution is then shaken with an aqueous solution of sulphurous anhydride, dried, and evaporated on a water-bath. The crude ethyl dihydroxyterephthalate thus obtained is dissolved in warm glacial acetic acid and water (5–10 per cent. of the weight of the glacial acetic acid used), and three additional equivalents of bromine are added. On allowing the mixture to remain over night in a closed flask, ethyl dibromoquinoneterephthalate separates in crystals; a further quantity of it is precipitated on the addition of water (yield 84.5 per cent. of theory). G. T. M.

Indigo from Phenylglycine. By K. HEUMANN (*J. pr. Chem.* [2], 43, 111–112; compare this vol., p. 311).—The author does not question Lederer's observation that indigo is obtained when phenylglycine is melted with sodium hydroxide, but he denies that it was published prior to the appearance of his own patent in the official journal. It has been known for 30 years and more that a "white" substance is formed when indigo is heated at 130–150° with melted potash containing a little water, and Biedermann and Lepetit have again drawn attention to the fact quite recently (this vol., p. 206). A. G. B.

Constitution of β -Benzopinacoline. By M. DELACRE (*Bull. Soc. Chim.* [3], 4, 470).—The author takes exception to the generally adopted formula for β -benzopinacoline, $\text{CPh}_2\cdot\text{COPh}$, which is based on the fact that by the action of alkali hydroxides and of oxidising agents it yields triphenyl-derivatives. Since on reduction it affords a hydrocarbon, $\text{CHPh}_2\cdot\text{CHPh}_2$, it should have a symmetrical constitu-

tion, and this is rendered probable since the alcohol obtained from β -benzopinacolone by the action of zinc ethyl yields by dehydration tetraphenylethylene, and the oxidation of this substance in acetic acid solution by potassium permanganate affords β -benzopinacolone, whereas by chromic acid it affords α -benzopinacolone. The author is about to work on this subject. T. G. N.

Derivatives of Dimethylaniline. By C. LAUTH (*Compt. rend.*, 111, 886—888).—Twenty parts of dimethylaniline is dissolved in 120 parts of acetic acid of 8° and 160 parts of water, and 20 to 30 parts of pure lead peroxide is added gradually to the liquid, care being taken that the temperature does not exceed 30—35°. The reaction is complete in from 5 to 10 minutes, and the product is washed with warm water, boiled with water, dried, and crystallised from benzene. It is purified by crystallisation from petroleum, alcohol, or ether. The aqueous mother liquor, freed from lead by means of sulphuric acid and neutralised with ammonia, gives a further quantity of the product.

The product is tetramethylbenzidine, $C_{18}H_{20}N_2$, and the yield is about 40 per cent. of the dimethylaniline. In presence of acetic acid it gives an intense green coloration with lead peroxide. To obtain the pure colouring matter, 10 grams of the base, dissolved in 7.5 c.c. of hydrochloric acid and 200 c.c. of water, is added to 600 c.c. of a solution of ferric chloride of 45°, diluted with 540 c.c. of water. After some time, the mixture deposits the colouring matter in perfectly pure, microscopic crystals, which are washed with water, then with alcohol, and finally with absolute alcohol and ether. The mother liquors deposit a further quantity of the product when mixed with sodium chloride and acetate.

With more concentrated solutions, or with excess of ferric chloride, an acid combination of the orange and green products is obtained as a beautiful, orange precipitate, but prolonged washing with alcohol converts the orange compound into a green salt, which likewise contains iron. The crystals dissolve in water with a green coloration, which becomes orange on the addition of acids. Sodium chloride precipitates the unaltered compound from its solutions. Zinc salts also form a compound almost insoluble in saline solutions, but soluble in alcohol, from which it is precipitated by ether.

This product dyes silk a very pure green, but it is extremely unstable, and even out of contact with air and light the silk becomes colourless. It exists only in the form of salts, and is decomposed by cold water and very rapidly by hot water, with separation of a white compound. Alkalis produce the same result, with formation of hydrogen peroxide. In a dry vacuum, the green crystals decompose in about 24 hours, but they keep better in the air. When heated on a water-bath, they become colourless, with evolution of water and hydrogen chloride. In all these reactions the green colour does not reappear on neutralisation, but it forms again on treatment with lead peroxide.

The crystalline green compound has the composition $C_{18}H_{21}ClN_2O$, and the white compound which separates in the various reactions is tetramethylbenzidine. The reaction with alkalis is represented by the equation $C_{18}H_{21}ClN_2O + NaOH = NaCl + C_{18}H_{20}N_2 + H_2O + O$.

A resinous product, which is probably a chlorine derivative of the base, separates at the same time. The green compound probably has the constitution $\begin{matrix} \text{C}_6\text{H}_4\cdot\text{NClMe}_2 \\ \text{C}_6\text{H}_4\text{---NMe} \end{matrix} > \text{CH}_2 + \text{H}_2\text{O}$, and is analogous to the product of oxidation obtained by Würster from tetramethylparaphenylenediamine.
C. H. B.

Dehydrobenzoylactic Acid. By F. FEIST (*Ber.*, 23, 3726—3736; compare *Annalen*, 257, 253).—Dehydrobenzoylactic acid does not yield any ammonium salt; the compound $\text{C}_{15}\text{H}_{11}\text{O}_3\text{Cl}$, which is formed by the action of phosphorus pentachloride, and was termed by Perkin "chlorodehydrobenzoylactic acid," is probably represented by one or other of the formulæ $\text{CPh} \begin{smallmatrix} \text{O} \text{---} \text{CO} \\ \diagdown \quad \diagup \\ \text{CH} \text{---} \text{CO} \end{smallmatrix} \text{C}:\text{CPhCl}$; $\text{CPh} \begin{smallmatrix} \text{O} \text{---} \text{CO} \\ \diagdown \quad \diagup \\ \text{CH} \text{---} \text{CCl} \end{smallmatrix} \text{C}:\text{COPh}$. On treating this compound with sulphuric acid at 130—150°, *diphenylpyronecarboxylic acid*,

is obtained, which is isomeric with dehydrobenzoylactic acid, and is deposited from benzene in small crystals melting at 201° with decomposition. The substance readily dissolves in chloroform, but is very sparingly soluble in water, dilute acids, or soda. The *ammonium salt* is crystalline and melts at 135°; the *barium salt* ($\text{C}_{15}\text{H}_{11}\text{O}_4$)₂Ba + 6H₂O, crystallises with difficulty; the *silver salt* forms an additive compound with silver nitrate: the remaining salts are amorphous. The acid gives a white precipitate with ferric chloride, which becomes pale-green after remaining for some time; with ferrous sulphate, a red precipitate is formed, changing to white and finally to violet-blue. On heating the acid, carbonic anhydride is eliminated, and 2—6-diphenylpyrone is formed (see below). By treating the acid with alcoholic ammonia at ordinary temperatures, a compound is obtained which melts at 237—240°, is insoluble in soda, and is probably *diphenylpyridonecarboxylic acid*, $\text{CPh} \begin{smallmatrix} \text{NH} \cdot \text{CPh} \\ \diagdown \quad \diagup \\ \text{CH} \text{---} \text{CO} \end{smallmatrix} \text{C}:\text{COOH}$.

2 : 6-Diphenylpyrone, $\text{O} \begin{smallmatrix} \text{CPh} \cdot \text{CH} \\ \diagdown \quad \diagup \\ \text{CPh} \cdot \text{CH} \end{smallmatrix} \text{CO}$, is prepared by heating dehydrobenzoylactic acid with a large excess of concentrated hydrochloric acid in a sealed tube for 15 hours at 230—260°; it crystallises from benzene in colourless, slender needles, softens at 128°, melts at 138·5—139·5°, and is sparingly soluble in ether or alcohol at ordinary temperatures. The pyrone is almost insoluble in water or alkalis, but dissolves in concentrated sulphuric acid with a violet fluorescence, which is unaltered by heating.

Attempts to prepare a triketone by the action of barium hydroxide and hydrochloric acid, resulted in the formation of a small quantity of an impure compound, which crystallises in prisms and melts at 110° with decomposition. On heating dehydrobenzoylactic acid with alcoholic ammonia in a sealed tube at 160°, *diphenylpyridone*,

is formed; it is very sparingly soluble, and melts at 267°.

From the analogy thus shown to exist between dehydracetic acid and dehydrobenzoylactic acid, it follows that the latter compound is really 6-phenyl-3-benzoylpyrone, and is represented by the formula

The two reduction compounds, $\text{C}_{18}\text{H}_{14}\text{O}_4$ and $\text{C}_{18}\text{H}_{12}\text{O}_3$, described by Perkin (Trans., 1885, 278), have probably one or other of the formulæ

J. B. T.

Ethyl Diphenylpyronedicarboxylate. By F. FEIST (*Ber.*, 23, 3736—3739; compare previous abstract).—*Ethyl cuprobenzoylacetate*, $(\text{CHBz} \cdot \text{COOEt})_2\text{Cu}$, is prepared by treating ethyl benzoylacetate with copper acetate, the liberated acetic acid being exactly neutralised with soda; it crystallises from benzene in small, green, lustrous needles, and melts at 180°; the yield is 50 per cent. of theory. By the prolonged action of carbonyl chloride in the cold on the copper compound, *ethyl 2:6-diphenylpyrone-3:5-dicarboxylate*,

is obtained; this crystallises in small, rectangular plates, melts at 140° with decomposition, and is sparingly soluble in water, dilute acids, or alkalis; the yield is very small. The compound gives no colour with ferric chloride, is entirely unacted on by heating with dilute sulphuric acid, and, on treatment with alcoholic potash, yields benzoic acid, acetic acid, acetophenone, and carbonic anhydride.

J. B. T.

Nitro- and Amido-derivatives of β -Naphthyl Ethyl Ether. By F. GAESS (*J. pr. Chem.* [2], 43, 22—38).—1:2-Nitronaphthyl ethyl ether has been obtained by Wittkampff (Abstr., 1884, 1036).

3:2-Nitronaphthyl ethyl ether is obtained by adding water to the mother liquor of 1:2-nitronaphthyl ethyl ether, and fractionally crystallising the precipitate from light petroleum; it is crystalline melts at 114°, and is very soluble in acetone, chloroform, and benzene, and sparingly in cold ether, alcohol, and petroleum; it is volatile with steam. By oxidation it is converted into β -nitrophthalic acid; this settles its constitution. It is not converted into the corresponding nitronaphthylamine when heated with alcoholic ammonia (compare *loc cit.*).

1:2'-Nitronaphthyl ethyl ether exists in the resin which is thrown down by still further addition of water to the mother liquor of 1:2-nitronaphthyl ethyl ether, and is extracted therefrom by light petroleum, from which it is recrystallised several times. It forms long, golden-yellow needles melting at 72—73°.

1 : 2-*Amidonaphthyl ethyl ether* crystallises in serrated tables, or in prisms and pyramids with reddish-blue fluorescence; it melts at 51° , and boils practically undecomposed at $300\text{--}302^{\circ}$ (by Siwoloboff's method, Abstr., 1886, 497), it dissolves in the usual solvents. The sulphate and hydrochloride were obtained; the acetyl derivative melts at 145° .

3' : 2-*Amidonaphthyl ethyl ether* crystallises in fluorescent pyramids, melts at $90\text{--}91^{\circ}$, boils at 330° , and dissolves in the usual solvents. The hydrochloride and acetyl derivative (m. p. 184.5°) were obtained.

1 : 2'-*Amidonaphthyl ethyl ether* crystallises in fluorescent prisms, melts at 67° , boils at 315° , and dissolves in the usual solvents. The hydrochloride, sulphate, and acetyl derivative (m. p. 139°) were obtained.

Two dinitronaphthyl ethyl ethers are obtained by treating 1 : 2-nitronaphthyl ethyl ether (1 part) with nitric acid of sp. gr. 1.42 (6 parts) at 0° , and separating by means of benzene.

Dinitronaphthyl ethyl ether (m. p. 144°) is easily soluble in benzene, and crystallises in yellow needles. When heated in a sealed tube at $180\text{--}190^{\circ}$ with 20 times its weight of alcoholic ammonia, it yields a dinitronaphthylamine melting at 242° , and the dinitronaphthalene from this melts at $166\text{--}167^{\circ}$, but its orientation is not yet decided.

Dinitronaphthyl ethyl ether $[(\text{NO}_2)_2 : \text{OEt} = 1 : 1' : 2]$ (m. p. 215°) is sparingly soluble in benzene, and crystallises in yellow needles; the corresponding dinitronaphthylamine melts at 223° , and the dinitronaphthol at 198° , with decomposition; the latter was converted into α -nitrophthalic acid (m. p. 160° , Abstr., 1882, 404), and this localises one of the nitro-groups, the other being ascertained by the conversion of the dinitronaphthylamine (m. p. 223°) into 1 : 1'-dinitronaphthalene (m. p. $170\text{--}172^{\circ}$).

When 3' : 2-nitronaphthyl ethyl ether is nitrated, it yields 1 : 3' : 2-dinitronaphthyl ethyl ether (m. p. 144°), which was described by Graebe and Drew (Abstr., 1884, 1036), and 1 : 2-nitronaphthyl ethyl ether yields the dinitro-derivative melting at 215° (see above).

A. G. B.

Naphthylene Dihydrosulphide and Dithiocyanate. By R. EBERT and E. KLEINER (Ber., 24, 144—147).—Naphthylene dihydrosulphide (dimercaptan) is best prepared by reducing disulphochloro- α -naphthalene $[(\text{SO}_2\text{Cl})_2 = 2 : 3']$ dissolved in acetic acid with zinc-dust; the dimercaptan is then precipitated with water, and purified by converting it into the lead salt, decomposing this with hydrogen sulphide, and finally extracting the product with absolute alcohol. It is obtained as a snow-white, crystalline mass, which, on cautious heating, sublimes in glistening colourless scales, melts at $173\text{--}174^{\circ}$, and is soluble in ether, hot alcohol, benzene, carbon bisulphide, chloroform, and alkalis. The yield is about 5 per cent. of that required by theory. The lead salt is an orange-yellow powder which, like lead β -naphthylmercaptide, is precipitated together with lead acetate, and is obtained pure by boiling with water and washing with alcohol and ether.

Naphthylene dithiocyanate, $\text{C}_{10}\text{H}_8(\text{SCN})_2$ [2 : 3'], is prepared by the action of cyanogen chloride on the above lead dimercaptide suspended

in alcohol; it melts at 78° , is soluble in alcohol, ether, benzene, chloroform, carbon bisulphide, and acetic acid, and cannot be sublimed. When an alcoholic solution of the dithiocyanate is mixed with alcoholic potassium hydrosulphide, it is converted into the dimercaptan. When heated with fuming hydrochloric acid at 180° , it yields the dimercaptan, carbonic anhydride, and ammonia.

E. C. R.

Halogen Derivatives of β -Naphthylamine. By A. CLAUS and O. PHILIPSON (*J. pr. Chem.* [2], 43, 47–61).—By brominating β -naphthylamine, or its acetyl derivatives, only one monobromoderivative is obtainable, namely, 1 : 2-bromonaphthylamine melting at 63° (Cosiner, *Abstr.*, 1881, 606); this is not a neutral substance, as Cosiner (*loc. cit.*) asserts, but is basic; its *hydrochloride* and *platinochloride* are described. When it is heated with acetic anhydride, *diaceto*-1 : 2-bromonaphthalide, $C_{10}H_6Br \cdot NAc_2$, is obtained; this crystallises in colourless tables which melt at 105° (uncorr.); on heating its alcoholic solution with aqueous ammonia, it is converted into *aceto*-1 : 2-bromonaphthalide (*loc. cit.*) melting at 140° .

1 : 3'-Dibromo-2-naphthylamine, m. p. 121° (Lawson, *Abstr.*, 1885, 1239), is best prepared by adding bromine (2 mols.) to a cold solution of *aceto*-1 : 2-bromonaphthalide in chloroform, warming it after a time on the water-bath, until no more hydrogen bromide is evolved, and heating the acetyl derivative which separates with hydrochloric acid in alcohol; its *hydrochloride* is described. The acetyl derivative melts at 212° (uncorr.), not 208° (*loc. cit.*). The *diacetyl* derivative forms colourless, lustrous prisms melting at 180° (uncorr.). The orientation of this dibromonaphthylamine is settled by two facts; first, that its oxidation with nitric acid yields β -bromophthalic acid (1 : 2 : 5, m. p. 68° ; *Abstr.*, 1887, 668), showing that the second bromine atom occupies one of the β -positions in the ring which does not contain the NH_2 group; secondly, that the dibromonaphthalene obtained by removing the amido-group (see below) is not 1 : 2'-dibromonaphthalene (m. p. 75° ; *Abstr.*, 1889, 894), showing that the β -position occupied by the second bromine atom is 3'.

1 : 3'-Dibromonaphthalene is obtained by dissolving 1 : 3'-dibromo-2-naphthylamine (10 grams) in alcohol (100 grams), adding a mixture of sulphuric acid (12 grams) and alcohol (60 grams), cooling to 0° , and dropping into the agitated liquid the calculated quantity of sodium nitrite solution; after a time, the retort is heated until no more nitrogen is evolved, water added, and the mixture distilled with steam, when the new compound separates from the distillate in flocks which may be crystallised from alcohol. It forms pale-yellow needles melting at 61° , and is soluble in the usual organic solvents; it is perhaps identical with Jolin's dibromonaphthalene (*this Journal*, 1887, ii, 901). When oxidised with nitric acid, this dibromonaphthalene yields chiefly 4-bromoterephthalic acid (m. p. 106°), and only a little 3-bromophthalic acid.

By diazotising 1 : 3'-dibromo-2-naphthylamine in the usual way, the corresponding *diazochloride* *platinochloride* was obtained as a yellow, crystalline precipitate.

1 : 2 : 3'-*Tri*bromonaphthalene forms colourless needles which melt

at 118°; it is little volatile with steam, sublimes in needles of the same melting point, and dissolves in alcohol, ether, and light petroleum.

1 : 3'-*Dibromo-2-chloronaphthalene* crystallises in long, slender, colourless needles, and melts at 102° (uncorr.); when the molten substance is quickly cooled, the melting point rises to 104—105°.

1 : 3'-*Dibromo-2-naphthonitrile* crystallises in slender, colourless, lustrous needles which melt at 178° (uncorr.), and dissolve in the usual organic solvents; it is sparingly volatile with steam; when heated for three days with 10 per cent. potash, it yields 1 : 3'-*dibromo-2-naphthoic acid* which crystallises in colourless, slender needles, melts at 245° (uncorr.), sublimes, and dissolves sparingly in water, but more freely in alcohol.

3'-*Bromo-1 : 2-naphthaquinone* is obtained by adding a cold solution of the above dibromonaphthalene diazochloride in small portions to boiling water, and heating until no more diazo-compound can be detected by sodium β -naphthol- α -disulphonate; the red colouring matter is collected, heated with water, and the solution cooled, when the quinone crystallises in yellow, feathery needles which darken at 100°, and melt with decomposition about 150°; it dissolves in the usual solvents when warmed, but not in sodium hydroxide solution. The corresponding *quinol* crystallises in soft, colourless needles, and decomposes without melting about 250°; it dissolves in warm chloroform and benzene; its solutions are coloured green by sodium hydroxide, and violet by ferric chloride; it reduces ammoniacal silver solution in the cold. These compounds are still under investigation.

Tribromo- β -naphthylamine, the orientation of which is being studied, is obtained by acting on a chloroform solution of 1 : 2-bromonaphthylamine with bromine (2 mols.) at a medium temperature, until no more hydrogen bromide is evolved, evaporating the solution, treating the residue with ammonia, and adding alcohol. It crystallises from a mixture of ether and alcohol in round, white, nodular aggregates, melts at 148° (uncorr.), and dissolves sparingly in alcohol and light petroleum, but freely in ether and chloroform. The *acetyl* derivative forms colourless, slender, feathery needles melting at 250—251° (uncorr.). The *diacetyl* derivative forms leaflets, and melts at 159° (uncorr.).

Attempts to obtain a series of chlorine derivatives corresponding with the foregoing bromine derivatives failed. When chlorine is passed into a cold chloroform solution of aceto-1-chloro-2-naphthalide, a *tetrachloroacetochloronaphthalide*, $C_{10}H_5Cl_4NHAc, Cl$, is formed; this crystallises from ether or acetone in colourless prisms or needles which melt at 140—145° with decomposition; it cannot be crystallised from alcohol or chloroform, as these solvents decompose it, evolving hydrogen chloride.

1' : 4'-*Dichloro-2-naphthylamine* is prepared by passing chlorine (2 mols.) into normal β -naphthylamine sulphate (1 part) suspended in 80 per cent. sulphuric acid (50 parts) until the solution has become lemon-yellow; the mixture is then poured into ice water, the precipitated flocks washed with dilute ammonia, and crystallised

from alcohol, or distilled with steam. It crystallises from light petroleum in long, colourless needles which rapidly become coloured; it melts at 96° (uncorr.). The *acetyl* derivative forms large, colourless prisms melting at 209° (uncorr.). When this dichloronaphthylamine is treated with sulphuric acid and sodium nitrite, it is converted into 1':4'-dichloronaphthalene (m. p. 68°), and when it is oxidised by dilute nitric acid, it yields 3:6-dichlorophthalic acid, whose anhydride melts at 183° (uncorr.); this acid is not identical with that obtained from dichlorortho-xylene, as stated by Beilstein (*Lehrbuch*, 2nd edition, 2, 1160).

2:1':4'-Trichloronaphthalene, melting at 69° , has been obtained, and is being investigated. A. G. B.

Formation of Quinalizarin from Alizarin. By C. GRAEBE (*Ber.*, 23, 3739—3740).—Blue-green and green dyes are formed by heating alizarin-blue (dihydroxyanthraquinolinequinone) with concentrated sulphuric acid; the former of these compounds is found to be derived from the trihydroxy- and tetrahydroxy-quinones; the tetrahydroxy-compound may be readily purified, and is found to be identical with quinalizarin, to which Liebermann and Wense assigned the formula $C_6H_2(OH)_2 < \begin{smallmatrix} CO \\ CO \end{smallmatrix} > C_6H_2(OH)_2$ [OH : CO : CO : OH = 1 : 2 : 3 : 4; 3 : 6 : 4 : 5]. No phthalic acid is formed from the trihydroxy-derivative on oxidation. J. B. T.

Action of Sodium Benzyloxide on Cyanocamphor. By J. MINGUIN (*Compt. rend.*, 112, 50—53).—When cyanocamphor is heated with benzyl alcohol and sodium in sealed tubes at 200° , the compound $CN \cdot CH_2 \cdot C_8H_{14} \cdot COOC_7H_7$ is obtained, and after crystallisation from ether or, better, toluene, forms transparent lamellæ melting at 70 — 71° . It dissolves easily in cold benzene, toluene, and xylene, but is less soluble in ether, and in methyl, ethyl, and propyl alcohols. Its rotatory power in solution in toluene is $[\alpha]_D = +42.8$. When treated with aqueous potash, or with concentrated hydrochloric acid, it yields hydroxycamphocarboxylic acid, $COOH \cdot CH_2 \cdot C_8H_{14} \cdot COOH$.

The aqueous mother liquor from the preparation of this compound, when treated with an acid, yields a precipitate of the acid

which crystallises from ether in distinct crystals melting at 164° , and somewhat soluble in ether and alcohol. Its molecular rotatory power in alcoholic solution is $[\alpha]_D = +64^{\circ} 61'$. With aqueous potash, it yields hydroxycamphocarboxylic acid, with evolution of ammonia. The sodium salt, obtained by neutralising the acid with sodium carbonate, forms a white, gummy mass, very difficult to dry; the copper salt is a green powder which contains 1 mol. H_2O , and becomes blue when heated at 100° . The lead salt is anhydrous; the barium salt crystallises in needles containing 6 mols. H_2O . The silver salt blackens rapidly when exposed to light. C. H. B.

Action of Cyanocamphor on Sodium Phenoxide and Sodium Naphthoxide. By J. MINQUE (Compt. rend., 112, 101—102).—Cyanocamphor, phenol, and sodium when heated in sealed tubes at 200—220° for 24 hours yield the compound $\text{CN}\cdot\text{CH}_2\cdot\text{C}_6\text{H}_4\cdot\text{COOPh}$, a viscous, brown oil, which boils with partial decomposition at 265—270° under a pressure of 40 mm.; rotatory power in alcoholic solution $[\alpha]_D = +26^\circ 66$. With aqueous potash, it yields ammonia, phenol, and hydroxycamphocarboxylic acid. The acid $\text{CN}\cdot\text{CH}_2\cdot\text{C}_6\text{H}_4\cdot\text{COOH}$ is found in the aqueous mother liquor from the crude product.

β -Naphthol, under the same conditions, yields an analogous compound, which crystallises in white crystals, soluble in benzene and toluene, but less soluble in alcohol and ether. With aqueous potash, it yields ammonia, naphthol, and hydroxycamphocarboxylic acid.

C. H. B.

The Presence of Ethylene Linkages in Terpenes. By V. MARKOVNIKOFF (Ber., 24, 67—70).—A reply to the communication of Wagner (Ber., 23, 2307), who attributes to the author views which he has never entertained.

Kuro-moji Oil. By W. KWASNICK (Ber., 24, 81—82).—Kuro-moji oil is the ethereal oil of *Lindera fericia*, Bl., one of the Japanese *Lauraceae*, the use of which in Europe has largely increased of late. It is obtained from the leaves, and has a dark-yellow colour, a sp. gr. of 0.901 at 18°, and a powerful aromatic smell. Its small optical activity is due to the fact that it is a mixture of dextro- and lævoro-rotatory constituents. By fractional distillation and treatment with sodium, it yields two terpenes, which have been identified by their derivatives as *dextrolimonene* and *dipentene*. In addition, two substances containing oxygen are present, namely, inactive terpineol and lævocarvole. The former has hitherto only been found in the oil of cardamon seeds and in kesso oil, obtained from a Japanese valerian. The carvole differs only from that obtained from cummin oil in possessing opposite optical properties.

H. G. C.

Massoyene. By R. Woy (Arch. Pharm., 228, 687—690).—The existence of this terpene (Abstr., 1890, 638) has been disputed by Wallach (*ibid.*, 1316), who contends that the terpene described by the author is probably limonene, perhaps mixed with other terpenes. The latter obtained his results with a fraction boiling at 172°, whilst Wallach founds his criticism on results obtained with material boiling at 170—175°, the boiling point of limonene being 175—177°. The author hopes to publish the results of his further investigations on the terpenes of massoy bark shortly.

J. T.

Ethereal Oils contained in Asafetida. By F. W. SEMMLER (Ber., 24, 78—81; see also this vol., p. 322).—The second fraction obtained on distilling asafetida in a vacuum, and which boils at 80—85° (9 mm.), has a sp. gr. of 0.9721 at 15°, rotates the plane of polarised light $-12^\circ 30'$ with a column 100 mm. in length. Its composition is $\text{C}_7\text{H}_{14}\text{S}_2$, the vapour density being found as 165 and 164, instead of 162. The fraction is homogeneous, and boils at

210—212° (uncorr.) with slight decomposition under the ordinary pressure, and on distillation in a vacuum over small quantities of potassium, may be obtained as a perfectly colourless liquid boiling at 83—84° (9 mm.). It is a bisulphide, from which zinc-dust removes half the sulphur, and contains a saturated and an unsaturated radicle. It forms a *mercuriochloride*, $C_7H_{11}S_2 \cdot 2HgCl_2$, crystallising from alcohol in beautiful needles. When oxidised, it yields a deliquescent sulphonic acid, which has not been obtained pure. The bisulphide is present in the crude oil to the extent of 45 per cent.

The third fraction, boiling at 120—130° (9 mm.), has a sp. gr. of 1.0120 at 15°, and a column 100 mm. in length rotates the plane of polarisation $-18^\circ 30'$. It decomposes on distillation under the ordinary pressure with evolution of most repulsive smelling gases. It has the composition $C_{11}H_{20}S_2$, the vapour density in an atmosphere of nitrogen being found to be 219 instead of the theoretical 216. It loses half its sulphur on treatment with zinc-dust, and is therefore also a bisulphide.

Notwithstanding the similarity between the odours of oil of garlic, oil of onions, and asafetida, the latter contains no trace of allyl sulphide. The composition of the two former oils is now being investigated.

H. G. C.

Suberin and Cork Cells. By F. A. FLÜCKIGER (and GILSON) (*Arch. Pharm.*, 228, 690—700).—Kügler (1884) showed that suberin contained an appreciable amount of fat and extracted stearic acid; he also isolated the crystalline phellonic acid, which, however, does not belong to the fatty series. Gilson (1890) maintains that suberin is that part of cork texture which is insoluble in neutral liquids, and is not taken up either by concentrated sulphuric acid or by ammonio-copper oxide solution, but is dissolved by alcoholic potash, and with nitric acid yields suberic and other fatty acids soluble in ether and alcohol. He finds the colouring matter of cork to be very soluble in sodium carbonate solution, which scarcely attacks suberin even on prolonged boiling. After treating finely divided cork with sodium carbonate, the suberin is extracted by a 3 per cent. alcoholic potash solution. The solution filtered hot gives a precipitate on cooling, which, after washing with water and recrystallisation from alcohol, consists mainly of potassium phellonate. The alcoholic filtrate freed from alcohol, diluted with water, and treated with hydrochloric acid, gives a semi-fluid deposit; the decanted liquid yields glycerol. Gilson dissolves the deposit in ether, washes out the hydrochloric acid with water, expels the ether, dissolves in alcohol, and boils with potassium carbonate, when the addition of an alcoholic solution of magnesium chloride precipitates phloionic acid; the solution on further treatment yields suberinic acid. Kügler gives $C_{22}H_{42}O_5$ as the formula for phellonic acid, whilst Gilson prefers $C_{22}H_{43}O_5$. The latter gives the melting point as 102°. When heated at 105° with hydrochloric acid, the anhydride $C_{22}H_{40}O_5$ is obtained. *Phloionic acid*, $C_{22}H_{44}O_5$, is insoluble in cold water, but dissolves in hot water, forming crystalline needles on cooling; it is very soluble in alcohol, but only slightly in ether and in chloroform; it melts at 62—63°. *Potassium phloionate* is

very soluble in ether, less so in alcohol. *Silver phloionate* is rapidly decomposed in the light, whilst the corresponding phellonate is only slowly coloured. *Magnesium phloionate* forms a crystalline precipitate when an alcoholic solution of a magnesium salt is added to a solution of phloionic acid. *Suberinic acid*, $C_{17}H_{30}O_3$, when gently warmed, forms a liquid miscible with alcohol, ether, and chloroform, but not with light petroleum. Its alkaline salts are soluble in water and alcohol; in the alcoholic solution no precipitate is produced either by magnesium or barium acetate. When heated without access of air, suberinic acid gradually forms a transparent, elastic mass, for which no solvent has yet been found. No water appears to be separated; the change appears rather to be due to polymerisation. *Potassium suberinate* is soluble in water and alcohol, but not in ether. The *silver* salt is rapidly decomposed. Gilson has observed a characteristic test for phellonic acid, which consists in the beautiful reddish-violet colour produced on moistening the acid with a very dilute, alcoholic iodine solution, and adding sulphuric acid (sp. gr. 1.8); the reaction succeeds best with potassium phellonate, and may be obtained with iodine in aqueous solution of potassium iodide, or with iodine in zinc iodide. The foregoing relates entirely to cork from *Quercus suber*. Gilson has, however, glanced at that from *Ulmus campestris* var. *suberosa*, and finds that this is much poorer in suberin. It yielded phellonic and suberinic acids, but neither phloionic acid nor glycerol.

J. T.

Derivatives of Homopiperidinic Acid. By W. ASCHAN (Ber., 23, 3692—3701).—*Ethyl γ -phthalimidopropylethylmalonate*,

is prepared by adding powdered γ -bromopropylphthalimide (11 grams) to a clear solution consisting of sodium (1.2 grams) dissolved in absolute alcohol (12 c.c.), and mixed with ethyl ethylmalonate (11 grams), and heating the mixture for some hours in a reflux apparatus. It crystallises from petroleum in short, colourless prisms, melts at 62° (uncorr.), and dissolves easily in alcohol, ether, benzene, chloroform, and carbon bisulphide, sparingly in light petroleum, and is insoluble in water.

α -Ethylhomopiperidinic acid, $COOH \cdot CHEt \cdot [CH_2]_3 \cdot NH_2$, prepared by heating the above compound with hydrochloric acid at 160° in a sealed tube, is easily soluble in water, insoluble in alcohol and ether, and melts at 200 — 200.5° (uncorr.) with frothing. The hydrochloride gives an *aurochloride*, which forms bright yellow, oily drops, crystallises when dried in a vacuum over sulphuric acid, and is very hygroscopic. The *platinochloride* is easily soluble.

β -Ethylpiperidone, $CH_2 < \begin{smallmatrix} CHEt \cdot CO \\ CH_2 - CH_2 \end{smallmatrix} > NH$, obtained by distilling *α -ethylhomopiperidinic acid* under 42 mm. pressure at 140 — 142° , melts at 68° (uncorr.), has an odour resembling that of coniine, and is very easily soluble in all the usual solvents with the exception of petroleum; when crystallised from hot petroleum, it is obtained in thin, shining, colourless plates. The *aurochloride* is very hygroscopic,

crystallises when dried in a vacuum, and dissolves easily in all the ordinary solvents. The *platinochloride* resembles the *aurochloride*.

Ethyl γ-phthalimidopropylbenzylmalonate,

prepared in a similar way to the corresponding ethyl compound, crystallises from 90 per cent. alcohol in flat prisms, and melts at 108—110°. When heated at 190—195° in a sealed tube with hydrochloric acid, it is converted into *α-benzylhomopiperidinic acid*, $\text{NH}_2\cdot[\text{CH}_2]_3\cdot\text{CH}(\text{C}_7\text{H}_7)\cdot\text{COOH}$, which melts at 195—196°, is easily soluble in hot water, only slightly in cold water or alcohol, and is insoluble in ether. It yields an *aurochloride* which crystallises in long, lemon-yellow prisms, melts at 102—103° without decomposition, and is very easily soluble in alcohol and ether, slightly in water; the *platinochloride* forms a microcrystalline powder, decomposes on heating without melting, and is sparingly soluble in water, insoluble in alcohol and ether.

β-Benzylpiperidine, $\text{CH}_3<\frac{\text{CH}(\text{C}_7\text{H}_7)\cdot\text{CO}}{\text{CH}_2}\text{CH}_2>\text{NH}$, obtained by distillation of *α-benzylhomopiperidinic acid*, crystallises from hot water in beautiful, thin plates of nacreous lustre, melts at 117—118°, and is insoluble in cold water, easily soluble in hot water, alcohol, ether, and benzene. The *aurochloride* forms viscous, oily drops, as also does the *platinochloride*; both are easily soluble in alcohol and ether. The *picrate* forms small, short crystals, melts at 97°, decomposes at about 150°, and is sparingly soluble in water.

Nitroso-β-benzylpiperidone, $\text{C}_{12}\text{H}_{13}\text{ON}\cdot\text{NO}$, obtained by the action of potassium nitrite on *β-benzylpiperidone* dissolved in dilute sulphuric acid, crystallises from warm alcohol in beautiful, long prisms, melts at 61.5—62.5°, decomposes at about 100°, and is insoluble in water, sparingly soluble in cold alcohol and ether. When treated with excess of soda, nitrogen is evolved and ether extracts from the acidified solution *α-benzyl-δ-hydroxyvaleric acid*; this distils at 360°, and yields *α-benzyl-δ-valerolactone*, $\text{C}_{12}\text{H}_{14}\text{O}_2$, which forms a colourless oil having an odour resembling that of camphor and peppermint.

Ethyl γ-phthalimidopropylpropylmalonate,

prepared in a similar way to the corresponding ethyl compound crystallises from methyl alcohol in oblong prisms, melts at 57° (uncorr.), and is insoluble in water, sparingly soluble in light petroleum, but easily in alcohol and ether. When heated with hydrochloric acid for four hours at 190°, it is converted into *α-propylhomopiperidinic acid*, $\text{COOH}\cdot\text{CHPr}\cdot[\text{CH}_2]_3\cdot\text{NH}_2$. The latter is soluble in alcohol, ether, petroleum, benzene, and water; from a mixture of water, alcohol, and ether, it crystallises in beautiful, colourless crystals belonging to the monoclinic system, $a : b : c = 1.04145 : 1 : ?$; $\beta = 99^\circ 41' 50''$, and melts at 186° (uncorr.) with frothing and partial decomposition. The *aurochloride* is not crystalline; the *platinochloride* crystallises in thin, yellow leaflets, melts at 206—209° with frothing and decom-

position, and is insoluble in alcohol and ether, sparingly soluble in water.

β-Propylpiperidone, $\text{CH}_2\langle\begin{smallmatrix} \text{CHPr}\cdot\text{CO} \\ \text{CH}_2-\text{CH}_2 \end{smallmatrix}\rangle\text{NH}$, obtained by distilling *α*-propylhomopiperidinic acid under 40 mm. pressure at 156°, crystallises from light petroleum in snow-white needles, melts at 59° (uncorr.), and is easily soluble in the ordinary solvents. The *anurochloride* is very hygroscopic, and forms yellow, oily drops which partially solidify when dried in a vacuum or over sulphuric acid. The *platinochloride* resembles the *anurochloride*. Both salts are very easily soluble in alcohol and ether. E. C. R.

Phenylisoxazalone. By L. CLAUEN and W. ZEDL (*Ber.*, 24, 140—143).—*Phenylisoxazalone*, $\text{CO}\langle\begin{smallmatrix} \text{O}-\text{N} \\ \text{CH}_2\cdot\text{CPh} \end{smallmatrix}\rangle$, is prepared by heating ethyl benzoylacetate (1 mol.), dissolved in 8 to 9 times its weight of glacial acetic acid, with finely-powdered hydroxylamine hydrochloride until the latter is dissolved. The greater part of the acetic acid is distilled off, the rest evaporated on the water-bath, and the product purified by crystallisation from alcohol. It melts at 147° with decomposition, is sparingly soluble in ether and cold alcohol, somewhat easily soluble in boiling alcohol, from which it crystallises in pale-yellow needles; it dissolves in dilute alkali and alkaline carbonates to a yellow solution, and is not reprecipitated by carbonic anhydride. The alcoholic solution reduces silver nitrate, and gives with ferric chloride a brownish-black coloration.

Isonitrosophenylisoxazalone is prepared by allowing a mixture of phenylisoxazalone, dissolved in the calculated quantity of normal soda and excess of sodium nitrite, to drop into well-cooled dilute sulphuric acid. It crystallises from hot water in bright-yellow, slender needles, melts at 143° with decomposition, is easily soluble in alcohol, ether, and acetic acid, and dissolves easily in alkalis and in alkaline carbonates to a light rose-red solution.

Benzeneazophenylisoxazalone, $\text{C}_6\text{ONO}\cdot\text{N}\cdot\text{NHPh}$ or $\text{C}_6\text{ONHO}\cdot\text{N}_2\text{Ph}$, is obtained by adding a solution of diazobenzene chloride to an ice-cold solution of phenylisoxazalone in normal potash. It crystallises from alcohol in small, orange-yellow prisms, melts at 166°, and is easily soluble in ether, acetic acid, and hot alcohol. E. C. R.

Imido-ethers and their Derivatives. By A. PINNER (*Ber.*, 23, 3820—3826).—In the hope of obtaining a new series of compounds, the author has investigated the action of ethyl imidobenzoate, $\text{HN}\cdot\text{CPh}\cdot\text{OEt}$, on ethyl acetoacetate, but finds that the chief product is the same as that obtained from benzamidine under similar conditions, namely, *phenylmethylhydrozypyrimidine*, $\text{CPh}\langle\begin{smallmatrix} \text{N}-\text{CMe} \\ \text{N}\cdot\text{C(OH)} \end{smallmatrix}\rangle\text{CH}$. It is probable that the ethyl imidobenzoate is first converted into ethyl benzoate and ammonia, and that the latter then converts another portion of the imidobenzoate into alcohol and benzamidine, which unites with the ethyl acetoacetate.

Formaldehyde acts readily on a solution of benzamidine in alcoholic ether at the ordinary temperature (compare this vol., p. 61), and, after a short time, a small quantity of cyanophenine separates. On adding water to the solution, a viscous liquid is precipitated which dissolves in hydrochloric acid, but quickly separates in beautiful prisms, an odour of formaldehyde being also observed. The same crystals are obtained directly by heating the amidine and formaldehyde at 100°. This substance, *methylenedibenzamide*, $\text{CH}_2(\text{NH}\cdot\text{COPh})_2$, melts at 249.5°, is sparingly soluble in hot water and alcohol, and almost insoluble in acetone and chloroform. The first product of the reaction is probably the corresponding *di-imido-compound*,

which is decomposed by hydrochloric acid at the ordinary temperature and by water at the boiling point, with formation of methylenedibenzamide.

The compound obtained by the action of ethyl bromide and potash on dimethylhydroxypyrimidine (Abstr., 1889, 1007), to which the constitution $\text{CMe} \begin{smallmatrix} \text{N} \\ \text{N} \end{smallmatrix} \begin{smallmatrix} \text{CMe} \\ \text{C}(\text{OEt}) \end{smallmatrix} \text{CH}$ was assigned, really contains the ethyl group combined with the nitrogen atom, and has the formula $\text{CMe} \begin{smallmatrix} \text{NEt} \cdot \text{CMe} \\ \text{N} \end{smallmatrix} \text{CO} \text{CH}$, corresponding with the compound described by E. v. Meyer (Abstr., 1881, 54), as the hydrobromide, on heating, remains unaltered, whilst the hydrobromides of pyrimidines containing the ethoxy-group, such as phenylmethylethoxypyrimidine, $\text{CPh} \begin{smallmatrix} \text{N} \\ \text{N} \end{smallmatrix} \begin{smallmatrix} \text{CMe} \\ \text{C}(\text{OEt}) \end{smallmatrix} \text{CH}$, lose ethyl bromide on heating, passing into the corresponding hydroxy-compounds.

The products prepared by treating ethyl salicylate and ethyl cresotate with benzamidine have been partially re-examined, and it has been found that the phenolic oxygen has not been displaced by nitrogen, as on heating the product from ethyl salicylate with hydrochloric acid at 130–150°, it is decomposed; the first products are doubtless benzamidine and salicylic acid, but these are further acted on, with formation of ammonia, benzamide, benzoic acid, phenol, and carbonic anhydride. For the constitution of this product, the author proposes the alternative formulæ:—

As already shown by Glock (Abstr., 1889, 1290), paratolylmethylhydroxypyrimidine, $\text{C}_7\text{H}_7\cdot\text{C} \begin{smallmatrix} \text{N} \\ \text{N} \end{smallmatrix} \begin{smallmatrix} \text{CMe} \\ \text{C}(\text{OH}) \end{smallmatrix} \text{CH}$, is readily obtained by the action of tolenylamidine on ethyl acetoacetate. If ethyl ethylacetoacetate be substituted for the latter, the corresponding *paratolylmethylethylhydroxypyrimidine*, $\text{C}_7\text{H}_7\cdot\text{C} \begin{smallmatrix} \text{N} \\ \text{N} \end{smallmatrix} \begin{smallmatrix} \text{CMe} \\ \text{C}(\text{OH}) \end{smallmatrix} \text{OEt}$, is formed; it crystallises in hair-like needles, melts at 218°, and is insoluble in

water, sparingly soluble in cold, fairly readily in hot alcohol. *Paratolylmethylbenzylhydroxypyrimidine*, $C_{19}H_{18}N_2O$, forms slender needles, insoluble in water, sparingly soluble in boiling alcohol, readily in pyridine, and melts at 240° . *Paratolylphenylhydroxypyrimidine*, $C_{17}H_{14}N_2O$, obtained from ethyl benzoylacetate, also forms slender needles melting above 290° .
H. G. C.

Phenazines. By K. EICKER (*Ber.*, 23, 3803—3810).—An extension of the synthesis of phenazine derivatives, described by O. Fischer and Hepp (*Abstr.*, 1890, 801, 1444), to other azo-colouring matters, the latter being prepared by the method also given by Fischer and Hepp (*Abstr.*, 1890, 908).

Benzeneazo- α -ethylnaphthylamine crystallises from a mixture of ether and light petroleum in red, prismatic crystals with a bluish reflex, which, after frequent recrystallisation, melt higher than previously stated, namely, at 88° . Its *hydrochloride* forms reddish-violet needles, melts at 181° , is sparingly soluble in alcohol, and partially dissociated by water. *Benzeneazo- α -dimethylnaphthylamine* is obtained by the action of diazobenzene chloride on α -dimethylnaphthylamine, and forms a scarlet syrup with a bluish reflex, which has not been obtained crystalline. Its *hydrochloride* forms thin, indigo-blue needles melting at 105° .

α -Ethylamido- α -naphthaphenazine, $C_6H_4 \begin{smallmatrix} \text{N} \\ | \\ \text{N} \end{smallmatrix} C_{10}H_7 \cdot NH\text{Et}$, is prepared by heating orthodiamidobenzene and benzeneazoethylnaphthylamine hydrochloride, in molecular proportion, with double the quantity of absolute alcohol at 140° for 5—6 hours. The separated crystalline mass, which consists chiefly of the new base, is washed with water and dilute alcohol, and recrystallised twice from alcohol. A larger quantity is contained in the liquid portions of the tube contents, and is isolated by precipitating with water, dissolving in dilute alcoholic hydrochloric acid, reprecipitating with sodium acetate, and repeatedly crystallising the hydrochloride. The base is insoluble in water and alkalis, sparingly soluble in ether, benzene, and cold alcohol, and still less so in chloroform, the solutions showing a beautiful, yellowish-green fluorescence. It separates from benzene on the addition of light petroleum as a yellow, crystalline powder, and sublimes in yellow, woolly needles, partially carbonising at the same time. Its salts crystallise well, and show a metallic lustre, the solution having a magenta colour, and readily dissociating when warmed. The *hydrochloride* forms garnet-red needles with a coppery lustre; the *platinohydrochloride*, $(C_{16}H_{15}N_3)_2 \cdot H_2PtCl_6$, is a scarlet precipitate, consisting of microscopic slender needles; whilst the *aurochloride*, $C_{16}H_{15}N_3 \cdot HAuCl_4$, is a red, microcrystalline powder, sparingly soluble in alcohol. The *nitrate*, $C_{16}H_{15}N_3 \cdot HNO_3$, crystallises from alcohol in brownish-red, slender needles which have a metallic lustre; and the *acetyl* compound, $C_{16}H_{14}N_3 \cdot Ac$, crystallises from acetic acid in very sparingly soluble, straw-yellow, rhombohedral crystals. On heating with concentrated hydrochloric acid at 175 — 180° , α -ethylamidonaphthaphenazine is converted into ammonia, alcohol, and the α -hydroxynaphthaphenazine already described by Fischer and Hepp (*loc. cit.*).

α-Ethylamido-α-naphthalolazine, $C_6H_5Me \begin{smallmatrix} N \\ | \\ N \end{smallmatrix} > C_{10}H_7 \cdot NHEt$, is prepared in a manner similar to the preceding compound, 1:3:4-diamidotoluene being employed in place of diamidobenzene. It forms stellate groups of needles or golden-yellow plates, melts at 182° , and closely resembles the foregoing base, but is rather less soluble. The *hydrochloride* and *sulphate* form coppery needles, whilst the *nitrate* separates from alcohol in brownish-red needles with a bronze lustre. The *platinochloride* forms small, scarlet needles; the *aurochloride* a scarlet, microcrystalline powder; and the *acetyl* compound straw-yellow, prismatic crystals, sparingly soluble in almost all indifferent solvents.

α-Phenylamido-α-naphthalolazine, $C_6H_5Me \begin{smallmatrix} N \\ | \\ N \end{smallmatrix} > C_{10}H_7 \cdot NHPh$, is prepared from 1:3:4-diamidotoluene and benzeneazo-*α*-phenyl-naphthylamine hydrochloride (Abstr., 1890, 908); it crystallises with some difficulty from alcohol in slender, brass-yellow needles, melts at 214° , and is sparingly soluble in most solvents. The solutions are reddish-yellow, and show a strong, yellowish-green fluorescence. The salts are likewise sparingly soluble, and have a Bordeaux-red colour in solution. The *hydrochloride* forms brownish-red needles with a metallic lustre, which are readily soluble in alcohol; and the *nitrate*, slender, brown needles with a bronze lustre, which are also fairly soluble in alcohol. The *platinochloride*, $C_2H_7N_3H_2PtCl_6$, forms dark-red, microscopic needles, and the *aurochloride* a brownish-red, microcrystalline powder.

α-Dimethylamido-α-naphthaphenazine, $C_6H_4 \begin{smallmatrix} N \\ | \\ N \end{smallmatrix} > C_{10}H_7 \cdot NMe_2$, is prepared from orthodiamidobenzene and benzeneazo-*α*-dimethylnaphthylamine; it crystallises from alcohol in slender, brownish-yellow needles, melts at 221° , is sparingly soluble in ether and light petroleum, more easily in benzene, toluene, and cold alcohol, forming yellowish-red solutions with a yellowish-green fluorescence. The base also sublimes in woolly needles, and is taken up by concentrated hydrochloric and sulphuric acids with a greenish-red colour, whilst the solution in acetic acid or dilute mineral acids is cherry-red. An isomeric compound has been described by Witt (Abstr., 1888, 491) as *dimethylnaphthila-eurhodine*, in which the dimethylamido-group is situated in the benzene nucleus. The *hydrochloride* of the new base forms garnet-red needles with a coppery lustre, whilst the *nitrate* crystallises from alcohol in bronze-coloured needles; the *sulphate* forms coppery needles, the *platinochloride* and *aurochloride* brownish-red needles.

α-Dimethylamido-α-naphthalolazine, $C_6H_5Me \begin{smallmatrix} N \\ | \\ N \end{smallmatrix} > C_{10}H_7 \cdot NMe_2$, crystallises best from boiling alcohol, and forms brownish-yellow needles melting at 230° . It closely resembles the foregoing base, but is rather less soluble, and sublimes with partial carbonisation in woolly needles; it dissolves in dilute mineral acids with a cherry-red colour, and in concentrated sulphuric acid with a green colour. The

hydrochloride and *sulphate* form garnet-red needles with a coppery lustre, readily soluble in alcohol; the *nitrate* crystallises in slender, sparingly-soluble needles with a bronze lustre, and the *platinochloride* and *aurochloride* in brownish-red needles.

The formation of α -dimethylamido- α -naphthaphenazine and tolazine proves that the α -amido- α -naphthaphenazine prepared from them really contains the primary amido-group, as already maintained by Fischer and Hepp against Kehrman (Abstr., 1890, 1266, 1444).

H. G. C.

Oxidation of Phenylmethyltriazolecarboxylic Acid; Phenyltriazolecarboxylic Acid and the Constitution of α -Phenyltriazolecarboxylic Acid. By J. A. BLADIN (*Ber.*, 23, 3785—3789).—In the author's previous communication (Abstr., 1890, 1165), the preparation of the acid potassium salt of phenyltriazolecarboxylic acid by the oxidation of phenylmethyltriazolecarboxylic acid was described. All attempts to obtain the free acid have been without success, as it loses carbonic anhydride so readily, forming α -phenyltriazolecarboxylic acid. The salts also, with the exception of the normal potassium salt, and probably also the normal sodium salt, readily undergo the same decomposition when boiled. The *normal potassium salt* is extremely soluble in water, as are also the *calcium* and *barium* salts. The *potassium ammonium salt*, obtained by dissolving the acid potassium salt in ammonia and adding alcohol, is an amorphous, very soluble mass which is decomposed at 100°. The *silver salt*, $C_6N_3Ph(COOAg)_2 + \frac{1}{2}H_2O$ (?), is a white, amorphous, sparingly-soluble, voluminous precipitate which is partially decomposed at 100°; the water of crystallisation being evolved at 80°. The *copper salt*, $C_6N_3Ph(COO)_2Cu + 4H_2O$, is sparingly soluble in water, and crystallises in small, blue needles which lose their water at 100°, simultaneously undergoing further decomposition.

The *dimethyl salt*, $C_6N_3Ph(COOMe)_2$, is prepared by the action of methyl iodide on the silver salt; it crystallises from alcohol in hard, laminated crystals, or very slender, elastic needles, and melts without decomposition at 167°. The *diethyl salt*, $C_6N_3Ph(COOEt)_2$, crystallises from solution in a mixture of ether and light petroleum in slender, elastic needles melting at 81.5°.

From the above formation of α -phenyltriazolecarboxylic acid, it might have a constitution represented by either of the following formulæ:—

In order to decide which of these is correct, the formyl compound of dicyanophenylhydrazine (Abstr., 1885, 980) was boiled with alcoholic potash, ammonia being given off. On adding water, evaporating off the alcohol, and adding hydrochloric acid, a brown, crystalline mass was obtained, which, on purification, was found to be identical with α -phenyltriazolecarboxylic acid. The condensation of formyldicyanophenylhydrazine in all probability takes place in the following manner:—

the cyanogen group being then converted into carboxyl. The acid must therefore have the first of the formulæ given above.

H. G. C.

Nicotine. By A. PINNER and R. WOLFFENSTEIN (*Ber.*, 24, 61—67).—When nicotine is mixed with platinum sponge and such a quantity of hydrogen dioxide that 3 atoms of active oxygen are present for each molecule of the base, and the whole allowed to remain for several weeks, the nicotine odour completely disappears. The liquid is then evaporated at 40—50° in a vacuum, and the pale-yellow syrup extracted with alcohol. After evaporating off the latter in a vacuum, and allowing the residue to remain in an exsiccator, it solidifies to a crystalline, deliquescent mass very soluble in water and alcohol, insoluble in ether. It is a base, most of the salts of which are syrups, but the *platinochloride* and *picrate* have been obtained in crystals. The former is prepared by adding platinic chloride to a mixture of the base with a little hydrochloric acid, allowing to remain for two days, and collecting the granular, crystalline, orange-red salt. This is soluble in hydrochloric acid, is reprecipitated by soda with partial decomposition, and has the composition $\text{C}_{10}\text{H}_{13}\text{N}_2\text{O}_2\text{H}_2\text{PtCl}_4$. The *picrate*, $\text{C}_{10}\text{H}_{13}\text{N}_2\text{O}_2\cdot 2\text{C}_6\text{H}_3\text{N}_3\text{O}_7$, is formed by adding an excess of a saturated solution of picric acid to an aqueous solution of the base, and forms slender, seemingly rhombic needles melting at 154—158°. The base has, therefore, the composition $\text{C}_{10}\text{H}_{13}\text{N}_2\text{O}$, being formed from nicotine by the substitution of one atom of oxygen for two atoms of hydrogen, and may be termed for the present *orynicotine*. It is not volatile in a current of steam, is scarcely acted on by aqueous potash, and has physiological properties resembling, but much feebler than, those of nicotine. On oxidation with potassium permanganate, it is converted into nicotinic acid.

Attempts were made to obtain evidence of the presence of imido-groups in nicotine by treating it with nitrous acid, acetic anhydride, and benzoic chloride in alkaline solution, but without any definite result. Acetic anhydride does act on nicotine at 150—170°, but the nature of the product is not yet ascertained. Benzoic chloride in alkaline solution does not act on the nicotine, but is simply converted into benzoic anhydride. By the action of benzoic chloride on the base itself at the ordinary temperature or at 100°, a product is formed which, however, does not seem to be a benzoyl derivative of nicotine, and is not identical with the additive product of 2 mols. of benzoic chloride and nicotine obtained by Will (*Annalen*, 118, 206). These products are being further investigated.

H. G. C.

Solanidine of Potato Sprouts. By A. JØRISSEN and L. GROU-
JEAN (*Chem. Centr.*, 1890, ii, 788; from *Bull. Acad. Belg.* [3], 19, 245).—By extracting the young sprouts of potatoes with ether, recrystallising the residue of the ether extract from alcohol, dissolving in a mineral acid, precipitating with alkali, and finally recrystallising from ether, a substance is obtained which is identical with the solan-

idine obtained from solanine. It crystallises in long, white, silky needles, is nearly insoluble in water, soluble in alcohol, very soluble in ether, and melts at 204° . It is alkaline to litmus, has a sharp, bitter taste, and combines with acids to form salts. If the solution of the base in acetic acid be concentrated on the water-bath, concentrated hydrochloric acid and a little ferric chloride added, and the mixture then evaporated to dryness, a violet coloration is produced. About 1.5 grams of the base is obtained from 100 grams of the fresh sprouts. J. W. L.

Metallic Derivatives of Cupreine. By A. C. OUDEMANS, Jun. (*Rec. Trav. Chim.*, 9, 171—183).—The sodium and potassium compounds of cupreine separate as crystalline scales when a solution of the alkaloid in slight excess of the corresponding hydroxide is subjected to cold. The separated scales are dried by a filter pump, washed rapidly with strong alcohol, and placed in a desiccator over potassium hydroxide for some time. *Potassium cupreine*, $C_{19}H_{21}KN_3O_2 + 6H_2O$, forms acicular crystals or hexagonal scales. *Sodium cupreine*, $C_{19}H_{21}NaN_3O_2 + 5H_2O$ and $+ 8H_2O$, forms large scales which are greasy to the touch. The potassium compound appears to be more soluble in mixtures of aqueous and alcoholic alkalis than the sodium derivative.

In contradistinction to Hesse, who denied the existence of an ammonium derivative of cupreine, the author states that the alkaloid dissolves easily in concentrated ammonia solution, to a smaller extent in weaker solutions, and inasmuch as the specific rotatory power of such solutions is similar to that of like solutions of the sodium derivative, he concludes that an ammonium compound does exist. Solutions of lithium hydroxide and of barium hydroxides also dissolve cupreine. All the metallic derivatives of cupreine assume an orange or brick-red colour after prolonged drying or on heating above 120° .

Hesse having proved that cupreine behaved as a phenol in which hydrogen may be displaced by a metal, the author has investigated the influence such replacement has on the specific rotatory power of the alkaloid, in order to determine if the alkaloid and the base combined molecule for molecule, in which case an excess of base ought not to affect the specific rotatory power to any great extent, and he publishes very complete tables of the specific rotatory power of the alkaloid in both aqueous and alcoholic solutions of potassium and sodium hydroxides, in aqueous solutions of lithium and barium hydroxides, and in ammonia solution.

The results of the observations are as follows:—1. Approximately the same values obtain for the sp. rot. power of cupreine for similar concentrations of alkaloid and either potassium, sodium, lithium, and barium hydroxides in aqueous solution, but in the case of the ammoniacal solution the rotatory power has a higher value, and differs in the values obtained from its solution in fixed alkalis in the fact that an increased strength of ammonia solution augments the sp. rot. power. 2. The sp. rot. power of the alkaloid diminishes inversely with the amount present in the alkaline solution, and also with the amount of alkaline hydroxide present. 3. The highest values for the sp. rot.

power are obtained when the amounts of alkaloïd and of hydroxide associated are approximately those represented by their molecular weights; in this respect cupreïne is analogous to quinamine and conquinamine in acid solution. It is to be noted that the values obtained in alkaline alcoholic solution are much higher than those in aqueous solution, and that in this case additional alkali increases the rotatory values.

The mean rotatory power for 1 mol. (in milligrams) of cupreïne in 20 c.c. of water with 1—2 mols. (in milligrams) of alkaline hydroxide is about -205° .
T. G. N.

Dextrococaines. By A. DEKERS and A. EINHORN (*Ber.*, **24**, 7—12; compare Abstr., 1890, 649, 913).—By the action of cinnamic chloride on methyl dextroecgonine at $150-160^{\circ}$, the latter is converted into *methylcinnamyl dextroecgonine*,

When the product is poured into water, some cinnamic acid is precipitated; the filtrate is made alkaline with potassium carbonate, and the alkaloïd extracted with ether and purified by conversion into the hydrochloride. When precipitated from the latter, it forms an almost colourless oil which soon solidifies to long, radially grouped prisms melting at 68° . A 2.11 per cent. alcoholic solution in a 200 mm. tube rotates the plane of polarisation $+2^{\circ}$. The *hydrochloride*,

crystallises from hot water in white needles melting at $186-188^{\circ}$; the *platinochloride*, $(C_{19}H_{23}NO_4)_2 \cdot H_2PtCl_6$, from alcohol in small, pale-yellow needles melting at $208-210^{\circ}$; and the *aurochloride*, $C_{19}H_{23}NO_4 \cdot HAuCl_4$, in orange needles melting at 164° . The *hydrobromide*, $C_{19}H_{23}NO_4 \cdot HBr$, forms small needles melting at 209° , and the *nitrate*, $C_{19}H_{23}NO_4 \cdot HNO_3$, beautiful, long needles melting at 197° .

Cinnamyl dextroecgonine,

is prepared by the action of cinnamic chloride or anhydride on dextroecgonine, and forms an oil which only solidifies after a long time, and then crystallises from hot water in badly-developed crystals. The *hydrochloride*, $C_{19}H_{23}NO_4 \cdot HCl$, crystallises in white needles which darken at 228° and melt with decomposition at 236° , whilst the *platinochloride* forms pale-yellow needles which melt with decomposition at 223° .

Methylisovaleryl dextroecgonine,

is prepared in the same way from isovaleric chloride and methyl dextroecgonine at $112-114^{\circ}$, and forms a transparent oil, a 2.01 per cent. solution of which rotates the plane of polarisation $+1.02^{\circ}$ in a 200 mm. tube. The *hydrochloride*, $C_{19}H_{25}NO_4 \cdot HCl$, and the *nitrate*, $C_{19}H_{25}NO_4 \cdot HNO_3$, form small, nacreous plates melting at 192° and 163° respectively; the *platinochloride*, $(C_{19}H_{25}NO_4)_2 \cdot H_2PtCl_6$, crystallises in

lemon-yellow needles melting at 202° , and the *anrochloride* in pale-yellow needles melting at 88° . *Isovaleryl dextroecgonine*, $C_{14}H_{23}NO_2$, obtained by acting on dextroecgonine with isovaleric chloride, and treating the hydrochloride thus formed with silver oxide, crystallises from a mixture of methyl alcohol and ether in small needles melting at 224° with decomposition. The *hydrochloride*, $C_{14}H_{23}NO_4 \cdot HCl$, forms small, lustrous needles which darken at 206° and melt at 236° ; the *platinochloride*, $(C_{14}H_{23}NO_4)_2 \cdot H_2PtCl_6$, crystallises in orange prisms melting at 216° .

Dimethylbutolphthalylid dextroecgonine,

is formed by heating equal weights of orthophthalic chloride and methyl dextroecgonine at 150 – 160° . It is a reddish oil, and forms salts, of which only the *hydrindide*, $C_{26}H_{38}N_2O_8 \cdot 2HI$, has been obtained crystalline. *Orthophthalylid dextroecgonine*, $C_{26}H_{38}N_2O_8$, prepared from dextroecgonine by the action of phthalic anhydride, is also an oil; its *hydrindide*, $C_{26}H_{38}N_2O_8 \cdot 2HI$, forms yellowish, badly-developed crystals melting at 103° .

H. G. C.

Ptomaines formed in the Cultivation of the Swine Fever Bacillus. By E. A. v. SCHWEINITZ (*Chem. Centr.*, 1890, ii, 759–760; from *Med. News*, September 6th, 1890).—The bacillus of swine fever was cultivated in peptone broth at 37° . The broth was afterwards acidified with hydrochloric acid, concentrated on the water-bath, the residue extracted with 95 per cent. alcohol, and the extract precipitated with mercuric chloride solution. The precipitate, suspended in water, was treated with hydrogen sulphide, and in the filtrate cadaverine, a primary amine of unknown composition, and an alkaloid, the platinochloride of which had the formula $C_{14}H_{23}N_2PtCl_6$, were found. The free base could not be isolated; the hydrochloride forms a syrup soluble in alcohol. If the broth containing the bacillus cultivation be treated with excess of alcohol, an amorphous precipitate is formed which dissolves in water. By repeatedly precipitating this and redissolving it several times, an albumose is separated which may be obtained in a crystalline form by concentrating in a vacuum over sulphuric acid. Neither this nor the above-mentioned base has poisonous properties.

By treating the broth, after cultivation, in the manner described by Brieger and Fränkel, an albumose of properties corresponding with the toxalbumose is obtained, which also is without poisonous properties when subcutaneously injected into the guinea pig.

J. W. L.

Egg Albumin free from Ash. By E. HARNACK (*Ber.*, 23, 3745–3752, compare Abstr., 1890, 272).—The author gives further details of the method employed for the preparation of pure albumin free from ash by treatment of the copper derivative with concentrated potash. The albumin so obtained is soluble in boiling water; the addition of alcohol causes no change, but neutral salts immediately produce a flocculent precipitate. On heating the moist pre-

paration under water, it melts before dissolving. Ammonium sulphate yields a crystalline albumin derivative, which, however, only contains about 5 per cent. of albumin.

Albumin reddens blue litmus-paper, and is not precipitated from solution by many organic acids, such as formic acid, acetic acid, tartaric acid, citric acid, or lactic acid. The precipitate caused by most mineral acids consists of unaltered albumin, as is proved by the fact that after filtration and washing it is soluble in water.

Alkalis prevent the precipitation of albumin by neutral salts.

Free albumin, even in presence of moisture, shows no tendency to ferment or decay.

The paper closes with a discussion of the part played by albumin in the animal economy. J. B. T.

Compound of Gelatin and Metaphosphoric Acid. By R. LORENZ (*Pflüger's Archiv*, 47, 189—195).—It was thought interesting to investigate the proportion of metaphosphoric acid in the precipitate produced by adding that acid to solutions of gelatin, in view of recent researches by Krüger on the relation of gelatin to bases. There was some difficulty in obtaining a precipitate which could be readily collected and washed, especially with β -gelatin, that is, gelatin which has been rendered non-gelatinisable by prolonged boiling. In three different preparations of ordinary gelatin (gelatin α), the percentage of phosphoric anhydride was respectively 7.5, 5.3, and 6.1. It was found that this was probably due to the length of time during which the washing was continued; prolonged washing with water dissolving out more and more phosphoric acid. The same preparation was analysed at intervals with the following results:—

After 2 days' washing,	7.1 per cent. of P_2O_5 .
" 10 "	6.4 " "
" 22 "	5.8 " "
" 35 "	4.5 " "

Estimation of the phosphoric anhydride in two preparations made from β -gelatin gave respectively 6.9 and 8.35 per cent.

W. D. H.

Metaphosphoric Acid in the Nuclein of Yeast. By L. LIEBERMANN (*Pflüger's Archiv*, 47, 155—160).—The author has previously stated (Abstr., 1888, 510, 1889, 1021) that metaphosphoric acid can be separated from nuclein; the present paper relates to the preparation of the barium salt of the acid from acid extracts of yeast nuclein.

The following results of elementary analyses of three preparations, are considered sufficiently near to the percentages calculated from the formula to support the author's previous contention.

	I.	II.	III.	By calculation.
Ba	38.61	37.33	40.73	46.44
PO_4	53.26	58.11	59.25	53.56

W. D. H.

Action of Hydrofluoric Acid on Diastase. By J. EIFFRONT (*Bull. Soc. Chim.* [3], 4, 627—632).—Hydrofluoric acid in amounts

varying from 5—10 milligrams per 100 c.c. of malt infusion exercises a marked influence in the conservation of the diastatic properties of the infusion, and this is probably due to the retarding influence of the acid on the development of the lactic and butyric fermentations which cause coagulation of the diastase (see p. 488).

In presence of these small quantities of hydrofluoric acid, the degree to which the hydrolysis of starch paste by malt infusion can be carried is augmented, and the most favourable temperature for such is 30°.

Similar results obtain in the case of worts derived from raw grain. Numerous experimental data are given. T. G. N.

Myohæmatin. By S. M. COPEMAN (*Proc. Physiol. Soc.*, 1890, 22).—By treating defibrinated and slightly diluted blood with a small quantity of minced muscular tissue, and subsequently keeping the mixture at 38° for nearly three weeks contact with the air being prevented, a form of myohæmatin is produced of which the spectrum resembles that figured by MacMunn, except for a slight difference in shading of the band nearest the violet. It is easily distinguishable from hæmochromogen and hæmatoporphyrin. On heating to near the boiling point, the bands disappear, becoming visible again on cooling, as observed in the case of MacMunn's modified myohæmatin.

Similar experiments carried out with small quantities of hepatic and other tissues macerated in blood resulted in the formation of alkaline hæmatin only, instead of a form of histo-hæmatin.

W. D. H.

Physiological Chemistry.

In what Form is Iron Absorbed? By C. A. SOGIN (*Zeit. physiol. Chem.*, 15, 93—139).—Experiments were performed in three cases on dogs: the iron contained in yolk of egg, the food selected, was estimated; the faeces and urine were then examined for iron, and the amount found there in two out of the three cases was much greater than in the food. From these experiments, the conclusion is drawn that a simple comparison of the amounts of iron ingested and excreted affords no trustworthy data in the solution of questions relating to the metabolism of iron.

Mice were then selected as the animals on which the remaining experiments were performed. They lived normally when fed on yolk of egg, from which the conclusion is drawn that the organic iron-containing compounds (hæmatogen) in that article of diet are assimilable; this was supported by the fact that the iron excreted was less than that ingested. Mice fed on artificial diets constructed of iron-free proteids, carbohydrates, and fat soon died; but they died equally soon if inorganic or organic compounds of iron were mixed with this diet.

From this, the conclusion is drawn, that a life-sustaining artificial diet, although apparently containing all that is necessary, cannot yet be constructed.

Among other conclusions arrived at are the following:—Filtered urine of animals fed on normal diet contains only traces of iron; serum albumin prepared from hæmoglobin-free serum contains no iron.

W. D. H.

Influence of Muscular Work on Proteid Metabolism. By O. KRUNMACHER (*Pflüger's Archiv*, 47, 454—468).—Argutinsky (this vol. p. 350) found that excessive muscular work produced in himself an increase in the output of nitrogen, derived presumably from an increase in the destructive metabolism of the proteids of the body. In case this should have been due to an idiosyncrasy, it was deemed necessary to repeat the experiments. The present paper is an account of such an experiment carried out on the author's own person; full details are given. The general conclusion is the same as that of Argutinsky.

W. D. H.

Fate of Morphine in the Animal Organism. By E. TAUBER (*Chem. Centr.*, 1890, ii, 666—667; from *Arch. experim. Path. Pharm.*, 27, 335).—Since the researches into the change or otherwise which morphine undergoes in the animal organism, which have been undertaken by different workers, have led to contradictory results, the author has both added the alkaloid to blood directly, and has injected it subcutaneously into a dog. From the blood, 95 per cent. of the alkaloid was recovered by the following method:—The blood was coagulated by the addition of acetic acid, and the coagulum washed with acidified water until colourless. The filtrate was then precipitated with lead acetate, the precipitate washed with water followed by alcohol, the alcohol distilled off, the lead precipitated as sulphide, the filtrate evaporated, the residue extracted with alcohol, the alcohol again distilled off, and the residue extracted with a little water. From this solution, the morphine is precipitated with sodium hydrogen carbonate. An allowance of 1 milligram must be made for the morphine which remains in solution. In another experiment, 1.6 grams of morphine hydrochloride was subcutaneously injected into a dog during ten days, after which 0.512 gram of morphine was found in the faeces.

J. W. L.

Fate of Peptone. By L. E. SHORE (*J. Physiol.*, 11, 528—560).—There is no doubt that peptone absorbed from the alimentary canal undergoes during the process of absorption a reversion into ordinary proteids. Hofmeister (*Zeit. physiol. Chem.*, 5) considered that the leucocytes of adenoid tissue and of the blood, but more especially of the lymph, had the power of effecting this change. Heidenhain (*Pflüger's Archiv*, 43, Supplemental No.) showed, however, that the amount of and percentage of proteid in chyle will not account for the large quantities of proteid absorbed, and he calculated that if the transformation were effected by leucocytes, 20 grams of dry cell substance would have to fix and transform 274 grams of dry proteid (compare Neumeister, this vol., p. 233). In the present research, the questions

especially investigated were the fate of peptone when introduced directly into the lymphatic channels, and by experiments on lymphatic glands, whether lymph cells can assimilate peptone or not. The word peptone as used here includes the small admixture of albumoses present in the preparation used (Grübler's). The method of detecting peptone was with slight modifications that already used by Neumeister. The animals used were dogs. It was found that peptone, when injected into the blood stream, rapidly reappears in the urine, but that when the renal vessels are ligatured, it disappears from the blood, and passes into (is secreted into, Heidenhain) the lymph. When peptone is injected into the ligatured bile-duct, it also reappears in great measure in the lymph; some of it, however, passes into the blood, and finally (with a small amount of bile pigment) into the urine. From the lymph in the tissues, the peptone is gradually carried to the thoracic duct, and then enters the blood again. In this course it must enter lymphatic glands, and as a large percentage is ultimately recoverable in the urine, it suffers little or no transformation by the lymphatic leucocytes. When peptone (in these experiments dissolved in the lymph serum obtained from the thoracic duct of the same animal) is injected directly into a lymphatic vessel in the lower limbs, it is for a time recoverable as such in the lymph of the thoracic duct. This lymph must have passed through lymphatic glands; in fact, the anatomical relation of these glands to the vessels was accurately determined by injection of sodium sulphindigotate. The cells of lymphatic glands have, therefore, not the power of assimilating peptone. It was also found that the cells of the liver and spleen take no part in the transformation of peptone. The general conclusion is therefore drawn that this is normally brought about by the epithelial cells of the mucous membrane of the alimentary canal. Heidenhain, under whose superintendence this work was done, believes that five minutes is the length of time necessary for the passage of fluid through these cells, and that this is sufficient for the accomplishment of the transformation.

W. D. H.

Cutaneous Pigment as an Antecedent of Hæmoglobin. By S. DELÉPINE (*Proc. Physiol. Soc.*, 1890, 27—34).—Although chlorophyll and hæmoglobin bear so many resemblances to one another, light is an essential factor in the production of the former, but as red blood corpuscles are formed in parts of the body not exposed to light, it would seem not to be so in that of the latter. The influence of sunlight in the production of melanin in the epidermis afforded at one time no key to the explanation of this difference, as melanin, like other animal pigments, was considered to have its origin in hæmoglobin.

It having been shown, however, that hæmoglobin is decomposed in the liver, the iron being retained by the liver cells, and probably used for the formation of new hæmoglobin, attention was directed to the way in which the rest of the pigment was reproduced. The examination of melanotic tumours gave a clue to the question, and the facts collected in support of the view that melanin (formed in the skin under the influence of light) is the precursor of hæmoglobin, are the following:—

Although the production of melanin is often increased in the skin under the influence of certain stimuli, it gradually disappears when these stimuli cease to act. It must be transformed into some colourless product, which must pass either towards the surface or into the deeper tissues. Instances of such stimuli are luminous heat (sunburn), chemical irritants (mustard poultices), mechanical stimuli (scratching), pregnancy, certain pathological states, &c. The pigment deposited is in the *deep* layers of the *rete Malpighi*. Melanin is never produced when the epidermis is absent. The pigment can, moreover, be traced to the lymphatics in the true skin.

There are certain conditions in which the formation of melanin is lessened; absence of heat and light; when the skin is inactive, or atrophied, as over scars, or its nerves divided or diseased as in the patches of leprosy, and in the complex state of things present in albinism. Imperfect production of cutaneous pigment is, moreover, often, if not always, associated with diminution in the hæmoglobin of the blood.

The following facts show that melanin is developed not from hæmoglobin, but independently of it:—(1) Melanin appears in many embryonic parts before any blood is formed. (2) In the adult, parts removed from all blood vessels, such as the crystalline lens, may become deeply pigmented. (3) The amount of melanin in the skin is not proportional to the amount of blood circulating through or extravasated into the subjacent tissues. The conclusion is therefore drawn that melanin is elaborated in certain epithelial cells, like products of glandular activity out of lymph, and is not a derivative of hæmoglobin.

The next series of facts deal with the fate of melanin. When the skin is deeply pigmented as in negroes, some, but a very small portion, of the melanin passes into the superficial layers of the epidermis, and so reaches the surface. The greater part of the pigment, as is well seen in pathological specimens, passes into the lymphatics of the *cutis vera*, in some cases so much so as to partially obstruct them. Other forms of obstruction, as the pressure of tumours, will cause similarly a natural injection of the lymphatics with melanin. Under normal circumstances, however, this is not visible, as the melanin seems to be dissolved, and is absorbed and removed in a colourless form. This may be constant or intermittent; the most important conclusion arrived at, however, is that ultimately it is used in the formation of new hæmoglobin. The production of pigment in the skin should be limited by the accumulation of precipitated melanin in the *rete*. Such accumulation, as in negroes, diminishes the intensity of the light reaching the deepest and most active parts of the epidermis, and therefore regulates the amount of normal stimulus acting on the cells.

W. D. H.

Effect of Peptone on the Clotting of Blood and Lymph.
By L. E. SHORE (*J. Physiol.*, 11, 561—565).—After rapid injection of peptone into the blood, that fluid, and also the lymph, if withdrawn within an hour after the injection, do not clot (Schmidt-Mulheim, Fano). In the present research, it was found that slow injection of peptone into the blood does not prevent, or only very slightly, its

coagulation when withdrawn, but that the lymph has no tendency to clot.

In experiments made with lymph out of the body, it was found that the addition of considerable quantities of peptone solution had no anti-clotting power, but that the addition of mere traces of peptone to the lymph prevented its coagulation.

W. D. H.

Action of Leech Extract on Blood. By W. L. DICKINSON (*J. Physiol.*, 11, 566—572).—The general properties of the extract of the anterior part of the medicinal leech which as Haycraft showed (*Proc. Roy. Soc.*, 36) possesses a strong anti-clotting action on blood are the following:—It is neutral to litmus paper; its specific gravity is not appreciably higher than that of the medium used for extraction. Boiling causes no precipitate, and no loss of activity. Alkalis cause no precipitate. A trace of acetic acid causes cloudiness readily soluble in excess. Strong acetic acid causes no precipitate in salt-free, but a copious cloud in salt-saturated, extracts. Nitric acid in the cold causes a precipitate soluble on boiling, and reappearing on cooling. Saturation with ammonium sulphate causes a precipitate, after which no proteid remains in solution; saturation with magnesium sulphate or sodium chloride, on the other hand, causes no precipitate. If all salts are removed from the extract by dialysis, there is no precipitate produced, and no loss of power. Copper sulphate, lead acetate, and mercuric chloride give precipitates insoluble in excess of the reagents. Copper sulphate and potash give a pink (biuret) reaction. Alcohol causes no loss of the activity of the extract.

The leech extract, therefore, contains a proteid having some features in common with Kühne's proto-, and others with deutero-albumose. The albumose precipitated by ammonium sulphate has all the anti-clotting power of the original extract; the extract *minus* the albumose has no such powers. Hence, probably the albumose is itself the active principle.

Clotting in plasma obtained from blood, prevented from coagulating by admixture with leech extract (either intravenously or after it is shed), cannot be induced by carbonic anhydride or by dilute acetic acid; it can, however, always be induced by a sufficient quantity of fibrin ferment. Such plasma gives no precipitate on cooling.

Fibrin soaked in leech extract fails to yield ferment when subsequently treated with 8 per cent. sodium chloride solution. The extract, however, still contains cell-globulin. Cell-globulin prepared from lymphatic glands by Halliburton's method (*Abstr.*, 1888, 974) retains all its properties, except its fibrinoplastic power, when treated with leech extract. This is regarded as an argument in favour of the non-identity of the cell-globulin and fibrin ferment.

W. D. H.

Transformation of Hæmoglobin in the Bile. By W. FLEHNF (*Chem. Centr.*, 1890, ii, 790; from *Arch. Path. Anat.*, 121, 605).—In view of the researches of Wertheimer and Meyer (*Abstr.*, 1889, 636), the author was led to repeat some experiments previously undertaken by him, but these were now made on the living animal instead of immediately after death. The earlier experiments with phosphorus,

arsenic, antifebrin, and glycerol were repeated, and hæmoglobin was again found in the bile of rabbits and dogs, although not in large quantity.
J. W. L.

Excretion of the Digestive Ferments from the Animal. By J. BENDEBSKI (*Chem. Centr.*, 1890, ii, 791; from *Arch. Path. Anat.*, 121, 554—597).—The author has determined that a substance is always present in normal urine which dissolves fibrin in presence of an acid, and that it is destroyed at a boiling heat. The quantity varies considerably with different persons when in health, and consequently the variation in the amount of this substance in illness cannot have any importance, at least for diagnostic purposes. The author names it *uropepsin*. The presence of pepsin in urine must not therefore be considered indicative of the excretion of peptone by the animal, but of the formation of uropepsin in the urine.

In healthy urine, a trypsin is found which varies in quantity, and may be increased, or altogether wanting, in cases of disease. The author does not consider it identical with the pancreatic ferment. It differs from the latter in that it is not destroyed by boiling. It has been named *urotrypsin*.

An amylolytic ferment occurring in urine, and which is similar to, but not identical with, the ferment ptyalin, has been named *uroptyalin* by the author.

In animal sweat, another ferment occurs which behaves like uroptyalin with starch, and is named *hidroptyulin* by the author; it is an altered ptyalin.

Trypsin was not found in sweat, but a pepsin was observed which had an activity intermediate between that of pepsin and uropepsin.

J. W. L.

Excretion of Uric Acid and Nitrogen in cases of Leucæmia. By C. BOHLAND and H. SCHURZ (*Pflüger's Archiv*, 47, 469—509).—Three cases of leucæmia are described with clinical details; most attention was devoted, however, to an examination of the urine and a comparison of the excretion of uric acid and of nitrogen with that of normal individuals on the same diet. An absolute increase of the output of uric acid was seen in all three, but more especially in two of the cases. Pott gives the relation of uric acid nitrogen to total nitrogen in health as 1 to 19·7. In the three cases of leucæmia, the proportion was respectively 1 to 9·4, 1 to 12·8, and 1 to 24·4. In this last case, there was a good deal of fever which no doubt produced a greater proportional output of total nitrogen than of uric acid.

The following are the mean numbers obtained:—

	Total nitrogen.	Uric acid.	Proportion of uric acid nitrogen to total nitrogen.
Normal.	—	0·65 grams	1 : 19·7
Case 1	13·1 grams	1·5 „	1 : 9·4
„ 2	8·7 „	0·68 „	1 : 12·8
„ 3	14·5 „	1·8 „	1 : 24·4

W. D. H.

Calcium Salts in Urine. By G. HOPPE-SEYLER (*Zeit. physiol. Chem.*, 15, 161—178).—A large number of observations on the quantity of calcium salts in the urine of numerous hospital patients are recorded. The special point investigated is the influence of rest and muscular movement on the amount of these salts in the urine. It was found that rest in bed produces a great increase in the output of these salts. This is especially noticeable in children and young people. On these rising from bed and resuming activity, the output sinks to the normal, which is stated by Neubauer (*J. pr. Chem.*, 67, 65) to be 0.33 gram of calcium phosphate per diem.

Neubauer's method of estimation was used in the present analyses. Reckoned as calcium phosphate, the daily output in those lying in bed was found to average 0.721, while in those who were not confined to bed it was 0.37 gram. An exception to this occurs in febrile disorders, where there is a diminished excretion of calcium salts; this is doubtless in part dependent on the small amount of food taken. Injection of calomel in syphilitic patients was found to lead to an increased output of calcium salts in the urine.

W. D. H.

Urine and Blood in a Case of Melanotic Sarcoma. By F. HOPPE-SEYLER (*Zeit. physiol. Chem.*, 15, 179—188).—The case of melanotic tumour from which specimens of blood and urine were obtained was a hæmorrhagic one, and thus fairly large quantities of blood were collected.

Analysis of the blood, performed in the usual way, gave the following results:—

1000 parts of blood yielded 320.99 parts of red corpuscles, and 679.01 parts of plasma.

The composition of red corpuscles and serum may be stated in a table as follows:—

	Red corpuscles.	Serum.
Oxyhæmoglobin	404.06	—
Proteids	0.81	67.68
Lecithin.....	1.62	2.323
Cholesterol	5.70	0.654
Fat.....	—	3.473
Alcoholic extract.....	1.59	1.63
Aqueous extract	7.72	2.18
<hr/>		<hr/>
Solid organic matters	423.41	77.94
Water	576.59	{ 914.53
Inorganic salts.....		
<hr/>		<hr/>
	1000.00	1000.00

Special attention is directed to the low percentage of water (as compared with other mammals and other tissues), of lecithin and of proteid matter (other than hæmoglobin) in the red corpuscles. Nothing noteworthy, from a pathological standpoint, was, however, noted in the blood.

In connection with the urine, special attention was directed to the

pigment which gave the urine a dark-brown colour darkening on exposure, or on heating with nitric acid. It was found to consist of urobilin in small quantities, and a second pigment which is very soluble; the latter is precipitable by normal lead acetate, and on fusing with alkali gives off ammonia, whilst a residue of humic acid and protocathechuic acid remains behind. It therefore somewhat resembles a humous substance. Indole was also formed as a result of fusion with alkali; proteid was, however, not present in the urine.

W. D. H.

Action of Poisons on Nerve-fibres and Peripheral Nerve-cells. By J. N. LANGLEY and W. L. DICKINSON (*J. Physiol.*, 11, 509—527).—The superior cervical ganglion of an anæsthetised rabbit was exposed, and a 1 per cent. solution of the poison was applied to it locally, or the drug was injected subcutaneously. The effect of stimulation of the sympathetic nerve, on each side of the ganglion, on the size of the pupil and blood vessels was then observed. Those substances which have no effect are atropine, hyoscyne, eserine, muscarine, pilocarpine, picrotoxin, caffeine, and antipyrine. Those substances, local application of which annuls more or less readily the irritability of nerve-fibres, but injection of which has little or no effect, are codeine, apomorphine, aconitine, and cocaine. Those substances which on injection into the blood, or applied locally, have a more or less paralysing action on the ganglion are coniine, curarine, brucine, and strychnine. The pupillo-dilatator nerve-cells are paralysed far more readily than the vaso-constrictor nerve-cells. The authors have previously shown that the action of nicotine is similar.

W. D. H.

Action of Nicotine on Invertebrates. By M. GREENWOOD (*J. Physiol.*, 11, 573—605).—The authoress thus summarises her own observations:—

The toxic effect of nicotine on any organism is determined mainly by the degree of development of the nervous system. Thus for *Amæba* or *Actinosphærium* it cannot be regarded as exciting or paralysing; it is rather inimical to continued healthy life. As soon as any structural complexity is reached, the action of the drug is discriminating in such a fashion that the nervous actions which are the expressions of automatism, which imply co-ordination of impulse, are stopped first. This is seen dimly in *Hydra*, and it is more pronounced among the *Medusæ*, where spontaneity, irradiation of impulse, and direct motor activity are affected successively. When structural development goes further, the selective action is traced readily, as in *Antedon*. In the case of the higher invertebrates, the paralysing action of nicotine is preceded by a phase of stimulation. This becomes marked in *Ophiurids* and *Crinoids*. As this positively-exciting action becomes noticeable, nicotine becomes more and more a medium in which life is impossible. Thus *Amæba* is not killed at once by a 1 per cent. solution of nicotine tartrate; *Hydra* dies speedily in such concentration, but will live over night in 0·05 per cent., while *Lumbricus* is killed by this strength, but lives for some hours in a 0·01 per cent. solution.

When very simple animals (*Actinosphærium*, *Hydra*, *Medusæ*) die

under the influence of nicotine, death is often associated with injury of their substance, so that it tends to disintegrate; and the definite poisoning that occurs in higher types has sometimes, as one of its after-effects, a lingering trophic disturbance. An extreme form of this is seen in *Palaemon*, where there may be actually a progressive death of tissues from behind forwards. Similar lesions find expression in the growth of fungus on a paralysed *Crayfish*, and in the clinging of earth particles to the body of a poisoned *Earthworm*. Though nicotine acts on any organism according as the nervous system is or is not developed, closely allied animals may yet react differently, according to their individual balance of organisation.

W. D. H.

Effect of Morphine on Cats. By L. GUINARD (*Compt. rend.*, 111, 981—983).—When morphine is administered to cats by hypodermic or intravenous injection, in doses varying from 0.0004 gram to 0.09 gram per kilo. of body weight, it never produces sleep or narcotic prostration. On the contrary, it produces a remarkable degree of excitement, increasing in intensity with the dose given. This excitement is accompanied by evident disorder in the functions of the brain, and if the dose is large, terminates in a period of convulsions, ending in the death of the animal.

Milne-Edwards (p. 983) has been unable to obtain narcotism by administration of morphine to cats either by ingestion with food or by injection. He has also found that lions and tigers offer a similar resistance to the narcotising influence of the alkaloid. C. H. B.

Action of Strychnine. By K. SCHLICK (*Pflüger's Archiv*, 47, 171—189).—Whilst mechanical, thermal, and electrical stimulation of a strychnine-poisoned frog produce a marked increase in the reflex responses, chemical stimuli do not produce this result. A chemical stimulus, which is very active before the injection of the alkaloid, produces little or no effect on the poisoned animal. Under all conditions, the reflex time is lengthened by strychnine. W. D. H.

Physiological Action of Cocaine. By U. Mosso (*Pflüger's Archiv*, 47, 553—601).—Cocaine applied locally to a motor nerve paralyses it; it also acts injuriously on the nerve-cells of the spinal cord. It has been supposed that cocaine acts on the sensory nerves, as curare does on the motor nerves, but the present experiments do not entirely support this view; cocaine has no specific action, but its effects are similar to those produced by the application of cold to the nervous system.

In an animal in which a large part of the spinal cord remains intact while the rest is poisoned with cocaine, sensibility is lost after motility; cocaine, therefore, arrests the outgoing impulses from the cord.

Regarding doses, the following are the numbers obtained from experiments on dogs:—0.0005 gram per kilo. of body weight produces no action on the muscles; 0.001 gram produces increased contraction; 0.003 gram acts in the opposite way. This action of the drug on the motor apparatus seems to have been missed by previous

observers, because attention has been, as with other anæsthetics, more particularly directed to its influence on sensibility; the great advantage of cocaine as an anæsthetic appears to be the fact that it is completely destroyed in the organism; its effects soon pass off, and leave no bad after-effects.

Experiments on human beings gave the following results:—Doses of 0.1 gram given by the stomach increase the capacity for muscular work; if it is injected into the blood stream, there is first increased then lessened excitability of the motor apparatus as in animals. The beneficial action of cocaine is even greater when the muscles have been previously fatigued, or the individual has been fasting; in the latter case the work may be as much as doubled. This was tested graphically by recording the contraction of the fingers, the muscles of which were stimulated electrically; after a long march, fatigue does not ensue so readily with as without cocaine. Small doses (0.05 gram to 0.1 gram given by the mouth) increase the sensibility of the skin, and shorten the reaction time. The drug increases the quantity of air inspired, even though the frequency of respiration does not rise, as it, however, generally does; small doses cause marked contraction of the blood vessels.

It increases the body temperature in frogs. Very small doses increase, larger ones abolish, the patella tendon reflex. The intensity of the action of cocaine differs in different classes of vertebrates. In plants, as tested by the growth of seedlings, small doses further, larger ones paralyse, the vital processes.

W. D. H.

Physiological Action of Curare. By W. NIKOLSKI and J. DOGIEL (*Pflüger's Archiv*, 47, 68—115).—The curare which reaches Europe is of different strengths; in many samples, calcium carbonate and phosphoric acid are present, and the preparations called "curarin" or "curarin sulphate" are by no means pure. The poison is not absorbed through the skin at all, and only with difficulty through mucous membranes; injected, however, under the skin or into the blood stream its effects are at once noticeable, and fairly equally so in all the classes of the animal kingdom with which experiments were performed, namely, mammals, birds, amphibians, reptiles, crabs, insects, and annelids. Curare has an influence on the central nervous system, the endings of motor nerves in voluntary muscles, in the cardiac and plain muscles, and also produces changes in the muscular tissues.

The point of injection makes considerable difference as to which part of the body is first affected. If the injection be made into the carotid artery, the cerebrum is affected first; if into a limb artery, paralysis of that limb is the first phenomenon produced.

The motor nerve endings are not all paralysed equally; thus plain muscles resist its action longest, and among voluntary muscles there are also differences found. Among different animals varying results are obtained, for instance, the drug acts less powerfully on the vaso-motor centre of rabbits and cats than of dogs; applied to the conjunctiva of mammals, the pupil is not dilated, whereas in birds it is; atropine, on the other hand, produces pupillary enlargement in

mammals, and not in birds. But if curare is injected into the circulation, the pupil of mammals is slightly widened. This action is thus probably not due to paralysis of the motor nerve endings in the *sphincter pupillæ*, but to some effect in the central nervous system.

The weakening or abolition of vagus influence on the heart is caused by smaller doses of curare in cats than in dogs and rabbits; the paralysis of the vagus endings in stomach and intestine occurs later, but unequally so in the three mammals mentioned.

The ultimate cause of the physiological action of curare is, doubtless, an alteration in the protoplasm of muscle and nerve, but this is not simultaneous nor equally great in the two tissues.

By washing out the curare from the voluntary muscles, paralysis passes off. There is a corresponding return of movements after irrigation in amœbæ and lymph corpuscles the activity of which has been stopped by curare.

Death in curare-poisoning in mammals is due to the effect of the drug on the respiratory centre, rather than on the motor nerve endings in the respiratory muscles. Curare subjected to the action of ozone loses its usual effects on the animal organism. W. D. H.

Chemistry of Vegetable Physiology and Agriculture.

Action of Mineral Acids on the Lactic and Butyric Fermentations. By J. EFFRONT (*Bull. Soc. Chim.* [3], 4, 337—339).—The action of hydrochloric, hydrofluoric, and sulphuric acids on these fermentations in distillery worts is to enfeeble or to arrest their progress even when the wort is maintained at the most favourable temperature. Both the lactic and butyric fermentations are arrested by the addition of 0.025 gram of hydrogen fluoride per 100 c.c. of wort, and a similar effect is produced by the employment of 0.200 gram of hydrogen chloride or 0.300 gram of hydrogen sulphate. Data are given which confirm these results, and which show that the presence of hydrogen fluoride in worts to the extent of 0.020 gram per litre will prevent their acidifying, its action being especially unfavourable to the butyric fermentation. T. G. N.

Influence of Artificial Gastric Juice on the Acetic and Lactic Fermentations. By E. HIRSCHFELD (*Pflüger's Archiv*, 47, 510—542).—If pure cultures of the *Bacillus aceticus* be grown in nutritive media made feebly acid with acetic acid, and containing 5 per cent. of alcohol, acetic acid is formed from the alcohol, the amount formed varying with the original quantity of the acid added. A small addition of hydrochloric acid (0.01 to 0.02 per cent.) causes an energetic increase of oxidation. Slightly larger quantities (0.03 to 0.5 per cent.) increase the oxidation, but not so vigorously, and a percentage of 0.6 to 0.7 stops it altogether. Pepsin plus hydrochloric acid acts in the same way as the acid alone. The feeble anti-bacterial action of the mixture observed in connection with the lactic

acid fermentation is not observable with the acetic fermentation. The presence of phosphates and their nature has apparently no influence; but free phosphoric acid (0.1 per cent.) stops the oxidation of the alcohol. The percentage of hydrochloric acid necessary to stop the fermentation does not kill the bacteria, as they resume activity after neutralisation of the excess of acid. The bacteria are, however, killed by a percentage of 0.12 of the pepsin hydrochloric acid mixture.

The following conclusions were drawn from similar experiments on the lactic acid fermentation:—The *Bacillus acidi lactici* was grown in milk, and lactic acid forms most abundantly from the thirteenth to the twenty-fourth hour afterwards; as the acid increases, the bacteria become less active, as is shown by the following averages:—

First day, percentage of lactic acid	0.16
Second day, percentage of lactic acid	0.23
Third day, percentage of lactic acid	0.29

Small amounts of hydrochloric acid (0.01 to 0.02 per cent.) hinder the action markedly; larger quantities act in the same way until a percentage of 0.07 to 0.08 stops the fermentation altogether. Pepsin alone has no influence; but pepsin *plus* hydrochloric acid acts more energetically than the acid by itself, complete stoppage of the bacterial action being produced by 0.1 per cent. of the mixture. The same results were obtained with pure cultures of the bacillus. Phosphoric acid (0.2 per cent.) also stops the activity of the micro-organism, but phosphates have no influence one way or the other.

These results, supported by most careful experiments, of which full details are given, place on a scientific basis the belief in the germicidal action of gastric juice so long held.

W. D. H.

Behaviour of the Fatty Substances and the Rôle of the Lecithins during Normal Germination. By W. MAXWELL (*Amer. Chem. J.*, 13, 16—24; compare this vol., p. 511).—Experiments on the germination of *Phaseolus vulgaris*, *Gossypium*, and *Zea mays* show that the young plants, during the early stage of their growth under the influence of light, are capable of utilising the inorganic phosphorus present in the seed for the formation of lecithins. At a later stage, when the plants are becoming independent of the seed, those substances are decomposed and utilised in the continued development of the organisms.

G. T. M.

Change in the Nitrogenous Substances of Barley during Germination. By A. HILGER and F. VAN DER BECKE (*Bied. Centr.*, 19, 860).—The substances examined were:—Barley, softened barley, fresh malt, and dried malt. The total nitrogen, the nitrogen of the constituents insoluble in water and that of the several soluble constituents, was determined; the percentage results are given in the following table:—

	Barley.	Softened barley.	Fresh malt.	Dried malt.
Water	14.470	43.341	47.958	8.431
Total nitrogen	1.801	1.750	1.751	1.542
Nitrogen of insoluble constituents .	1.6789	1.6853	1.372	1.165
Nitrogen as albumin (soluble)	0.0600	0.0354	0.1571	0.1194
" peptone	0.0046	0.0009	0.0058	0.0233
" ammonium salt.....	0.0169	—	0.0290	0.0057
" amido-acids.....	0.0417	0.0294	0.1417	0.2257
" amides	—	—	0.0505	0.0029

In fresh malt and softened barley the total nitrogen is the same; in fresh malt 21.96 per cent. (of the total nitrogen) is soluble, but in softened barley only 3.75 per cent. During germination the soluble albumin, peptone, and amido-acids increase considerably. Dry malt contains less total nitrogen, owing to the falling away of the radicles. Soluble albumin, ammonium salts, and amides decrease; peptones and amido-acids increase. N. H. J. M.

Localisation of Active Principles in the Seeds of Cruciferae. By L. GUIGNARD (*Compt. rend.* 111, 920—923).—An account of an investigation, chiefly microscopical, made with a view to localise the various active principles in different cellules and tissues.

C. H. B.

Nitrogenous Bases in Seeds. By E. SCHULZE (*Zeit. physiol. Chem.*, 15, 140—160).—The seeds of the vetch, *Vicia sativa*, were found to contain not only vicine, a base described by Ritthausen (*Abstr.*, 1881, 1158), but also choline and betaine. 20 kilos. of the seeds yielded 8—9 grams of choline platinochloride = 3—3.5 grams of choline, and 11—12 grams of betaine; the latter was weighed partly as aurochloride, partly as the free base. In the course of the research, the observation was made that the choline platinochloride, when allowed to crystallise slowly from water, appears in the form of plates, but when crystallised rapidly, assumes the form of very slender prisms or needles; from alcohol it crystallises as regular octahedra.

From the seeds of the pea, *Pisum sativum*, the platinochloride of choline was also obtained (1 gram of choline from 3.5 kilos. of the seeds). Another base resembling betaine was found in smaller quantity; it is, however, not betaine, as its aurochloride contained only 41 per cent. of gold, instead of 43.1.

The question arises, do these compounds occur free, or combined in the seeds? It is possible that choline might occur in combination as lecithin, but certain considerations excluding this possibility, the conclusion is drawn that the bases are free in the seeds; they are, however, present in such small quantities that they do not have any poisonous action.

W. D. H.

Composition of the Leaves of *Maclura aurantiaca*. By A. PIZZANI (*Chem. Centr.*, 1890, ii, 766; from *Staz. sper. agr. ital.*, 18 589—596).—The leaves of *Maclura aurantiaca* are used in the silk-

worm culture as a substitute for the mulberry. The following is the analysis :—

Water	65·710
Fat	0·643
Proteids	4·775
Non-proteid nitrogenous substance ..	3·230
Cellulose	9·522
Sugar, starch, &c.	12·679
Mineral matter	3·421

The composition of the ash is :—

K ₂ O.	Na ₂ O.	MgO.	CaO.	Fe ₂ O ₃ .	SiO ₂ .	P ₂ O ₅ .	SO ₂ .	Cl.	Loss, &c.
9·244	6·156	6·727	25·732	3·814	26·247	17·543	2·405	1·327	1·805

The total nitrogen = 1·2841 per cent. Of the total proteid substance, which amounts to 13·88 per cent. of the dry matter, 7·03 per cent. is undigested, and 6·85 digested by gastric juice. The composition of mulberry leaves, as given by several authors, and that of the leaves of *Maclura aurantiaca* is thus very similar. J. W. L.

The Behaviour of some Vegetable Substances towards Copper and some of its Compounds. By E. FORMENTO (*Bied. Centr.*, 19, 844—845; from *Staz. sper. agr. ital.*, 18, 686—693).—In vine culture, copper compounds are used as a cure for peronospora, it being assumed that the copper salt penetrates to the inside of the plants. The author made experiments to determine the manner and extent of the absorption of copper by vegetable tissues. When a solution of copper sulphate is mixed with clear, saturated lime-water, cupric hydroxide is not precipitated, but a more or less basic copper sulphate, according to the amount of copper sulphate present. The basic sulphates are soluble in water saturated with carbonic anhydride. The results of the author's experiments make it probable that copper can only reach the inner parts of plants by dialysis when a copper-lime mixture is used. When established inside the plant, copper compounds long resist the dissolving action of acids or of ammonia. An experiment in which an insoluble copper salt was separated by parchment paper from an acid sap showed that little or no copper passed through when free lime was present. N. H. J. M.

Acquisition of Atmospheric Nitrogen by Plants. By W. O. ATWATER and C. D. WOODS (*Amer. Chem. J.*, 13, 42—63; compare this vol., p. 353).—The results of further experiments with peas, alfalfa, and with cereals, are described, and point to the following conclusions :—

1. That atmospheric nitrogen is undoubtedly acquired during the growth of peas and alfalfa, and that the amount of nitrogen gained increases with the number of root tubercles.

2. That the addition of soil-infusion is not necessary for the production of root tubercles, a fact which may be accounted for by supposing that the micro-organisms or their spores exist in the air, and are deposited in the pots where the plants grow.

3. That the cereals do not, as a rule, manifest the power of acquiring nitrogen from the air, nor are root tubercles formed on them, as in the case of leguminous plants. G T. M.

The Nitrogenous Substance of Arable Soil. By L. L'HÔ¹¹ (*Biol. Centr.*, 19, 795—796; from *Jour. d'agric. pract.*, 1890, 365—366).—The following table shows the percentage of nitrogen in three soils, and in the organic matter of the soils separated by washing with water, and in the humic acid. This was extracted from the soil (previously extracted with weak hydrochloric acid to remove lime) with dilute aqueous potash (1:20), precipitated by hydrochloric acid, and dried in a vacuum over sulphuric acid.

	Soil, natural state.	Soil treated with water.	Organic matter from 100 pts. of soil.	Humic acid (dried at 100°).
1. Garden soil	0·372	0·369	0·316	4·78
2. Arable soil (St. Pierre) .	0·087	0·086	0·070	6·07
3. „ (Serquigny).	0·140	0·136	0·089	5·41

The percentage of nitrogen in the humic acid approaches that obtained by Thénard with humic acid from rotten farmyard manure (*Compt. rend.*, 1857, 980). Humic acid in alkaline solution is absorbed by clay. The organic matter of soils is precipitated from its solutions by ferric chloride (compare Pigot, *Ann. Chim. Phys.*, 1864).

N. H. J. M.

Effect of Artificial Manuring on Clover Land and Meadows. By W. v. KNIERIEM (*Bied. Centr.*, 19, 814—817; from *Balt. Wochenschr. f. Landw.*, 1890).—The experiments first described were made to ascertain the effect of different amounts of gypsum on clover land, and also the effect of early and late application of the manure. The application of 443 kilos. of gypsum per hectare on March 2 raised the yield by 45 per cent.; the same amount applied April 14 and May 15 raised the yield by 25 and by 4 per cent. respectively. With 665 kilos. per hectare (applied in March), the increase in produce over the unmanured plot was 42 per cent. In the next season the effect of gypsum had ceased. But it was observed that where no gypsum had been applied the first season, the grass was stronger the second season. This was due to the fact that the growth of clover had been so much increased by the gypsum that the grasses were kept back in their growth.

In other experiments, the plots were manured with (1) potash; (2) superphosphate; (3) bone meal; (4) potash and superphosphate; (5) superphosphate and ammonium sulphate; (6) lime. All those plots gave much more produce the first year than the unmanured plot did. The increase (taking both seasons) was 63 per cent. in No. 4; 52 per cent. in No. 5; 38 per cent. in No. 1; 30 per cent. in Nos. 2 and 3; and 27 per cent. in No. 6. In every case, except where superphosphate was used alone, the beneficial action of the manures extended to the second year's crop.

N. H. J. M.

Experimental Plots of Mangold and Sugar Beet at Grignon, in 1890. By P. P. DEHÉRAIN (*Ann. Agronom.*, 16, 542—558).—Five varieties of mangold, tankard, giant Vauriac, globe, Barres ovoid, and mammoth were grown; and Vilmorin's improved sugar beet from seed obtained direct from Vilmorin, and from the seed of the same variety saved at Grignon. For the sugar beet, 40,000 kilos. of farmyard manure per hectare was used; for the mangolds, 20,000 kilos. of farmyard manure per acre was applied to those plots which had been manured the previous year, and 30,000 to the rest; with 200 kilos. of Chili saltpetre in each case. The rows were 0·35 metre apart, and the roots 0·25 metre apart in the rows; by thus leaving the plants rather thick upon the ground, small or medium roots were obtained, which are much richer in solid matter and in sugar, and more free from nitrates than large roots. The average weights of the roots thus grown were: tankard, 900 grams; *géante de Vauriac*, 1070; globe, 860; *ovoïde des Barres*, 980; mammoth, 920; Vilmorin's sugar beet, 620; ditto, Grignon seed, 690. The roots were not only weighed, but sampled and analysed, in order to compare their true nutritive value, as shown in the total weight of dry matter *per hectare*, total sugar, and total nitrogenous organic matter; the nitrogen, as potassium nitrate, was also estimated in each case, the author considering the presence of much of this diuretic in the roots to be injurious to the cattle fed on them.

The sampling was done by taking 100 roots at random from each lot, and arranging them in three groups, large, medium, and small roots; if there were 20 large, 50 medium, and 30 small, 2, 5, and 3 average roots from their respective groups would be selected, and a cylindrical portion of each removed with a sound (as in cheese-tasting). The 500 grams or so thus obtained was cut into small pieces, weighed, dried, and the nitrogen estimations carried out on the dry matter. Organic nitrogen was estimated by Kjeldahl's method after removing nitric nitrogen by ebullition with ferrous chloride and hydrochloric acid; nitric nitrogen by Schloesing's method, in the hot water extract of the dry matter, after successive precipitation with lead acetate and sodium sulphate. The sugar was estimated in the juice by the shadow polarimeter in the usual way, and the density of the juice being taken, the sugar in the entire root was calculated.

The following table gives a *résumé* of the most important results of the trials:—

Arranging the varieties in order, under the heads (1) yield of dry matter; (2) yield of sugar; (3) yield of nitrogenous organic matter; and (4) poverty in potassium nitrate; and then adding up the positions under each head, the small-leaved globe is at the head, then tankard, giant Vauriac, Barres yellow, and mammoth, in the order named. Valuing the mangold roots at 15 fr. per tonne, the gross return is about 1200 fr. per hectare in each case; the manure is valued at 250 fr. and 350 fr. A plot unmanured since 1875 yielded 17,300 kilos. tankard mangolds per hectare only, and one receiving only 200 kilos. of potassium chloride yielded only 19,700 kilos. of the same roots. Valuing the sugar beet at 28 fr. to 37·5 fr. per tonne, according to density of juice, the gross return from Vilmorin's seed is 1552 fr.,

Plots.	Varieties.	Composition of root.		Yield per hectare.				
		Dry matter.	Sugar.	Roots	Dry matter	Sugar.	Nitrogen.	
							Organic.	Nitric.
20, 22, 23	Barres' yellow oval mungold	per cent. 13.2	per cent. 10.8	kilos 81,170	kilos 10,713	kilos. 8859	kilos. 124.0	kilos. 25.7
24, 26	Tunkard	14.2	9.9	81,800	11,704	8102	94.7	6.9
25, 27, 28	Vaurac giant yellow	14.4	9.0	82,980	11,942	7480	128.9	20.2
29, 30, 32	Small-leaved globe	14.8	9.9	81,000	11,987	8018	119.8	10.7
31	Mammoth	14.2	10.0	77,400	10,990	7740	102.2	7.6
71, 72, 73	Vilmorin's improved sugar beet ...	22.9	16.2	48,470	9,959	7044	88.5	5.9
74, 75	Ditto, from Grignon seed	28.2	15.1	46,650	10,822	7043	57.6	7.5

and from Grignon seed, 1351 fr. per hectare; the manure is valued at 400 fr. It is remarkable that rather more sugar per hectare is obtained from the mangold crop than from the sugar beet, but as against this advantage, the gross weight of the crop is nearly double, and the foreign matter and potassium nitrate associated with the sugar much larger. Distillers find it to their advantage to grow a sugar beet (*betterave à collet rose*) poorer in sugar than Vilmorin's improved, but yielding a larger crop, more sugar per hectare, and more pulp for cattle.

A cow eating 25 kilos. yellow ovoid mangolds per day would consume 50 grams of nitre, a quantity the author considers injurious. He quotes Barral's analyses of the enormous roots sent over for show from England, of Sutton's mammoth, Berkshire, and oxheart varieties, which compare very disadvantageously with the small roots obtained by growing the same or similar varieties closer together. Thus Sutton's mammoth roots, averaging 14,150 grams each, contained only 5.81 per cent. dry matter, and the dry matter contained as much as 13.89 per cent. of potassium nitrate, and as little as 17.21 per cent. of sugar, with 22.13 per cent. of proteids.

Analytical Chemistry.

Detection of Chlorides, Bromides, and Iodides. By G. DENIGES (*Bull. Soc. Chim.* [3], 4, 481—483).—The mixture is strongly acidified with sulphuric acid and the iodine and bromine are separately liberated by successive treatment with ferric chloride and potassium chromate. The iodine is characterised by starch paper, and the bromine by introducing a rod moistened with sodium hydroxide solution into the tube in which the halogen is being evolved. On then placing the rod in aniline water, the hypobromite formed gives an orange-yellow coloration. If all three halogens are present, the iodine and bromine must be removed by continuous boiling of the acidified solution with potassium chromate; potassium permanganate is then added, and the chlorine evolved tested with a rod dipped in soda solution, as in the case of bromine; it gives a violet coloration with aniline water.

T. G. N.

Volumetric Estimation of Chlorides in Urine. By A. CORVI (*Chim. Centr.*, 1890, ii, 795; *L'Orosi*, 13, 253—255).—The chloride is precipitated with an excess of N/10 solution of silver nitrate, and the excess of silver determined by titration with potassium ferrocyanide solution of equivalent strength; ferric sulphate is employed as indicator.

10 c.c. of urine is acidified with a few drops of nitric acid, and 50 c.c. of the silver chloride solution is added. The volume of the solution is noted, then filtered, and one third of the filtrate titrated with ferrocyanide.

J. W. L.

Estimation of Nitric and Nitrous Acids in Potable Waters. By M. ROSENFELD (*Zeit. anal. Chem.*, 29, 661—664).—Under certain conditions, the reaction of nitric and nitrous acids with pyrogallol affords one of the most sensitive means for their detection and approximate estimation. 3 c.c. of the water to be tested is rapidly mixed in a conical test glass with 6 c.c. of concentrated sulphuric acid; one drop of a 1 per cent. solution of pyrogallol is then added, and cautiously mixed with the upper two-thirds of the liquid. In a few minutes or immediately, according to the amount of nitric acid present, a dark-brown to violet colour is produced. As little as 1 milligram of nitric anhydride per litre can be detected, and up to 15 milligrams per litre comparisons of the depth of colour with standards furnish a roughly approximate estimation. The test-glass for the operation must not be wiped, nor must more than one drop of the pyrogallol solution be used, unless the colour disappears on shaking, which may happen when much nitrate is present.

For nitrous acid, a solution is made containing 0.5 gram of pyrogallol, 90 c.c. of water, and 10 c.c. of sulphuric acid. Of this mixture, 2 c.c. is added to 100 c.c. of the water in a cylinder. 0.04 milligram of nitrous anhydride in the 100 c.c. produces a yellow colour immediately; with 0.01 milligram, the colour develops only in seven hours. Up to 0.05 milligram, a difference of 0.005 milligram is perceptible.

M. J. S.

Detection of Carbonic Oxide in Blood. By M. RUBNER (*Zeit. anal. Chem.*, 30, 112; from *Arch. Hygiene*, 10, 397).—The blood is shaken for a minute in a test-tube with four or five volumes of lead acetate solution. Blood containing carbonic oxide remains red, whilst normal blood becomes brownish, and ultimately chocolate-brown and greyish-brown. The difference is still recognisable when the carbonic oxide blood is diluted with eight or nine volumes of normal blood.

M. J. S.

Analytical Methods for Alkali Works. By G. LUNGE (*J. Soc. Chem. Ind.*, 9, 1013—1019).—*Estimation of Sulphur in Pyrites.*—The author's method (Abstr., 1881, 193) adopted in the "Pocket Book for Alkali Makers," although severely criticised by Jannasch and Richards (Abstr., 1889, 926), has stood the test of practical application since its introduction in 1881. Jannasch confused the method with an older process, and subsequently acknowledged that the author's 1881 method gave results agreeing closely with the numbers obtained by his own method (Abstr., 1889, 1244). For estimating the sulphur in burnt pyrites, the author now prefers the method recommended by Watson (Abstr., 1889, 306).

Testing Pyrites Burner Gases.—Reich's method can no longer be considered accurate, as it has been proved by many observers that burner gases contain sulphuric anhydride. The author therefore proposes to estimate the total sulphur acids in burner gases by absorption in a solution of soda, using phenolphthaleïn as indicator. For this purpose, Reich's apparatus is employed, but it is found desirable to modify the absorbing bottle by sealing the inlet-tube for the gas at the bottom, and perforating it below the level of the

liquid with several pin-holes, through which the gases issue in minute bubbles instead of one large bubble. In calculating the results, it is necessary to take careful readings of the thermometer and barometer for correcting the volume of gas aspirated.

Testing the Chamber Exit Gases.—The well-known prescriptions of the English Alkali Makers' Association can be greatly simplified by introducing the above process with caustic soda and phenolphthaleïn, which has already been done with great practical success. It has also been found necessary to revise the methods for estimating the nitric oxide in the exit gases. With regard to the best form of absorbing apparatus, the author after many trials decided in favour of the 10-bulb tube, which for greater security may be enlarged to 15 bulbs. Concerning the best absorbent, the final conclusion was that so far no better mode of estimating the nitric oxide contained in the exit gases is known than that of passing them through a titrated solution of potassium permanganate strongly acidified with sulphuric acid, and contained in a 15-bulb tube. At the end of the operation an excess of a titrated solution of ferrous sulphate is added, and the mixture again titrated with standard permanganate.

Estimation of Free Lime in Black Ash.—50 grams of the sample is quickly, but thoroughly, ground to a fine powder, which is transferred to a litre flask, and covered with lukewarm distilled water freed from carbonic anhydride by boiling. The mixture is at once well shaken, and the agitation is repeated several times during two hours. This prevents the formation of a hard cake at the bottom which does not further disintegrate. The flask is then filled up to the mark, and special samples are taken out with a pipette for the estimation of free lime, and if required for total lime (see below), the contents being thoroughly shaken up each time. In the test for free lime, the contents of the pipette are run into a beaker, an excess of barium chloride is then added, and the solution titrated in the cold with N/5 oxalic acid, using phenolphthaleïn as indicator.

Estimation of Total Soda and Total Lime in Black Ash.—In the test for total lime, the contents of the pipette are transferred to an Erlenmeyer flask, mixed with a few c.c. of strong hydrochloric acid and boiled. A drop of methyl-orange is now added, and sodium carbonate solution run in until the pink colour has just disappeared. 30 c.c. of N/5 sodium carbonate is then added from a burette, and the mixture boiled to precipitate all the calcium carbonate. This is then washed into a 200-c.c. flask, and 100 c.c. of the clear portion titrated with N/5 hydrochloric acid to determine the quantity of sodium carbonate taken up by the lime present. For the ordinary black ash tests, the clear portion of the original black ash solution is used.

Estimation of available Soda in Alkali Waste.—At some Lancashire works, the aqueous extract is treated with carbonic anhydride, the mixture boiled to decompose the calcium hydrogen carbonate, and the clear solution titrated. The author finds that this method gives concordant results practically identical with those obtained even more quickly by zinc carbonate, which requires only 15 minutes' boiling, whilst the treatment with carbonic anhydride must be carried on for at least one hour (less being insufficient).

Estimation of Hydrogen Sulphide and Sulphurous Anhydride in the same Gaseous Mixture.—The author proposes to pass the gases through a bulb apparatus containing iodine solution, followed by another apparatus containing a little standard soda solution. At the end of the operation the contents of both apparatus are united. The mixture should have an acid reaction, otherwise it must be acidified with a known quantity of standard acid. The unused iodine is then estimated by means of sodium thiosulphate, after which methyl-orange is added, and standard soda run in to neutral reaction. This method gives all data required for estimating sulphurous anhydride and hydrogen sulphide, since the latter liberates only its equivalent of hydrogen iodide, whilst the former, in addition to its equivalent of hydrogen iodide, also yields an equivalent quantity of sulphuric acid. If m represents the difference between the quantity of iodine solution originally employed and that of thiosulphate used in retitrating, n the decinormal soda solution originally employed, and o the quantity of soda used in the end for establishing neutrality, the quantity of sulphur present is found by the following expressions:—

$$\begin{aligned} \text{S in H}_2\text{S and SO}_2 &= 0.0016m. \\ \text{S in SO}_2 &= 0.0016(n + o - m). \end{aligned}$$

D. B.

Estimation of Available Soda in Commercial Caustic Soda. By J. WATSON (*J. Soc. Chem. Ind.*, 9, 1107—1108).—In the preceding abstract, Lunge, in referring to the method used at some Lancashire works, mentions that less than one hour's treatment with carbonic anhydride is not sufficient to effect the necessary reaction. The author has used the method in question for a number of years, and has always obtained satisfactory results by proceeding in the following manner:—20 grams of waste is treated with about 150 to 200 c.c. of warm distilled water; after stirring and allowing to remain for about an hour, the clear liquid is decanted, and carbonic anhydride passed in for three to five minutes. This at first causes a milkiness, owing to precipitation of calcium carbonate, the solution subsequently becomes clear as the carbonate is dissolved as calcium hydrogen carbonate in the excess of carbonic anhydride, hydrogen sulphide is then evolved, and at this point the author considers that sufficient gas has been passed through the solution. He then evaporates to at least half the original volume, filters off, and washes the calcium carbonate, titrating the alkali in the filtrate with a dilute standard acid, and using methyl-orange as indicator.

D. B.

Test for Thiosulphate in Sodium Hydrogen Carbonate. By F. MUSSET (*Zeit. anal. Chem.*, 30, 45).—5 grams of the salt is rubbed with 0.1 gram of calomel and two drops of water. The smallest trace of thiosulphate reveals itself by blackening the calomel.

M. J. S.

Analysis of Commercial Sodium Fluoride. By E. HINZ and H. WEBER (*Zeit. anal. Chem.*, 30, 30—33).—A specimen of this material was strongly alkaline, and showed by qualitative analysis the presence of much sodium carbonate and silica, with smaller

quantities of sulphates and chlorides, potassium, calcium, magnesium, aluminium, and ferric oxides.

Estimation of Silica and Fluorine.—About 2—3 grams of the sample was boiled with ammonium carbonate in a platinum basin, and the insoluble residue preserved. The filtrate was treated with a solution of zinc oxide in ammonia, and the ammonia boiled off; the precipitate was then dissolved in nitric acid, and the silica rendered insoluble by evaporation. The united portions of impure silica were fused with sodium carbonate and recovered by evaporation with acid. The filtrate from the zinc precipitate was precipitated hot with calcium chloride, and the precipitate thus produced, consisting of calcium carbonate and fluoride, was, after washing and ignition, decomposed by acetic acid; the excess of acetic acid was evaporated, and the calcium fluoride washed, ignited, and weighed.

For estimating the sulphuric acid, 20 grams was heated with water and made up to a litre; a portion of the clear solution was acidified in a platinum basin, precipitated with barium chloride, filtered in a platinum funnel, and the precipitate fused with sodium carbonate for its purification. Similarly, for the estimation of the chlorine by precipitation with silver nitrate, the operations were performed in platinum. The carbonic anhydride was expelled by boiling with tartaric acid, collected, and weighed.

For the various bases, the substance was evaporated with sulphuric acid and the metals separated by ordinary processes. The water was estimated by heating a weighed quantity in a stream of dry air and collecting the water in a calcium chloride tube.

For estimating that portion of the silica present as sand, the insoluble residue of the original substance was boiled with sodium carbonate and hydroxide, and the insoluble matter purified by hydrochloric acid.

The composition found was as follows:—

Sodium fluoride.....	65.65
„ chloride.....	0.74
„ carbonate.....	13.89
„ sulphate.....	1.96
Potassium sulphate.....	0.74
Soda (combined with silica).....	1.50
Silica (partly combined with soda).....	10.11
Calcium carbonate.....	0.25
Magnesium carbonate.....	0.32
Ferric oxide.....	0.48
Alumina.....	0.17
Water.....	3.97

M. J. S.

Analysis of Commercial Barium Hydroxide. By E. HINTZ and H. WEBER (*Zeit. anal. Chem.*, 30, 24—29).—A specimen examined by the authors contained barium hydroxide, carbonate, sulphate, thio-sulphate, sulphide, and sulphite. On treatment with water, the

carbonate, sulphate, all the sulphite, and part of the thiosulphate remained undissolved.

About 20 grams of the substance was treated with boiling water, made up to 500 c.c., allowed to deposit, and the total barium in 50 c.c. of the clear solution determined gravimetrically. For the sulphide estimation, 250 c.c. was poured into pure potash, to which a few drops of lead acetate had been added. The precipitate of lead sulphide and barium carbonate was oxidised by bromine and hydrochloric acid, and the lead sulphide thus converted into barium sulphate. In this operation it is necessary to use enough potash to prevent precipitation of lead thiosulphate; also, if much sulphide is present, the barium sulphate precipitate may contain lead sulphate, in which case it must be fused with alkaline carbonates, and the aqueous solution treated with carbonic anhydride before reprecipitating as barium sulphate. The filtrate from the lead sulphide was now oxidised by bromine and hydrochloric acid, to convert the thiosulphate into barium sulphate. This precipitate may also contain lead. The difference between the total soluble barium and that found as sulphide and thiosulphate gave the amount of hydroxide.

For estimating the sulphate, 5 grams was boiled with dilute hydrochloric acid in a stream of carbonic anhydride. The whole was evaporated to dryness, taken up with water and a few drops of hydrochloric acid, and the undissolved portion fused with alkaline carbonates; the sulphuric acid was then precipitated from the solution of the fusion. For the sulphite and undissolved thiosulphate, the insoluble residue of 10 grams was treated with hydrochloric acid, in a flask connected with an inverted condenser and two Pélignet tubes containing bromine and hydrochloric acid, whilst carbonic anhydride was passed through the apparatus. The sulphurous anhydride from both the sulphite and thiosulphate was retained by the bromine, and, after evaporating to dryness, was weighed as barium sulphate. The thiosulphate was estimated from the sulphur left in the decomposition flask with barium sulphate. It was oxidised by bromine and hydrochloric acid, and weighed after fusion with carbonates and reprecipitation.

The carbonate was estimated by mixing 10 grams of the substance with a strong solution of potassium permanganate and decomposing by nitric acid. The carbonic anhydride evolved was passed through a tube containing pumice stone moistened with permanganate and inserted between the evolution flask and the absorption tube.

The composition of the specimen analysed was as follows:—

Barium hydroxide, $\text{Ba}(\text{OH})_2 + 8\text{H}_2\text{O}$	94.31 per cent.
„ sulphate	0.52 „
„ sulphite	0.07 „
„ thiosulphate	0.70 „
„ carbonate	1.75 „
„ sulphide	0.04 „

M. J. S.

Separation of Barium from Calcium. By R. FRESSENIUS (*Zeit. anal. Chem.*, 30, 18—23).—Precipitation by normal ammonium

chromate from a dilute, hot solution of the two chlorides, feebly acidified with acetic acid, filtration after cooling, and washing, first with ammonium chromate and then with warm water, gave a fairly satisfactory result, the baryta found being 0.3127 gram, instead of 0.3104. A little calcium was therefore retained by the precipitate, and this was also the case when more acetic acid was used (2 c.c. to 200 c.c. of solution containing 0.5 gram of the bases), together with 6 grams of ammonium acetate, and the precipitate was most thoroughly washed by digesting with hot water and filtering after cooling. By double precipitation, a slight deficiency of barium and a trifling excess of calcium were obtained; the separation was, however, more nearly perfect. The first precipitate was dissolved in a little nitric acid, and the diluted solution precipitated by ammonium acetate and chromate.

Precipitation with hydrofluosilicic acid and washing with dilute alcohol did not give complete separation, a little calcium being precipitated. A more satisfactory, but still not quite perfect, separation resulted when the precipitate, after slight washing with weak alcohol, was repeatedly digested with cold water, the aqueous washings concentrated, reprecipitated with 4 drops of hydrofluosilicic acid and one-third volume of alcohol, and the small precipitate added to the main one. A combined method, precisely similar to that finally adopted for strontium (Abstr., 1890, 925), gives an almost perfect separation.

M. J. S.

Detection and Estimation of small quantities of Aluminium in Iron and Steel. By A. CARNOT (*Compt. rend.*, 111, 914—916).—10 grams of the metal is dissolved in hydrochloric acid in a platinum vessel, diluted, and filtered. The greater part of the free acid is nearly neutralised, first with ammonia and afterwards with sodium carbonate. Sodium thiosulphate is added, and when the violet coloration has completely disappeared and the solution contains only ferrous salt, 2 to 3 c.c. of a saturated solution of sodium phosphate and about 20 c.c. of a solution of sodium acetate are added, and the liquid is boiled until all sulphurous anhydride is expelled. The precipitate, which consists chiefly of aluminium phosphate, with some silica and ferric phosphate, is washed with boiling water, redissolved in dilute hydrochloric acid, the silica filtered off, the filtrate diluted to 100 c.c., and the precipitation repeated in precisely the same manner. The precipitate is washed with boiling water, dried, and weighed.

C. H. B.

Estimation of Ferric Oxide and Alumina in Phosphates. By v. GRUBER (*Zeit. anal. Chem.*, 30, 9—14).—The "conventional method" yields high results at the first precipitation, owing to the retention of much calcium phosphate with the insoluble phosphates, whilst after a second treatment, the results are too low, in consequence of the solubility of aluminium phosphate in acetic acid. The author has not been able to obtain accurate results by Stutzer's method, in which the phosphoric acid is removed by molybdate. Glaser's method, however (Abstr., 1890, 420), affords results which are in all cases concordant, and has been accepted by the Conference of the Representatives of the Artificial Manure Industry, held at Bremen. Only

in cases where it is desirable to estimate the iron and aluminium separately, is there any necessity for the removal of the phosphoric acid by molybdate.

M. J. S.

Dry Assay of Tin Ores. By H. O. HOFFMANN (*Chem. News*, 62, 276—277, 291—293, 300—302, 316—317; continued from p. 246).—Rickett's method for the assay of the ores containing silica only, namely, fusion with hæmatite, potassium cyanide, and charcoal in a luted, charcoal-lined crucible, is regarded as of little value to the assayer, beyond substantiating the fact that iron carries down all the tin. With such ores, it is best to separate the black tin by vaning, and then reduce it with potassium cyanide. Mitchell's method of fusion with ferric oxide, fluorspar, and charcoal for the assay of siliceous tin ores and slags, gave neither buttons nor prills in the hands of the author, who recommends, in preference, decomposing the finely pulverised slag with sodium or potassium hydrogen sulphate and treating with acid; the tin is easily estimated in the resulting mixture of stannic oxide and silica. Experiments with the method due to Bloxam, namely, mixing 5 grams of ore with 5 grams each of potassium cyanide and ferrocyanide, reserving 5 grams of the former salt for the top of the crucible, give results differing by 1 gram.

By the Cornish methods of assaying black tin by heating in charcoal-lined crucibles, with or without anthracite and fluorspar, unsatisfactory results were obtained, owing to the difficulty of separating the heavy slag from the fine tin. Of all the various methods and modifications recommended by different authorities, the author is of opinion that the German method and the method of fusion with potassium cyanide are the only two which give entirely satisfactory results.

The next point taken into consideration is the influence of associated minerals on the working of these two methods. Pulverised quartz, felspar (albite), mica (muscovite), garnet (almandite), tourmaline, and columbite were respectively mixed with black tin in different proportions, and submitted to assay; the results are tabulated and described.

When the German method was used, the quartz decreased the proportion of soft slag formed on the top of the borax slag, which became finer, harder, more plentiful, and less vitreous as the silica increased, whilst the buttons separated well, but the yield of tin was diminished; mixing the ore with basic flux proved very detrimental; felspar gave slags similar to those with quartz, but more stony and adhesive to the button; the latter was dark, brittle, hard to cut, and contained iron, whilst some tin had slagged. Mica and tourmaline produced a similar, but more marked, effect than felspar, more iron was reduced and more tin lost, and when the proportions of added mineral amounted to 50 per cent., no proper fusion ensued; with the garnet, the salt slags were less crystalline than usual, the borax slags became stony, tough, and opaque, the buttons all dark-grey, hard to cut, brittle, and rich in iron, the results, in the author's opinion, were uniform, and appear to indicate that if tin is to be recovered from siliceous ore as an alloy, a basic silicate of iron is the best flux for the purpose; with columbite, the salt slags were stony and dull, the

borax slags brittle, vitreous, and of resinous lustre, whilst the buttons were dark-grey, becoming black and ferruginous, the quantity of iron increasing with the percentage of columbite added.

When the cyanide process was employed, quartz gave lustrous, coarsely crystalline slags, increasing in hardness as the quantity of quartz was increased, the appearance of the button being unaltered by the silica; felspar and mica produced but little effect beyond making the lower slag more porous, the buttons were unaltered, and the loss of tin was less than in the German process; tourmaline had no effect; garnet coloured the lower slag, which increased in quantity with the garnet added, the button was ferruginous, but some tin slagged; columbite gave an increasingly porous and coloured under slag, and a white, bright, malleable, soft button, containing but little iron.

With regard to the interference of impurities, the cyanide process therefore comes off the best, but the German method is cheaper.

Taking into account the interference of impurities, it is important to remove them as far as possible before the assay; most of them, the non-metallic ones, can be removed by crushing, sizing, and panning, the metallic ones by roasting, chilling, and treating with nitrohydrochloric acid. This also removes garnets, and metallic iron coming from the grinding implements; the concentrates may, if necessary, be treated with hydrofluoric acid; the roasting, moreover, makes some samples of cassiterite more friable and more readily reducible. Altogether, it is considered that by the careful use of the few correct methods of preparation and assaying, the dry assay of purified black tin and tin ores will give more accurate results than the dry assay of any other base metal.

D. A. L.

Analysis of Brandy and Alcohol. By E. MOHLER (*Compt. rend.*, 112, 53—55).—*Ethereal salts*.—100 c.c. of the distilled alcohol is boiled for an hour with 20 c.c. of decinormal potash in a reflux apparatus; the excess of potash is determined, and the rest is calculated to ethyl acetate.

Aldehydes are estimated by means of the coloration with rosanilino bisulphite, the intensity of the colour of the solution examined being compared, by means of a Duboscq colorimeter, with the coloration given by a solution of aldehyde of known strength; 10 c.c. of a 0.01 per cent. solution of acetaldehyde in alcohol of 50° is a convenient quantity to employ as a first standard.

Higher alcohols.—100 c.c. of the distilled liquid is mixed with 1 c.c. of aniline and 1 c.c. of phosphoric acid of 45°B to retain the aldehydes, and after cohobating for an hour, is distilled to dryness in a solution of salt. The distillate is treated with sulphuric acid of 66°, and the coloration is compared with that given by an alcohol containing 0.250 gram of isobutyl alcohol per litre.

Nitrogen compounds.—100 c.c. of the undistilled liquid is distilled to dryness with 2 c.c. of a solution of phosphoric acid of 45° B, the residue is dissolved in about 1000 c.c. of distilled water, mixed with 10 grams of sodium carbonate, and distilled, the distillate being Nesslerised. Alkaline potassium permanganate is then added, and distillation and Nesslerising is repeated. The first operation gives

the nitrogen present as ammonium compounds and amides, and the second gives the nitrogen existing as pyridine bases and alkaloids.

Several analyses of brandy and alcohol are given. C. H. B.

Estimation of Sugar in the Blood. By F. SCHENCK (*Pflüger's Archiv*, 47, 621—629).—In connection with a previous communication on this subject (this vol., p. 350), the author defends himself against criticisms passed on his method by Salkowski (*Centr. med. Wiss.*, 1890, No. 17), and Röhmman (*Centr. Physiol.*, 1890, Heft 1), but admits, after carrying out experiments on dialysis, that probably the sugar and the proteid are not in chemical combination.

W. D. H.

Testing Cassia Oil. By E. HIRSCHSOHN (*Zeit. anal. Chem.*, 30, 99—103; from *Pharm. Zeit. Russland*, 29, 225).—1. The oil is shaken in a graduated tube with three volumes of light petroleum (0·65). A diminution in its volume indicates the presence of other ethereal or fat oils, or of resin or kerosene; an increase would probably be due to the presence of much castor oil. 2. The petroleum extract is shaken with copper hydroxide. A blue solution indicates colophony or copaiba balsam. 3. One volume of the oil must give a clear or merely opaline solution with three volumes of 70 per cent. alcohol at 15°. A turbidity or sediment indicates the presence of petroleum, or of foreign ethereal or fatty oils, or of a large excess of colophony. 4. The alcoholic solution from 3 is poured into half its volume of a cold saturated solution of lead acetate in 70 per cent. alcohol. No precipitate should be produced.

To estimate the cinnamaldehyde in the oil, 75 grams of it is well shaken in a capacious flask with 300 c.c. of a boiling, 30 per cent. solution of sodium hydrogen sulphite. After a short repose, 200 c.c. of hot water is added, and the whole is warmed on the water-bath until the compound of the aldehyde with the sulphite is completely dissolved, when the constituents other than aldehyde and all the impurities form an oily layer on the surface. After cooling, this oily layer is dissolved in ether, and the filtered ethereal solution is evaporated in a tared beaker as rapidly as possible on the water-bath, and is weighed at intervals of ten minutes. When two weighings differ by no more than 0·3 gram, the last but one is taken as that of the non-aldehydic substances present. The cinnamaldehyde is known from the difference. Cinnamic acid, if present, may be removed by shaking the oil with hot sodium carbonate solution, and the amount found deducted from that of the aldehyde ascertained as above.

A rough technical method for the same purpose consists in placing 10 c.c. of the oil in a special flask of about 100 c.c. capacity, with a cylindrical neck graduated in tenths of a cubic centimetre. The oil is treated in the flask with the sodium hydrogen sulphite, and when the crystalline sulphite has been completely dissolved by prolonged heating on the water-bath, and the non-aldehyde constituents have formed a clear oily layer on the surface, they are driven up into the graduated neck by cautious addition of sulphite solution, and their volume read off when cold. The specific gravity of the non-aldehydic oil may, without serious error, be taken as 1·06 at 20°, or identical

with that of the original cassia oil. A good cassia oil should contain at least 75 per cent. of cinnamaldehyde. M. J. S.

Estimation of Acidity in Lubricating Oils. By HOLDE (*Chem. Centr.*, 1890, ii, 568; from *Mitt. könig. techn. Vers.-Anstalt, Berlin*, 1890, 151—153).—In the case of light-coloured oils, the author recommends measuring exactly 10 c.c. into a 300 c.c. Erlenmeyer flask, washing the measure with a mixture of 8 parts of ether and 2 parts of absolute alcohol containing a little phenolphthalein, and titrating with standard alcoholic soda (1 c.c. of which = 0.005 gram SO_2).

In the case of dark-coloured oils, where the colour would prevent the alkaline phenolphthalein from being seen, the author recommends that 20 c.c. of the oil should be agitated with 50 c.c. of absolute alcohol, and after the oil has again separated from the alcoholic extract, 25 c.c. of the latter is titrated with the alcoholic sodium hydroxide, after addition of 20 c.c. of the alcohol-ether mixture. If the amount of acidity is more than 0.03 per cent. (calculated as sulphuric anhydride), it is recommended to decant the remainder of the alcohol from the oil and to again extract with a further quantity of 50 c.c. of absolute alcohol.

Instead of using a burette marked in cubic centimetres, the author recommends one graduated in such volumes as are equivalent to percentages of acidity (= SO_2). J. W. L.

Estimation of Mineral Oils in Fat Oils. By A. GRITNER (*Zeit. ang. Chem.*, 1890, 261).—The following slight modification of Horn's method (*Zeit. ang. Chem.*, 1888, 458) allows the estimation to be made satisfactorily when the proportion of mineral oil is large. 2 or 3 grams of the sample is saponified in a small porcelain basin on the water-bath by 20 c.c. of alcoholic soda containing 20 to 25 grams of sodium hydroxide per litre of 95 per cent. alcohol. Heating and stirring are continued until the alcohol is entirely expelled, and then a quantity of sand (purified by hydrochloric acid) is mixed in. The mass is then treated in a Soxhlet's extractor with chloroform (purified by distillation with concentrated sulphuric acid), and the dissolved oil is dried at 100° after distilling off the chloroform. M. J. S.

Estimation of Oils, Fats, &c. By T. T. P. B. WARREN (*Chem. News*, 62, 215, 231).—In the first communication, equations are given for calculating, from data supplied by iodine absorption and also Maumené's reaction, the proportions of constituent oils, of which the presence has been undoubtedly ascertained, in mixtures of two or three oils. In the second communication, various oils, &c., are classified, according to their behaviour with sulphur chloride:—The first division contains those which give an insoluble product; this is of an elastic, spongy nature (except in the case of olive and cotton-seed oils, from which the sulphur at first dissolved separates on cooling) and is soluble in ether; but caoutchouc and gutta-percha are precipitated from such solutions by a few drops of alcohol; the following are the oils, &c., which have come under the author's notice, and behave in this manner:—Olive, poppy, "*papur. somnif.*," "*glauicum*"

flav.," almond, earthnut, walnut, sesame, nigerseed, castor, rapeseed, cotton, beechmast, and hempseed oils, also caoutchouc, gutta-percha, and allied substances, and the resins naturally associated with them. The second division includes those that do not behave in this manner, namely, sperm, whale, cod, lard, cocoanut, palm, and resin oils; spermaceti, lard, butter, beeswax, beef and mutton fat, pine resins, turpentine, Japan wax, petroleum and paraffin homologues; coal-tar, shale oil, and similar distillates from minerals, as well as glycerol and the fatty acids derived from the oils of the first division. Hence, oxidised, blown, or old oils of the first division produce more soluble products than the fresh oils. Oils of the second division yield less magma than oils of the first division; some of the former, petroleum and coal-tar distillates, for instance, simply act as solvents for the sulphur chloride. Any nitroglycerol, formed by the use of nitric acid, must be carefully removed when making tests. D. A. L.

Examination of Oils, Fats, and Allied Substances. By T. T. P. B. WARREN (*Chem. News*, 62, 288).—Points regarded as of importance in the examination of an oil are the specific gravity, the expansibility, and absorption of oxygen. The sp. gr. is taken in a bottle at 60° F. for thin oils; at 100° F. for thick oils, fats, &c. The expansion of an oil proceeds in a geometrical ratio giving a logarithmic curve in which the axes x and y follow a regular ratio of variation; therefore, in case there is any irregularity in the expansion of an oil, the temperature at which it occurs should be noted. For the oxygen absorption, the oil is exposed to a known volume of the gas, which is subsequently remeasured and analysed; the carbonic anhydride represents the glycerol set free, any further deficiency of oxygen being due to retention of that gas by the oil and fatty acids. D. A. L.

Adulteration of Olive Oil. By R. BRULLÉ (*Compt. rend.*, 111, 977).—10 c.c. of the oil is heated in a water-bath for half an hour with 5 c.c. of a 25 per cent. solution of silver nitrate in ethyl alcohol of 90°. Pure olive oil remains transparent and acquires a grass-green colour; earth-nut oil acquires a reddish-brown tint; oil of sesame acquires a very deep rum colour; colza becomes black and then dirty green; linseed oil acquires a deep reddish tint; cotton-seed oil becomes black; poppy-seed oil becomes greenish-black; oil of camelina becomes black, but in daylight, if the tube is inclined, it is seen to have a brick-red tint. C. H. B.

Analysis of Olive Oil and Seed Oils, Butter, and Margarine. By R. BRULLÉ (*Compt. rend.*, 112, 105—106).—12 c.c. of the oil is mixed with 5 c.c. of a 2.5 per cent. solution of silver nitrate in alcohol of 95°, and the mixture is heated in a test tube in a water-bath for 10 to 20 minutes. The oil must be filtered if it is not perfectly transparent.

The purest olive oil acquires a beautiful, delicate green colour; inferior olive oil at first blackens slightly or becomes pale red, but the colour soon changes to an intense green. Cotton-seed oil becomes quite black; earth-nut oil is at first red-brown, but afterwards

becomes green and turbid; oil of sesame becomes deep brown-red and does not turn green; colza oil and poppy-seed oil acquire a yellow-green colour and become turbid. The reaction will detect from 5 to 10 per cent. of impurity in olive oil.

Under these conditions, genuine butter from various sources retains its original colour, but butter containing margarine becomes brick-red. The reaction is distinct with 5 per cent. of margarine, and with 10 per cent. the red tint is strongly marked. C. H. B.

Composition of Butter Fat, as determined by the Reichert-Wollny Method.—By P. VIEH (*Milch. Zeit.*, 18, 541—545).—Although the method of determining the amount of volatile fatty acids in butter fat originally devised by Reichert and Meisl and afterwards modified by Wollny gives results which are perfectly concordant with one another, the amount of volatile fatty acids obtained from the fat of different samples of butter has varied within such wide limits, that the value of the method for the determination of the admixture of foreign fats with butter is correspondingly decreased. The results obtained by the author confirm those of other chemists.

There remains, therefore, the fact that butter fat varies in composition, and it was principally with a view to detecting, if possible, the cause of the variations that the author's experiments were made. The analysis of a sample of butter fat, received from Kiel on behalf of the "Kommission zur Feststellung der besten Butter-Prüfungs Methode," shows how little the amount of volatile fatty acids changes by lapse of time. (The results in this, as in all other cases, are expressed in c.c. of N/10 alkali, equivalent to the volatile fatty acids obtained from 5 grams of butter fat):—(a.) September 20th, 1888 = 31.8, 31.6, 31.8, 31.9, 31.9. (b.) January 17th, 1889 = 32.1. (c.) May 2nd, 1889 = 32.1.

From November, 1888, to May, 1889, 59 samples of butter fat were analysed. Of 28 samples of French butter the lowest value for volatile acids found was 26.1, and the highest, 30.6; of 22 samples of Swedish butter the lowest volatile fatty acid value was 26.9, and the highest, 29.4; of 3 samples of Holstein butter the lowest was 27.3, the highest, 29.1; finally, of 7 samples of butter made by the Aylesbury Dairy Company, Limited, the lowest value was 27.6, the highest, 29.2. Of the history of all these just enumerated, the author knew nothing, with the exception of those made by the Aylesbury Dairy Company. Further, 35 samples of milk were churned under the author's supervision, and the butter fat analysed. The vast majority showed a normal composition, and only two samples analysed had a less value than 25. From one farm, however, one belonging to the Aylesbury Dairy Company, butter was obtained from the fat of which very low fatty acid values were recorded. The cream was separated from the evening's milk, cooled, mixed with the cream of the following morning's milk, and sent up to London. After churning, the following values were found:—February 2nd, 1889 = 20.9 and 21.2; February 9th, 1889 = 21.4 and 21.2; February 15th, 1889 = 21.2 and 20.4. The herd comprised 39 Shorthorns, 16 Kerrys,

and 5 Jersey cows, but several changes occurred during the period of the investigations. Experiments were made to determine whether the breed had any influence on the quality of the butter fat; secondly, the food was altered, the silage, and then the oats, being replaced by other foods; but no important influence could be traced to any of these causes.

That the butter fat of the milk of cows which have been milked for a lengthened period sometimes contains a very low proportion of volatile fatty acids has been noticed by others, and the author found that the butter fat from two cows which had calved some months, in one case nearly fourteen months, previously, contained volatile acids equal to 1.4 to 1.6 c.c. N/10 alkali. The results of the analyses of the butter fat of the whole herd, when considered in relation to the length of time after calving, do not, however, show that the abnormally low values obtained can be referred to this as the principal cause.

J. W. L.

Analysis of Butter Fat by the Reichert-Wollny Method. By P. VIETH (*Chem. Centr.*, 1890, ii, 722—723; from *Milch. Zeit.*, 19, 721—724).—In addition to the results already published (preceding abstract), the author has determined the amount of volatile fatty acids in a further number of samples of butter fat.

The butter fat, which had been sent to a number of chemists from Kiel in the summer of 1888, contained, originally, fatty acids equal to 31.6—32.1 c.c. of decinormal alkali; on September 19th, 1889, 31.8 c.c.; on December 12th, 1889, 32.2 c.c.; on April 15th, 1890, 32.0 c.c. Of 29 samples of Schleswig-Holstein butter, 6 gave results below 25 c.c., 21.7 to 24.7 c.c.; these samples are of butter made at the time when most of the cows of Schleswig-Holstein are nearing the end of the period of lactation. Danish butter gave 29.8, 28.8, 29.9 c.c.; 39 samples of French butter had values varying from 26.9 to 30.8 c.c.; London-made butter, made from July 30th to November 12th, 1889, gave 25.8 to 27.1 c.c., and from March 25th to June 24th, 1890, 27.2 to 30 c.c. Some butter prepared by the author gave volatile fatty acids equal to 28.5 to 28.6 c.c. 55 samples of butter, made from milk obtained from the farms of the Aylesbury Dairy Company, the evening's milk being mixed with the following morning's milk, and then the cream separated, showed that during the months of February and March in 1889, and again in 1890, the proportion of volatile acids was abnormally low; the amount rose in April to 25 c.c., and stood above that amount during May and June. Similarly low figures were obtained in 1888. From June 11th, 1889, to June 30th, 1890, the figures varied from 21.3 to 26.2 c.c. The author cannot, however, offer any satisfactory explanation for the differences observed.

J. W. L.

Marchand's Method for Estimating Fat in Milk. By A. Sjöström (*Bied. Centr.*, 19, 855—856).—A mixture of equal volumes of ether (sp. gr. = 0.723) and pure alcohol (free from aldehyde) of 91—92 per cent. is used. 10 c.c. of milk is violently shaken in the lactobutylometer-tube with 20 c.c. of the ether alcohol mixture, kept

for a few minutes in a water-bath heated at 45° , again shaken until no more large pieces of casein are to be seen, and then heated for 12—15 minutes until the liquid has separated into three layers. The tube is now taken out of the water-bath, left for half an hour, and the volume of the layer of ether and fat read; the number of c.c. multiplied by 2.34 and added to 1.08 gives the percentage amount of fat by weight. A table given in the original paper (*Tidskr. f. landtmän*, 11, 552—556) shows the amounts of fat from 0.30 c.c. (= 1.78 per cent.) to 1.38 c.c. (= 4.31 per cent. of fat). For amounts outside these limits the method is of no use.

N. H. J. M.

A New Method for the Estimation of Butter Fat in Milk.

By S. M. BABCOCK (*Chem. Centr.*, 1890, ii, 723; from *Bull. Agric. Stat. Univ. Wisconsin*, 1890, 24).—17.5 c.c. of milk is measured into a long-necked flask of 45 c.c. capacity. The pipette employed is graduated at 17.6 c.c., an allowance of 0.1 c.c. being made for the amount of milk adhering to the sides. This amount of milk weighs 18 grams. The neck of the flask is graduated into ten parts, each such division being again subdivided into five divisions each measuring 0.4 c.c., and each principal division representing 1 per cent. of fat. To the 17.5 c.c. of milk an equal volume of concentrated sulphuric acid is added and gently mixed with the milk. The mixture is then allowed to remain at rest a short time, and placed in a centrifugal apparatus at a temperature of 93.3° ; hot water is next added until the fat rises to the neck, when it is again subjected to centrifugal force. Hot water is now finally added until the fat rises to the seventh division, and the volume is then read off. In the case of condensed milk, 8 grams is mixed with 10 c.c. of water, and the sulphuric acid added. Of cheese, 5 grams is treated with 18 c.c. of water, the same quantity of sulphuric acid being added. The following results are appended.

	Babcock.	Gravimetric.	
Cream cheese	57.05	56.80	per cent. fat.
Condensed milk	9.65	9.47	"
Common cheese	34.87	35.46	"
" "	33.73	33.77	"

J. W. L.

Analysis of Fats. By J. LEWKOWITZCH (*J. Soc. Chem. Ind.*, 9, 542—848).—After reviewing the methods at present employed in the analysis of fats, the author enters on the original part of his paper, which has special reference to the examination of the fatty acids. He examined the fat extracted from the Sawarri nuts, and obtained the following figures:—

Hehner's value	96.9 per cent. (insoluble acids).
Reichert's value	0.65 per cent. (soluble acids).
Köttstorffer's value	199.51
Mean molecular weight of the insoluble acids	272.82

Free acids (mol. weight 272.8)	2.4 per cent.
Glycerol	9.1 "
Iodine value of the fatty acids	51.5 "

The low Reichert's value and the high Hehner's value show that the amount of volatile soluble acids may be neglected. The mean molecular weight seems to point to the presence of oleic, palmitic, and stearic acids only. In order to resolve the insoluble fatty acids into their components, they were transformed into the corresponding lead salts and extracted repeatedly with ether. The results being unsatisfactory, it was attempted, by fractional crystallisation of the acids yielding the insoluble lead salts, to concentrate the unsaturated acid into one fraction, for which purpose the lead salts were decomposed with sulphuric acid and repeatedly boiled with slightly acidified water. The free acids were dissolved in alcohol and yielded seven consecutive crystallisations, the filtrate from the last crystallisation was freed from alcohol by evaporation and yielded an eighth quantity of acids, the iodine value of which showed that the unsaturated acid had accumulated in the final fraction. The iodine values of the other fractions point to the explanation that the first portion is nearly pure palmitic acid, which, in the higher fractions, is being partly replaced by stearic acid. The soluble lead salts were decomposed in the same way, the liquid acids repeatedly washed and freed from the last traces of water. After having been kept for some time in a desiccator, the liquid acids assumed a pasty consistence, from which, however, it was not possible to separate the solid constituent. The chemical and physical properties of the acids proved that, besides the supposed oleic acid, one or more other acids were present. The acids were, therefore, subjected to oxidation with permanganate according to Flazura's directions, and the potassium salts decomposed by sulphuric acid, when a precipitate of insoluble acids was obtained. These were extracted four times with ether. The first extract gave a gelatinous substance saponifiable by alcoholic potash. The fatty acid obtained therefrom gave an acid value of 182.5, corresponding with a molecular weight of 305. The substance, therefore, seems to be an inner anhydride of a hydroxylated fatty acid of the general formula

$\text{R-CH} \begin{array}{c} \diagup \text{CO} \\ \diagdown \text{O} \end{array}$, pointing to the existence of an acid of the formula

R-CH(OH)-COOH . The second, third, and fourth extracts consisted of small quantities of the acids which are not altogether insoluble in ether, and were later on added to the main portion. The bulk of the acids was repeatedly boiled out with water without, however, losing in weight, whereby the absence of linolic and isolinolic acids was proved. On repeatedly crystallising from alcohol, it was found that only one acid was present, all fractions yielding an acid melting between 125° and 130°. The last filtrate yielded, on evaporation, an acid melting between 117° and 119°, whereby the absence of sativic and isotrihydroxystearic acids was established. The oxidised acid was then recrystallised from alcohol, and the crystals, showing every sign of purity, and melting between 132° and 133°, gave, on analysis, numbers agreeing with the formula for dihydroxystearic acid, $\text{C}_{18}\text{H}_{34}(\text{OH})_2\text{O}_2$.

The acids soluble in water were obtained by neutralising the sulphuric acid after the dihydroxystearic acid had been filtered off, and boiling the solution down until potassium sulphate began to separate. The solution was then acidified and the bibasic acid extracted with ether. After repeated crystallisation from water, an acid was obtained melting between 126° and 130° , which proved to be a mixture of azelaic and suberic acids.

In conclusion, the author refers to his criticisms on Benedikt's acetyl values (Proc., 1890, 72 and 91). Benedikt, in his reply, declared the author's results to be wrong, and assumed that impure acetic anhydride had been used and that the fatty acids had not been washed free from acetic anhydride before titration. The author refutes Benedikt's alleged explanation for his supposed error, and in a somewhat lengthy discussion gives further proof in support of his views.

D. B.

Methods of Estimation of the Fatty Substances in Vegetable Organisms. By W. MAXWELL (*Amer. Chem. J.*, 13, 13—16).—Experiments with *Gossypium* (cotton seed) show that not only are the lecithins not wholly separated by treatment with ether, but that even the greater proportion of these substances resists the action of ether, and can be separated only by subsequent treatment with alcohol. In the case of cotton seed, the proportion of lecithins in the total fatty substances is very small; yet more than 50 per cent. of the substituted glycerides remain in the material after extraction with ether for 15 hours. In some other varieties of seeds, such as the legumes, the total ethereal and alcoholic extracts of the seeds (which seeds contain from 2.5 to 4 per cent. of fatty substances) are composed of lecithins to the extent of 25—45 per cent. If as much as 50 per cent. of the lecithins remain unseparated after treatment of the materials with ether only, it follows, therefore, that when ether only is used as an extractive agent, from 20 to 25 per cent. of fatty substances remain undetermined in those seeds in which the fatty substances consist largely of lecithins.

G. T. M.

Estimation of Morphine in Opium. By E. DIERICH (*Zeit. anal. Chem.*, 30, 105—107; from *Pharm. Centralhalle*, 31, 591).—6 grams of the finely-powdered opium is rubbed up with 6 c.c. of water, rinsed into a tared flask, made up with water to a total weight of 54 grams, shaken for 15 minutes, and poured on to a ribbed filter of 10 cm. diameter. 42 grams of the filtrate is mixed with 2 c.c. of dilute ammonia (17 grams of concentrated ammonia to 83 grams of water), avoiding shaking, and the mixture is immediately poured through a ribbed filter. 36 grams of this filtrate is then mixed, in an accurately weighed flask, with 10 grams of ethyl acetate and 4 grams of the above dilute ammonia, and, after corking the flask, it is shaken vigorously for 10 minutes. Another 10 grams of the ether is added, and the ethereal layer is poured off as closely as possible; this is repeated a second time. The liquid is then poured through a plain, 8 cm. filter, and flask and filter are twice rinsed with 5 grams of water saturated with acetic ether. After thorough draining and

drying at 100°, the contents of the filter are added to those of the flask, and the drying is completed. M. J. S.

Estimation of Colchicine in Colchicum Seeds. By KREML (*Zeit. anal. Chem.*, 29, 727; from *Pharm. Post*, 20, 38).—20 grams of the seeds is extracted in a percolation apparatus with 90 per cent. alcohol. The tincture is mixed with 25 c.c. of water and evaporated on the water-bath. The aqueous residue is filtered, and then four times shaken with 10—15 c.c. of chloroform. The residue from evaporating the chloroform is dissolved in water, filtered, and again extracted with chloroform. The residue from the second chloroform solution is heated on the water-bath with a few c.c. of water to decompose a compound of colchicine with chloroform, then evaporated, and finally dried over sulphuric acid to a constant weight. M. J. S.

Examination of Brewers' Pitch. By Z. v. MILKOWSKI (*Zeit. anal. Chem.*, 29, 570—576).—About a gram of the pitch is hydrolysed with alcoholic potash, evaporated to dryness, and taken up with water. The solution is treated with ether for the removal of neutral resins, which are dried and weighed. The soap is now treated with dilute hydrochloric acid, whereupon resin and fatty acids are precipitated. The precipitate is dissolved in ether, and the ethereal solution washed with water, then evaporated and dried at 100°. The residue is dissolved in 15—20 c.c. of alcohol, treated with excess of potash, evaporated to about 5 c.c., diluted with water, and precipitated with silver nitrate. The silver precipitate is either dried and then extracted in a Soxhlet's apparatus with ether, or the extraction may be performed with the precipitate still suspended in the aqueous liquid. Resin, with traces of silver salts, pass into the ether solution. The silver is removed by hydrochloric acid and the filtered ethereal solution evaporated for the resin. The undissolved silver salt is decomposed by acid, and the liberated fatty acids dissolved in ether, and weighed after evaporation. Special apparatus, modified from that of Schwarz (*Zeit. anal. Chem.*, 23, 368), for the extraction with ether, is figured. The average composition of the pitch is:—Neutral resin, 11.52; resin, 74.86; and fatty oil, 13.42 per cent.

M. J. S.

Estimation of Urea. By S. H. SMITH (*Pharm. J. Trans.* [3], 21, 294).—For the estimation of urea, exactly 5 c.c. of the urine is introduced into an Allen's nitrometer which has been filled with a strong solution of common salt. About 8 c.c. of solution of sodium hypobromite is then added. The latter is to be freshly prepared by adding 1 c.c. of bromine for every 10 c.c. of a stock solution in which 200 grams of sodium hydroxide is dissolved in 500 c.c. of water. Each c.c. of nitrogen evolved from 5 c.c. of urine represents 0.0539 per cent. of urea.

General and Physical Chemistry.

Measurement of Refractive Indices at High Temperatures by means of the Total Reflectometer. By J. W. БРЮНН (*Ber.*, 24, 286—296).—A description of a method of measuring refractive indices at high temperatures by the aid of Pulfrich's refractometer.

H. C.

Explanation of Optical Activity. By A. ФОК (*Ber.*, 24, 101—111).—Landolt divides optically active substances into three classes: those which rotate polarised light only when in the crystalline form; those which rotate it only in solution or when fused, that is to say, in the amorphous state, and, lastly, those which in both conditions show optical activity. Only one substance, strychnine sulphate, has hitherto been discovered belonging to the last class. The optical activity of crystals is generally explained by assuming for these a screw-shaped structure: that of liquids is referred to the nature of the chemical molecule and, more particularly, to the presence of an asymmetrical carbon atom.

The author does not regard the explanation of the optical activity of crystals usually given as satisfactory. It is not probable, and is not consistent with what is known of the symmetry of crystals. That the laws of circular polarisation are the same for both the crystalline and amorphous states, would also lead to the conclusion that the same explanation would hold in both cases. A key to this explanation may be sought in the fact that substances which are optically active when amorphous, crystallise in hemihedral forms. According to Schncke, hemihedrism may be explained by assuming a certain polarity in the molecules building up the crystal. The author shows, reasoning from the fact that the molecule of an optically active substance contains an asymmetrical carbon atom, that circular polarisation may be explained by assuming that the axis of polarity of the molecule coincides with its axis of rotation and with the direction which offers greatest and least resistance, according to the orientation of the molecule, to the passage of a ray of light.

H. C.

Relation between Electrical and Chemical Energy in Galvanic Cells. By E. ЛЕВАЙ (*Ann. Phys. Chem.* [2], 47, 103—114).—The object of these experiments was to determine for certain galvanic cells the heat generated chemically and the heat equivalent of the current, and to obtain an exact measure of the difference between the two. The heat evolved in the cell was determined calorimetrically, and that of the circuit was determined in like manner by means of a silver voltameter placed within the calorimeter along with the cell. Two cells were examined, the Daniell and the De la Rue, three determinations being made with each. With the Daniell, the heat equivalent of the current is greater than that generated chemically,

so that the cell works with absorption of heat. The reverse is true of the De la Rue cell; but in this case the relative amount of electrical energy increases with the concentration of the solution in the cell. The results are compared with those formerly obtained by Jahn, with which they show a close agreement. H. C.

Variations of Electromotive Force of Cells of Certain Metals, Platinum, and Nitric Acid. By G. J. BURCH and V. H. VELLY (*Proc. Roy. Soc.*, 48, 460).—When copper, silver, bismuth, and mercury are introduced into purified nitric acid of different degrees of concentration, and a couple made with platinum, the E.M.F. of the cell increases considerably until it reaches a constant, mostly maximum, value. The rise of E.M.F. is attributed to the production of nitrous acid by the decomposition of the nitric acid, and the final value is considered to be due to the former alone, although any impurity affects the result to a remarkable degree. If nitrous acid has been previously added to the nitric acid, the maximum E.M.F. is reached at once.

If the conditions favour a more rapid solution of the metal, and, consequently, a more rapid production of nitrous acid, then the rise of E.M.F. is concomitantly more rapid. If any substance is added which would tend to destroy the nitrous acid as fast as it might be formed (for example, carbamide), then the rise of E.M.F. is extremely slow.

J. W.

Electromotive Force of Galvanic Elements. By A. OBERBECK and J. EDLER (*Ann. Phys. Chem.* [2], 42, 209—226).—After giving a short account of the theoretical investigations on the E.M.F. of voltaic combinations, the authors proceed to describe their own experiments on non-reversible elements. They measured the E.M.F. of amalgams of zinc, cadmium, tin, lead, and bismuth against pure mercury in different salt solutions, using the compensation method and a mirror galvanometer. The amalgams, which, as far as polarisation is concerned, behave like the metals themselves, were prepared electrolytically, except in the case of bismuth.

From experiments with numerous solutions of sulphates, chlorides, bromides, iodides, &c., it appeared that the E.M.F., besides depending on the two metals which form the electrodes, is also dependent on the negative component of the salt solution: the metal of the salt only exerts an influence when it is the same as one of the electrodes, in which case the E.M.F. is diminished.

When the metals are arranged according to the magnitude of the E.M.F., they always follow each other in the same order (that, namely, in which they are given above), no matter what the salt or acid solution may be. In alkaline solution, the values for lead and tin are abnormally high. The authors finally indicate a connection between the E.M.F. and the heat of formation of certain salt solutions as determined by Thomsen.

J. W.

Chemistry of the Accumulator. By M. CANTOR (*Monatsh.*, 9, 433—451).—The charging and discharging of a secondary cell are accompanied by a chemical change in the electrodes and the electro-

lyte, and by an evolution of gas. In order to ascertain what chemical changes take place, it would be necessary to analyse the electrodes and electrolyte both before and after charging, and to collect and examine the gases given off. The latter, which consist of oxygen and hydrogen, would only require collecting separately and measuring. The change in the electrolyte is also readily ascertained, but that of the electrodes presents some difficulty. It may, however, be determined indirectly by charging each plate of the cell separately, using as the second pole an electrode the chemical composition of which remains unaffected. In such a combination, the change in the electrolyte is due solely to the reaction which takes place between it and the electrode and to the gas evolved. The change in the composition of the electrolyte can be determined, as also the gas evolved, and from these data the change which has taken place in the electrode is ascertained.

Applying this principle to the study of the changes that take place in the negative plate of a secondary cell, consisting of lead coated with a mixture of lead oxide and sulphate, the plate is so arranged that it forms the cathode, whilst platinum forms the anode, in a solution of sulphuric acid which is being submitted to electrolysis. Examination and measurement of the gas evolved and a determination of the change in the electrolyte gave rise to the following results:—The lead oxide contained in the plate is first converted into sulphate. The hydrogen, which is formed electrolytically, reduces the lead sulphate with the formation of sulphuric acid and metallic lead. The freshly reduced lead decomposes the sulphuric acid with evolution of hydrogen and the formation of lead sulphate. These two reciprocal processes continue until a condition of equilibrium is reached, when the cell is charged. It is to the local action, between freshly reduced lead and sulphuric acid, that those phenomena are due which led Streintz (*Abstr.*, 1890, 315) and others to conclude that lead in accumulators has the power of occluding hydrogen, which, however, is not the case.

H. C.

Electrical Resistance of Bismuth. By G. H. ZAHN (*Ann Phys. Chem.* [2], 42, 351—352).—The author confirms Lenard's observation that the electrical resistance of metallic bismuth is slightly less (about 0.12 per cent.) when measured with an alternating current than with a constant current.

J. W.

Conduction of Electricity by the Vapours of Heated Salts. By S. ARRIENIUS (*Ann Phys. Chem.* [2], 47, 18—76).—The spray from different salt solutions was introduced through the air holes of a Bunsen burner into the flame, and the alteration in the resistance between two platinum plates placed in the flame caused by the introduction of the salt was observed. From careful estimations, the proportional amount of the salt vapour present in the hot gases, or what the author terms the dilution of the salt vapour, could in each case be determined.

Salts of the alkali metals were first examined. It was found that the salts of each metal had a conductivity which was quite inde-

pendent of the nature of the negative radicle, salts of one and the same metal having all approximately the same conductivity for equal degrees of dilution. This law holds more particularly when the dilution is large, the individuality of each salt being somewhat more marked when present in a concentrated state, especially in the case of the sodium salts. As far as there is any difference among the haloïd salts, the iodides conduct better than the bromides, and the bromides better than the chlorides. The greater the atomic weight of the metal, the better do its salts conduct. The conductivity changes with the dilution so that it is always proportional to the square root of the concentration, except in the case of great dilutions when the increase in conductivity is somewhat greater, and for very small dilutions when the increase is somewhat less than that calculated from the square root of the concentration. The conductivity of hydrogen and ammonium salts is practically *nil*.

Whereas in the case of the alkali metals the flame immediately takes the conductivity characteristic of the salt introduced, this is not the case with salts of the metals of the alkaline earths; as on introducing one of these into the flame, the conductivity increases slowly until it reaches a maximum. The effect of the salt on the conductivity also does not immediately disappear when the supply of salt to the flame is stopped, but its influence remains perceptible for many hours, and can in fact only be finally removed by washing the electrodes in hydrochloric acid. The latter seem to become coated with the oxide or sulphide of the metal (hydrogen sulphide being sometimes given off on washing the plates in acid), and the presence of these as solid particles in the flame serves to bring about a conductivity perfectly independent of that of the salts themselves. For this reason, regularities similar to those noticed in the case of the salts of the alkali metals cannot be observed. It is found, however, that a maximum conductivity is reached most rapidly, the higher the atomic weight of the metal and the more concentrated the salt. The conductivity also seemingly increases with the atomic weight.

The salts of a large number of other metals were examined, but of these only silver and lead nitrates were found to have an appreciable conductivity in the Bunsen flame. Experiments with mixtures of potassium and sodium sulphates and chlorides led to the interesting result that the mixed salts behave as electrolytes having a common ion. Hence it was possible to calculate, within the limits of experimental error, the conductivities of such mixtures from those of the salts composing them, in accordance with the principles laid down by the author (*Abstr.*, 1890, 437).

It would seem that the conductivity of salt vapours in the Bunsen flame may be of two kinds, firstly, that of the solid particles which may be formed by decomposition of the salt; and, secondly, that due to the salt itself. The latter the author regards as being electrolytic in its nature. The conductivity takes place in accordance with Ohm's law for an E.M.F. not greater than 0.2 volt, but above this E.M.F. Ohm's law no longer holds. The fact that the salts of any alkali metal all have the same conductivity is readily explained if it is assumed that the salts at the temperature of the flame, about 1200°, undergo dis-

sociation. In the presence of the large amount of water vapour which the flame contains, the metal would then be converted into hydroxide and the acid set free. Since the latter has no conductivity, the former alone would in all cases be active, and hence the conductivity of the salts of any alkali metal would always be the same, namely that of the hydroxide. The author discusses the change of conductivity with concentration, regarding the conductivity as electrolytic, and applying those laws which have already been established for aqueous solutions. The agreement between the theoretical deductions and the experimental results he considers establishes the correctness of his assumption, and also of those gaseous laws which have been derived from the study of dilute solutions. H. C.

Conductivity of Isomeric Organic Acids and their Salts. By W. OSTWALD and by D. BERTHELOT (*Compt. rend.*, **112**, 229—231).—Ostwald claims priority in the determination of the electrical conductivities of isomeric acids, and in the discovery of the fact that tartaric acid and racemic acid have the same conductivities, which he regards as proof of the complete dissociation of the latter in dilute solution.

D. Berthelot replies that the application of measurements of electrical conductivity to the study of chemical problems is mainly due to Kohlrausch, Bouty, and Fousserau; that his method (this vol., p. 375) is different from that used by Ostwald; and that he has investigated the behaviour of mixtures, whilst Ostwald confined himself to the study of single electrolytes. The dissociation of racemic acid in solution had already been established by the thermochemical measurements of Berthelot and Jungfleisch. C. H. B.

Electrical Behaviour of Precipitated Membranes. By A. OBERBECK (*Ann. Phys. Chem.* [2], **42**, 193—208).—Two tubes closed at the bottom with parchment paper were filled with solution of zinc or copper salt, and immersed in a beaker containing a salt solution of such nature as to give a precipitate with either the metal or the acid radicle of the first salt. The precipitate is formed within the parchment paper, and exhibits electrical properties comparable to those of a metallic plate in the same position (compare Ostwald, *Abstr.*, 1890, 1354; Tammann, this vol., p. 140). The object of the author was to measure the polarisation caused by the introduction of such membranes into an electrolytic circuit. For this purpose, he introduced into the two tubes, as electrodes, rods of amalgamated zinc when a zinc salt was employed, and of copper when a copper salt was used. These electrodes are practically unpolarisable by the primary current, so that any polarisation observed must have its seat in the precipitated membranes. When the polarisation of these was measured separately, it was found only at that membrane where the precipitate was thickened by the action of the current. For instance, with copper sulphate in the two tubes and potassium ferrocyanide in the beaker, the ion FeC_6N_6 travels to the tube containing the anode, and consequently strengthens the membrane by meeting the copper ion there; the potassium ion, on the other hand, meets the

ion SO_4 in the membrane at the cathode, and no precipitate is formed. Such a membrane, then, as copper ferrocyanide the author calls an anodic membrane; the lead sulphate formed at the tube containing the negative electrode when the beaker is filled with a solution of a lead salt he calls a cathodic membrane.

Copper salts with potassium ferrocyanide, or ferricyanide, give an E.M.F. of polarisation rising to a maximum of about 1 volt. The primary current becomes much weaker as it flows, owing to the thickening of the membrane and the increasing resistance. Porous clay cells in place of the parchment paper offer much less resistance, so that the E.M.F. of polarisation with them is greater, corresponding with the increased current density. Zinc salts give a polarisation only about half that of copper salts. The polarisation here depends on the cation.

With lead solution in the beaker, the polarisation is as much as 2 volts. Spongy lead separates at the cathodic membrane, and the current increases, probably in consequence of this. The E.M.F. of calcium, strontium, and barium chloride against zinc sulphate is equal to 0.08, 0.39, and 0.73 volt respectively. Silver nitrate gives a polarisation of -0.26 volt against copper sulphate, and -0.24 volt against zinc sulphate.

The author finds no characteristic difference between permeable and impermeable membranes when long continued currents are employed. The opposite result found by Laumann he considers as due to the rapidly alternating currents used by the latter. J. W.

Relation between Atomic Weight and Magnetism. By L. ERRERA (*Ber.*, 24, 88—89).—The author maintains the impossibility in the present state of our knowledge of the subject of establishing any more definite relation between the magnetism and the atomic weights of the elements than that which he has formerly pointed out, namely, that the elements in the odd series in Mendeléeff's table are diamagnetic, and those in the even series paramagnetic. He criticises a paper by Bachmetieff (*J. Russ. Chem. Soc.*, 21, 39) dealing with this question, in which he points out several errors. II. C.

Thermal Dilatation of Liquid Bismuth near its Melting Point. By G. VICENTINI (*Rend. Acad. Lincei*, 6, ii, 121—125 and 147—152).—The following constants were previously obtained by the author, using large dilatometers (*Atti Real. Acad. Torino*, 22 and 23):—Sp. gr. of bismuth at $0^\circ/4^\circ = 9.787$; m. p. = 271° ; sp. gr. of solid bismuth at its melting point = 9.673; sp. gr. of molten bismuth at the melting point = 10.004; decrease in density on passing from the liquid to the solid state = 3.31 per cent.; mean coefficient of dilatation between its m. p. and $300^\circ = 0.000120$. From his observations, the author also concluded that liquid bismuth has its maximum density at its melting point. Lüdeking (*Abstr.*, 1888, 790), using small thermometers with capillary stems as dilatometers, found a different set of constants, and attributed the discrepancies to the presence of air in the author's large dilatometers. This is now denied by the author, who declares that Lüdeking's results are untrust-

worthy, on account of the uncertainty in the indications of the variation of the volume of the metal in the bulb, as shown by the column of bismuth in the capillary stem at temperatures close to the solidifying point, more especially as Lüdeking's use of a mercury-bath involved the exposure of a portion of the stem, which would, consequently, be at a slightly lower temperature than the bulb. The author found it necessary to adopt special precautions to secure the proportionate movement of the bismuth columns in his wide tubes, even when entirely immersed in a paraffin-bath. The slight expansion of the metal just before solidification from which Lüdeking inferred the existence of a point of maximum density, really takes place at a temperature at which, if maintained constant, bismuth slowly solidifies, and is due to a partial solidification. Lüdeking's metal, it is also stated, was contaminated with mercury.

The author has now made a series of experiments by the hydrostatic method, using a bath of purified petroleum residues, and cylindrical glass vessels containing 9 to 12 c.c. of bismuth. The results obtained confirm those of the previous experiments, and show that within the limits of sensibility of the apparatus, about 1/110,000, the volume of liquid bismuth gradually decreases when cooled from 281° to its melting point (271·5°) and even a little below (270°). The sp. gr. of liquid bismuth at its melting point is now found to be 10·064, the increase in volume in passing from the liquid to the solid state 3·39 per cent., and the mean coefficient of dilatation between its melting point and 280° 0·000306. S. B. A. A.

Determinations of the Heat of Capacity and Heat of Fusion of some Substances to Test the Validity of Person's Absolute Zero. By S. U. PICKERING (*Proc. Roy. Soc.*, 49, 11).—Person made determinations with eight substances to show that the temperature at which their heat of fusion became $n\bar{l}$, $t - \frac{l}{C - c}$ (t = temperature of fusion, l = heat of fusion at t° , C = heat capacity of liquid, c = heat capacity of solid), was -160° in all cases. This he called the absolute zero. His conclusions may for several reasons be questioned, the chief reason being that he determined C and c at any temperature which happened to be most convenient, and the value of these is largely dependent on temperature; they should both refer to the same temperature, and this is necessarily t° . The author deduces this value for C and c at t° from the determinations made at a series of different temperatures. The substances examined were, sulphuric acid and its monohydrate, hydrated calcium nitrate, and naphthalene, and their temperatures of no crystallisation were found to be -369° , -177° , -234° , and -214° respectively, thus refuting Person's conclusion. Water gives -167° when the values for C and c at 0° are taken. Benzene was also examined, but the heat capacity of the solid was found to be greater than that of the liquid. This is probably due to an incipient fusion occurring below the temperature of true fusion.

The following are the values given for C , c , and l per gram at the respective fusing points, t :—

	O.	a.	l.	t.
H ₂ SO ₄	0.3355	0.2721	24.031	10.352°
H ₂ SO ₄ , H ₂ O	0.4430	0.2273	39.918	8.53°
Ca(NO ₃) ₂ , 4H ₂ O ..	0.5185	0.3973	33.493	42.4°
C ₁₀ H ₈	0.4824	0.3612	35.625	79.86°
C ₆ H ₆	0.3957	0.4600	29.433	5.41°
H ₂ O	1.0	0.5243	79.25	0.0°

S. U. P.

Use of the Calorimetric Bomb for the Determination of the Heat of Combustion of Coal. By SCHEURER-KESTNER (*Compt. rend.*, 112, 233—236).—Berthelot's calorimetric bomb answers well for the determination of the heat of combustion of coal, but for accurate estimation, it is necessary to determine the percentage of sulphur in order to make the necessary correction after determining the acidity of the products. For practical purposes, this last correction may be omitted, since the heat of conversion of the nitrogen into nitric acid is practically the same as the heat of combustion of the carbon; and sulphur increases the heat of combustion in the furnace as well as in the bomb. The difficulty of determining the amount of ash is obviated by converting the powdered coal into pastilles as recommended by Berthelot. The results obtained are lower than those obtained 20 years ago by the author and Meunier Dollfus, a result partly due to a better knowledge of the corrections required, and they are also lower than those obtained with Favre and Silbermann's calorimeter. The corrected determinations reduce the number of coals with heats of combustion higher than those calculated from their elementary composition, and it is possible that coals exist with heats of combustion actually lower than those calculated by Dulong's formula.

C. H. B.

Dalton's Law. By M. MARGULES (*Ann. Phys. Chem.* [2], 42, 348—350).—The author draws attention to the difference between the results calculated by him (*Wiener Ber.*, 98, 893) and by Galitzine (this vol., p. 378) for the pressure of compressed gases, and attributes them to the employment by the latter of an unsatisfactory formula given by Sarrau (*Abstr.*, 1882, 686) for nitrogen.

J. W.

Determination of the Specific Gravity of Viscid Substances. By J. W. BRÜHL (*Ber.*, 24, 182—183).—The apparatus consists of a graduated flask; the neck is 2 mm. in diameter, and has a side tube at the upper end. A quantity of the substance under examination is first introduced into a pipette by the help of an air pump, the delivery tube of the pipette, which is long enough to reach to the bottom of the flask, is inserted in the neck of the flask, the connection between the neck of the flask and the pipette being made air-tight with a small piece of rubber tubing; on exhausting the flask by means of the side tube, the liquid flows out of the pipette. A flask with a capacity of 10 c.c. gives results which are stated to be accurate to four places of decimals.

J. B. T.

Determination of the Specific Gravity of Viscid Substances. By C. SCHIEBLER (*Ber.*, 24, 357—358).—J. W. Brühl has described a method of determining the specific gravities of viscid

substances (preceding abstract). The author draws attention to the fact that 12 years ago he described a method for determining the specific gravity of beet-molasses which is simpler and more accurate than that of Brühl, and is applicable to all liquids.

A pipette is used closed at both ends with glass taps, to which glass tubes are fitted by grinding. The capacity is determined once for all for a certain temperature; the pipette is then filled by sucking up the liquid whose specific weight is required, the bottom tap shut, the tube attached to it removed, and the whole put into a beaker containing water at the required temperature. The top tap is then closed, its tube removed, the outside of the apparatus wiped clean and dried, and the apparatus weighed. The advantages of the method are that it is applicable to all liquid substances, that the specific gravity can be determined at any required temperature, and that any convenient size of apparatus can be employed.

E. C. R.

Hypothesis of Electrolytic Dissociation. By S. ARRHENIUS (*Ber.*, 24, 224—231).—A reply to the criticisms of Traube (this vol., p. 255). According to the dissociation hypothesis, a salt in aqueous solution is dissociated into its ions, these latter being charged positively and negatively respectively. In any homogeneous solution, the ions exist perfectly free side by side, and owing to their freedom of motion they so intermingle that the homogeneity of the solution is never disturbed. But if the solution is not homogeneous, and varies in concentration, diffusion of the salt will take place from the more concentrated to the less concentrated portion. Since one of the ions will move more rapidly than the other, a larger number of these ions will pass into the less concentrated portion of the solution than of the others. This will cause this portion of the solution to take the charge of these ions, and the other portion that of those remaining. A certain tension will thus after a time be established, and a state of equilibrium result in which equal diffusion of both ions may be said to take place in unit of time. Electrolytic dissociation differs, therefore, from ordinary dissociation, as Traube asserts; but in the case of homogeneous solutions, both kinds of dissociation exhibit the same properties.

The dissociation hypothesis does not demand that *all* properties of dilute solutions shall be of additive nature. In cases, however, in which additive properties in solution may be predicted, these have always been found. This is illustrated by the specific conductivity and specific resistance of water. The first should, according to the hypothesis, be proportional to the amount of the dissolved salt, and this is found to be the case; for the second, the hypothesis makes no such prediction, and in practice it is not found to be the case. That the colour of any particular ion in solution should be the same is correct, but in the instances given by Traube, the ions are in every case different.

That the dissociation hypothesis stands altogether in contradiction to the hydrate theory, the author denies, having himself pointed out the possibility of the existence of molecular aggregates in concentrated solutions. The hydrate theory has, however, altogether failed

to give any explanation of the properties of dilute solution, to which the dissociation hypothesis has been so successfully applied, and even in other cases there is disagreement between the supporters of the hydrate theory themselves (see Pickering, *Abstr.*, 1890, 857).

Ostwald's application of the gaseous laws to electrolytic dissociation has led to the establishment of a formula which has been successfully tested in the case of a large number of acids. Exceptions have been found to the formula, but sufficient data do not exist at present to serve for the discussion of these. That heat is developed in some cases of electrolytic dissociation finds a parallel in the case of the development of heat attending the formation of oxygen (3 mols.) from ozone (2 mols.).

The author also points out that some of the statements made by Traube are erroneous, and that in calculating the values of i from the freezing point determinations and electrical conductivity, precautions were taken to make the numbers obtained from each strictly comparable.

H. C.

Nature of Osmotic Pressure. By R. NASINI (*Rend. Acad. Lincei*, 6, i, 175—182).—In this paper, Pfeffer's experiments, and the extent to which they may be considered as the experimental basis of Van't Hoff's formula $PV = Rf$, are discussed at great length. The author arrives at the conclusion that the results obtained with the cells hitherto constructed afford but little support to the theory, the expression of which in the form of Van't Hoff's formula he regards as a convenient method of implicitly assuming the identity of matter in the state of a gas and of a dilute solution, without premising conditions of temperature and pressure at which the existence of a solution might be impossible. This assumption, which has been explicitly made by Planck (*Abstr.*, 1888, 895) and by J. J. Thomson, may rather be regarded as having a measure of physical explanation in the osmotic phenomena hitherto observed.

S. B. A. A.

Velocity of Decomposition of Nitrous Acid in Aqueous Solution. By C. MONTEMARTINI (*Rend. Acad. Lincei*, 6, i, 263—270).—The solutions obtained by decomposing solutions of silver nitrite with dilute hydrochloric acid were allowed to remain, and the free nitrous acid determined at intervals by titration with potassium permanganate. The rate of decomposition may, in general, be represented by the formula $-dC/dT = kC$, or $k = 1/T \log C_0/C$ (T being the time in hours and C the concentration in grams per 100 c.c. of solution). k is, however, only constant between certain limits of concentration, and varies with the temperature. The decomposition of nitrous acid in solution is a true dissociation phenomenon which may be represented by the equation $3\text{HNO}_2 = 2\text{NO} + \text{HNO}_3 + \text{H}_2\text{O}$, and it accordingly depends on the vapour tension of the nitric oxide evolved. When the action is allowed to proceed in a current of carbonic anhydride, the theoretical amount of nitric acid is always found in the solution; in presence of air, however, the nitrogen tetroxide formed partially redissolves and increases the amount of nitric acid. The reaction may, to a certain extent, be reversed by passing a current of nitric oxide into a solution of 4 grams of nitric acid in

200 c.c. of water for about an hour, the experiment being performed in an atmosphere of carbonic anhydride, and a current of carbonic anhydride finally passed through the solution to remove any dissolved nitric oxide; the nitric acid was found to contain 0.1139 gram of nitrous acid. Solutions of nitrous acid allowed to remain in sealed tubes cease to decompose as soon as the vapour tension of the evolved nitric oxide is sufficiently great. Solutions of silver or potassium nitrite remain practically unaltered after two months' exposure to diffused light. S. B. A. A.

Unit of Atomic Weights. By W. A. NOYES (*Ber.*, 24, 238—240).—The author points out that the determinations of the combining ratio of oxygen and hydrogen which have been carried out within the last twenty years have, with one exception, all given numbers for the atomic weight of oxygen which are less than 15.90. If 15.89 be accepted as the most probable number for the atomic weight of oxygen, and the other atomic weights are calculated on this basis, the majority of the elements, particularly of the more common elements, will be found to have atomic weights which differ very largely from whole numbers. If, on the other hand, the atomic weight of oxygen is fixed as 16 (Brauner, *Abstr.*, 1889, 335) only six elements, Na, S, K, Ag, I, and Pt, are found to have atomic weights which differ from whole numbers (half numbers in the case of Cl, Cr, and Sr) by a larger amount than the possible error in the atomic weight itself. In this case, the atomic weight of hydrogen would be 1.007, but for all ordinary work the error introduced by employing unity in place of this number is so small that it may be neglected. The advantages of fixing $O = 16$ as the basis for the atomic weights of the other elements are, therefore, so obvious that the author urges its acceptance by chemists generally. H. C.

Mordants and the Periodic Law. By PRUD'HOMME (*Compt. rend.*, 112, 236—239).—In each group of the periodic system, taking the odd and even series, there is a continuous variation in the shade of colour produced, from blue to red or red to blue, as, for example, with magnesium, zinc, and cadmium, or with calcium, strontium, and barium. Boisbaudran has shown that in groups of elements such as these or potassium, rubidium, and cesium, the wave-lengths of corresponding lines in the spectra are proportional to the molecular weight. It would seem, therefore, that metallic oxides communicate to their combinations with colouring matters vibrations which are proportional to those of the elements which they contain. In each period, from the first to the fourth group, there is progression from blue to red; in the fifth to the eighth group the progression is from red to blue. Group 4 does not form a real maximum, since the shades of colour in this group have an excess of yellow. The orange term does not belong to Group 4, but is represented in Group 5 by vanadium. Tin, the atomic weight of which is nearly half that of uranium, represents in an especial manner yellow and orange shades. It is noteworthy that the colours of "lakes" often show progression the reverse of that obtained with the same oxides on the fabrics. The influence of

the bases is perceptible in the behaviour of many salts; and the influence of the haloids is well seen in the derivatives of fluorescein.

C. H. B.

Modification of the Sprengel Pump. By G. GUGLIELMO (*Rend. Acad. Lincei*, 6, ii, 153—155).—From the top of the Sprengel air chamber, a short tube provided with a stop-cock leads upwards into a glass globe, to the top of which a large cup or funnel is attached by a short stoppered neck. The branch tube connected with the receiver is soldered low down in the side of the air chamber and bent vertically upwards. The upper part of the fall tube is also fitted with a stop-cock. The cup and globe are filled with mercury, the stopper replaced in the cup, and all the stop-cocks opened until a moderate degree of exhaustion is reached. A good vacuum is thus formed in the globe, which effectually deaerates the mercury which is allowed to enter the globe from time to time by raising the stopper; moreover, any risk of access of air into the chamber is avoided. The pressure of the residual gas in the air chamber may be found by closing the stop-cock in the fall tube and allowing the mercury to rise in the branch tube until the volume of the gas in the air chamber is reduced to one-hundredth part of its previous volume, and then observing the difference between the levels of the mercury in the chamber and branch tube.

Inorganic Chemistry.

Hydrogen Nitride (Azoimide). By T. CURTIUS and R. RADENHAUSEN (*J. pr. Chem.* [2], 43, 207—208; compare this vol., p. 56).—Pure hydrogen nitride is obtained by fractionally distilling the aqueous solution, the preparation of which has been already described; the first portion of the distillate is again fractionated, until, after four repetitions of the process, an acid distils over at 45°; this contains 91 per cent. of hydrogen nitride, but the composition of the distillation does not correspond with that of a definite hydrate. The complete dehydration is effected by fused calcium chloride.

Hydrogen nitride is a clear, colourless, mobile liquid; it boils without decomposition at 37°, dissolves in water and alcohol, and has the same odour as its aqueous solution (*loc. cit.*), in a more marked degree. It explodes in contact with a hot substance, and sometimes even at the temperature of the room, with a blue flash. Researches on its electric conductivity by Ostwald lead to the conclusion that it is a somewhat stronger acid than acetic acid. Attempts to determine its vapour density were frustrated by its instability; when 0.05 gram of it was passed into a barometer tube at the ordinary temperature it exploded with such violence that the tube was pulverised and, along with the mercury, scattered in all directions; on another occasion, 0.7 gram of it exploded when the tube containing it was removed from the freezing mixture, shattering all the glass in the neighbourhood and wounding one of the authors of the paper.

Mendeléeff (this vol., p. 394) has suggested that the ammonium salt of this acid would undergo an isomeric change, like ammonium cyanate; the authors have not found this to be the case. *Ammonium nitride* crystallises in large prisms which are unchanged by heating with water or by sublimation; they are not hygroscopic, and gradually evaporate when exposed to the air. A. G. B.

Conditions of Chemical Change between Nitric Acid and Certain Metals. By V. H. VENABLE (*Proc. Roy. Soc.*, 48, 458—459).—Copper, mercury, and bismuth do not dissolve in 30 per cent. nitric acid at 30°, provided that nitrous acid is neither present initially nor formed subsequently. If the conditions are such that these metals dissolve, then the amount of metal dissolved and the amount of nitrous acid present are concomitant variables, provided that the nitric acid is present in considerable excess. Metallic nitrite, it would appear, is first formed, together with nitric oxide; the former is at once decomposed by the nitric acid with liberation of nitrous acid, whilst the latter reduces the nitric acid to form a further quantity of nitrous acid. Nitrous acid is invariably the initial product of reduction of the nitric acid.

Copper, mercury, and bismuth dissolve very readily in a 1 per cent. solution of nitrous acid. Under these conditions, nitric acid present in slight excess interferes with the chemical change instead of promoting it. This result is probably due to the greater stability of nitrons acid in presence of nitric acid.

Hydrogen reduces nitric to nitrous acid in presence of cupric or lead nitrate. It also converts mercuric into mercurous nitrate, but does not produce any change in solutions of bismuth or zinc nitrate dissolved in nitric acid. J. W.

Electro-metallurgy of Aluminium. By A. MINET (*Compt. rend.*, 112, 231—233; compare Abstr., 1890, 532 and 1040, and this vol., p. 152).—The steel crucible is made smaller, and is provided with an internal lining of carbon which serves as the negative electrode. The difference of potential between the two electrodes is 4.55 volts, and the yield 31.9 grams of aluminium per horse power per hour, or 31.3 horse powers per hour for 1 kilo. of aluminium. The author believes that it will be possible to reduce the difference of potential to 4 volts, and under these conditions there will be no electrolysis of the sodium chloride, and the yield will reach 70 per cent. of the theoretical quantity. The loss of 30 per cent. is due to the action of the fused fluorides on the aluminium, and does not occur when aluminium alloys are made, since in this case the electrolytic cell is composed of the other metal, and the liberated aluminium at once combines with it.

C. H. B.

Atomic Weight of Bismuth. By A. CLASSEN (*J. pr. Chem.* [2], 43, 133—138).—A reply to Schneider's criticisms (this vol., p. 271). Schneider's metal must have contained not only lead, but also copper, iron, and other metals. The same must be said of Marignac's metal, for even 16 fractional precipitations as basic bismuth nitrate are not sufficient to eliminate all impurities. Schneider naively points out

that Marignac made each of his seven determinations on equal weights of his bismuth oxide under the same conditions. It is evident that any decomposition of his sulphate at the temperature to which it was exposed would not have been made apparent by these experiments. Bailey (Trans., 1887, 676) has pointed out that bismuth sulphate begins to decompose at 405—418°.

A. G. B.

Auric Sulphide, Au_2S_3 . By U. ANTONY and A. LUCCHESI (*Gazzetta*, 20, 601—607).—Berzelius obtained a substance having the composition Au_2S_3 , by fusing metallic gold with an excess of potassium pentasulphide. The existence of such a compound has, however, been denied by Levol, Schrötter, and latterly by Hoffmann and Krüss (Abstr., 1887, 1019; 1888, 28). As the author's experiments on aurosoauric sulphide (Abstr., 1890, 1216) showed that the action of hydrogen sulphide on gold trichloride largely depends on the temperature of the solution, attempts were made to prepare auric sulphide by the action of hydrogen sulphide at a very low temperature, but without success. On passing, however, a rapid current of perfectly dry hydrogen sulphide through a U-tube containing potassium aurochloride kept at a temperature of -10° until the issuing gas was free from hydrogen chloride, a brown mass was obtained, but on attempting to separate the potassium chloride by treating this product with water at 0° , it underwent complete decomposition, hydrogen sulphide being evolved, gold precipitated, and *sulphuric acid* passing into solution. As neither aurous nor aurosoauric sulphide behaves in this manner, the experiment was repeated with lithium aurochloride, a deliquescent salt forming orange-coloured crystals which contain 2 mols. H_2O after prolonged drying in a current of air at 70° , become anhydrous when similarly treated at 90° , and begin to decompose at 100 — 105° . The perfectly dry hydrated salt was treated with hydrogen sulphide at -10° , the product freed from lithium chloride by extraction with absolute alcohol, and the residue dried in a current of nitrogen at 70° . It consisted of a black, amorphous, graphitic mass of the composition Au_2S_3 , from which no trace of free sulphur could be removed by treatment with carbon bisulphide. It completely decomposes into gold and sulphur when heated to 200 — 205° . Auric sulphide may likewise be prepared by decomposing the dry *anhydrous* lithium aurochloride with hydrogen sulphide at the ordinary temperature. Its properties and reactions are at present under investigation.

S. B. A. A.

Mineralogical Chemistry.

Native Nickel in River Sand near Biella (Piedmont). By A. SELLA (*Compt. rend.*, 112, 171—173).—The sand of the torrent Elvo, near Biella, contains grains which closely resemble metallic platinum, some being silvery or yellowish-white, whilst others have a steel-grey colour. They contain Fe, 26.6; Ni, 75.2 = 101.8, and

agree somewhat closely in composition with the alloy Ni,Fe. The grains are in all probability of terrestrial origin. C. H. B.

Brookite from Beura (Ossola). By G. STRUEVER (*Rend. Acad. Lincei*, 6, i, 77—79).—The author has discovered crystals of brookite, a mineral not hitherto found in Italy, in the gneiss caves of Beura, in the district of Ossola. It occurs among lamellar crystals of calcite in blackish plates with a bright, adamantine lustre, and is accompanied by needles of dark tourmaline and scales of chlorite. The tabular faces (100) are covered with vertical striæ, owing to their alternate combination with faces of vertical prisms. The crystals are 2 mm long, 1.5 mm. broad, and 0.25 mm. thick; they are generally opaque, but contain translucent patches which transmit dark-green light. The crystallographic measurements agree with those already given, but no chemical analysis has been made. S. B. A. A.

Rhodochrosite from Franklin Furnace, New Jersey. By P. E. BROWNING (*Amer. J. Sci.*, 40, 375—376).—The specimen of rhodochrosite, an analysis of which is given by the author, has a massive, cleavable structure and a bright-pink colour. Franklinite and willemite are immediately associated with it. The sp. gr. is 3.47, and the analytical results obtained were as follows:—

MnO.	CaO.	ZnO.	MgO.	FeO.	Fe ₂ O ₃ .	SiO ₂ .	CO ₂ .	Total.
45.02	11.28	2.32	1.76	0.22	0.16	0.32	38.94	100.02

B. H. B.

Kreitonite from Bodenmais. By OEBBEKE (*Jahrb. f. Min.*, 1891, i, Ref. 17).—The author found that on applying the magnet to the powder of the kreitonite of Silberberg, a green substance and a black one, magnetite, were obtained. The former gave on analysis:—

Al ₂ O ₃ .	Fe ₂ O ₃ .	FeO.	MgO.	ZnO.	Total.
48.40	7.47	14.79	2.64	27.40	100.70

B. H. B.

Occurrence of Nitrogen in Uraninite. By W. F. HILLBRAND (*Amer. J. Sci.*, 40, 384—394).—The author has found that nitrogen exists in uraninite in quantities up to over 2.5 per cent., and seems generally to bear a relation to the amount of uranium oxide present. This is the first discovery of nitrogen in the primitive crust of the earth. The condition in which the nitrogen exists is unknown; but it is entirely different from any hitherto observed in the mineral kingdom.

In studying the composition of uraninite in general, the author finds by analysis that this mineral from various localities varies widely in composition, and that its physical characteristics and its behaviour towards certain solvents are often as distinct as the chemical differences. The formulæ given by Comstock and by Blomstrand are inapplicable to the zirconia, thoria, and yttria uranites of North America and Norway. The author gives the results of analyses of

11 varieties of uraninite from North America and of 7 from Norway, and he proposes to continue the work in his laboratory as soon as opportunity may offer. He hopes that those possessing uraninite specimens will examine them on the lines suggested in his paper (compare Abstr., 1890, 456).
B. H. B.

New Borate from Stassfurt. By L. MILCH and by O. LUEDECKE (*Zeit. Kryst. Min.*, 18, 478—485).—This new borate is described by the two authors working independently. The analytical results they give differ so considerably that further investigation is necessary before the formula can be definitely settled. The interpretation of the crystallography of the mineral is also entirely different in the two papers.

The new borate is found, with pinnoite (Abstr., 1884, 1271), in the kainite beds of Stassfurt, in colourless, transparent, monosymmetrical crystals. The hardness of the mineral is 5, and its sp. gr. 2.127. Analysis gave the following results:—

	B ₂ O ₃ .	H ₂ O.	MgO.	K ₂ O.	Na ₂ O.	Cl.	Total.
I.	52.39	23.83	13.80	8.14	0.39	0.35	98.90
II.	60.53	19.85	12.23	7.39	—	—	100.00

The formulæ deduced from these two analyses are as follows:—

For the new borate, Milch proposes the name of *hintzeite*, after Professor Hintze, of Breslau; whilst Luedecke proposes that of *heintzite*, after Heintz, the discover of pinnoite.
B. H. B.

Apatite, Chlorite, and Mica from Belgian Localities. By C. KLEMENT (*Zeit. Kryst. Min.*, 18, 529—530, from *Bull. Musée Roy. de Belg.*, 5, 159).—1. *Apatite*, from the phosphorite beds of Ciply, occurring in pale, yellowish-green, transparent crystals (sp. gr. 3.226) in calcite, gave on analysis:—

P ₂ O ₅ .	F.	Cl.	CaO.	MgO.	Al ₂ O ₃ .	Fe ₂ O ₃ .
43.49	1.31	0.57	54.49	0.42	1.46	0.33

2. *Chlorite*, from Vielsalm, in thin leaves from quartz veins, with a sp. gr. of 2.835, yielded:—

SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	FeO.	MnO.	MgO.	H ₂ O.	Total.
27.13	24.70	5.84	9.72	1.98	20.52	11.35	99.24

3. *Mica* containing chromium, from Salm-Château, in green or white layers on quartz, gave on analysis:—

SiO ₂ .	Al ₂ O ₃ .	Cr ₂ O ₃ .	Fe ₂ O ₃ .	CaO.	MgO.	K ₂ O.	Na ₂ O.	H ₂ O.	Total.
45.68	34.17	0.84	2.35	0.27	3.84	4.47	2.23	4.65	98.50

B. H. B.

So-called Perovskite from Magnet Cove, Arkansas. By F. W. MAR (*Amer. J. Sci.*, 40, 403—405).—In 1877, Knop showed that the supposed perovskite of the Kaiserstuhl contained, besides titanium, some 23 per cent. of niobium and tantalum, and he accordingly classed it as an independent species under the name of *dysanallyte*. The following analysis of a similar mineral from Magnet Cove, Arkansas, shows that it also is distinct from perovskite, and should be classed with dysanallyte :—

CaO.	MgO.	FeO.	Fe ₂ O ₃ .	(Y,Er,Tr) ₂ O ₃ .	(Ce,La,Di) ₂ O ₃ .
33.22	0.74	0.23	6.16	5.42	0.10
Nb ₂ O ₅ .	Ta ₂ O ₅ .	TiO ₂ .	SiO ₂ .	Total.	Sp. gr.
4.38	5.08	44.12	0.08	99.53	4.18

B. H. B.

Constitution of Natural Silicates. By F. W. CLARKE and E. A. SCHNEIDER (*Amer. J. Sci.*, 40, 303—312, 405—415, 452—457).—In this elaborate paper, the authors show that gaseous and aqueous hydrochloric acid differ widely in their action on magnesian silicates. In this group of minerals, the gaseous acid appears to attack only that part of the magnesium which is present as the univalent group, $\text{Mg}\cdot\text{OH}$. In favour of this view, the authors adduce a large amount of evidence. Olivine, for example, which cannot contain hydroxyl, is almost unattacked by the gas within the range of temperature studied. Serpentine, which must contain MgOH , is attacked proportionally to the excess of oxygen over the orthosilicate ratio. Ripidolite behaves like serpentine, and gives an analogous formula; whilst the micas, which presumably contain little or no hydroxylated magnesia, are but slightly affected. The authors are inclined to believe, on the whole, that MgOH in a silicate has a lower order of stability towards gaseous hydrochloric acid than the compound $\text{Mg}(\text{OH})_2$.

B. H. B.

Eudialyte and Eucolite from Magnet Cove, Arkansas. By J. F. WILLIAMS (*Amer. J. Sci.*, 40, 457—462).—The author gives the results of a crystallographical examination of the rare mineral eudialyte, from Magnet Cove. The crystals are transparent and crimson in colour; they may be divided, according to their form, into two classes: (1) those in which the negative rhombohedra predominate, and (2) those in which the positive ones are the larger. As a rule, the crystals are terminated above and below by hexagonal basal planes. The faces observed are $0R$, $\infty P2$, $+R$, $-\frac{1}{3}R$, $-2R$.

All those crystals which have the form and composition of eudialyte, but negative double refraction, are to be considered eucolite. Yellowish-brown crystals of this kind occurring in the Arkansas rock are to be classed under this head. From the low sp. gr. and hardness, as well as the want of complete transparency in these crystals, it is probable that they consist of decomposed eudialyte.

B. H. B.

Anthophyllite from Franklin, North Carolina. By S. L. PENFIELD (*Amer. J. Sci.*, 40, 394—397).—The material examined

was collected at the Jenks Corundum Mine, Franklin, where it occurs in a pure and well-crystallised condition. The mineral appears never to have been fully identified from any locality in the United States hitherto. It occurs in orthorhombic crystals exhibiting only two forms, the prism and the brachypinacoid. The crystals are very transparent, and have a clove-brown colour. Their hardness is 6, and their sp. gr. 3.093. Analysis yielded the following results:—

SiO ₂	FeO.	MnO.	MgO.	CaO.	H ₂ O.	Al ₂ O ₃ .	Loss at 100°.	Total.
57.98	10.39	0.31	28.69	0.20	1.67	0.63	0.12	99.99*

The formula is RSiO_3 , where R represents Mg, Fe, H₂, and traces of Mn and Ca. B. H. B.

Fowlerite Variety of Rhodonite from New Jersey. By L. V. PIRSSON (*Amer. J. Sci.*, 40, 484—488).—The zinc-bearing rhodonite of Franklin and Stirling, in New Jersey, has been known since 1825 under the name of fowlerite. The crystalline form and physical properties have not hitherto been thoroughly investigated. The mineral occurs embedded in calcite. It is of a rose-pink colour and, in the small and perfect crystals, transparent. The axial ratios and angles measured in the crystallographical examination of this mineral agree very closely with those obtained by Flink (*Abstr.*, 1886, 778) in his determination of the crystalline form of rhodonite from Sweden. It was also found that the two varieties differed in no appreciable degree in optical orientation. Analysis of carefully selected fowlerite gave the following results:—

SiO ₂	FeO.	ZnO.	MnO.	CaO.	MgO.	Total.
46.06	3.63	7.33	34.28	7.04	1.30	99.64

These results give the correct formula for a meta-silicate, RSiO_3 . B. H. B.

Beryllium Minerals from Colorado. By S. L. PENFIELD (*Amer. J. Sci.*, 40, 488—491).—During the past few years, crystals of beryl, bertrandite, and phenacite have been abundantly found associated with one another at Mount Antero, Colorado. They are implanted either on granite or on crystals of the granitic minerals, quartz, and feldspar. The rare minerals bertrandite and phenacite occur in crystals of great beauty, some being of almost ideal symmetry.

B. H. B.

Composition of Mica and Chlorite. By R. SCHLAEFFER (*Jahrb. f. Min.*, 1891, i, Ref. 8—9).—The author has analysed eight minerals of the mica and chlorite group with the following results:—

* By an obvious misprint in the original, this total is stated to be 69.90.

	1.	2.	3.	4.	5.	6.	7.	8.
SiO ₂ ...	30.11	36.18	34.06	17.09	45.05	45.35	33.24	45.38

1, Clinocllore from Chester, Pennsylvania; 2, from Brewster, New York; 3, pennine from Zermatt; 4, valuewite from the Ural; 5, mica from Haddam, Connecticut; 6, from Zinnwald; 7, biotite from Miask; 8, muscovite from Bamle, Norway. B. H. B.

Nepheline-syenite of the Kola Peninsula. By W. RAMSAY (*Jahrb. f. Min.*, 1891, i, Ref., 97—99).—The author gives a detailed account of the geology of the Kola peninsula, and notes the occurrence of an extensive mass of nepheline-syenite between the Lakes of Lujavr and Imaudra. In the composition of this rock, microcline, albite, nepheline, sodalite, natrolite, ægirine, arfvedsonite, ainigmite, as well as five new minerals, take part. The absence of apatite, iron ores, and titanite is noteworthy. Analyses are given of the ægirino (I), and of one of the new minerals (II):—

	SiO ₂ .	Al ₂ O ₃ .	Fe ₂ O ₃ .	FeO.	MnO.	CaO.	MgO.
I. 51.82		0.60	21.02	8.14	1.00	3.01	1.47
II. 55.88		15.19		—	2.67	9.53	0.53
		Na ₂ O.	K ₂ O.	Ignition.	Total.	Sp. gr.	
I. 11.87		0.85	0.50		100.28	3.51	
II. 9.06		1.57	6.04		100.47	2.75	

The latter is isotropic or very slightly birefractive, of a bright red colour, transparent, easily fusible, and soluble with difficulty in acids. B. H. B.

New Meteoric Iron from North Dakota. By O. W. HUNTINGTON (*Proc. Amer. Acad. Sci.*, 25, 229—232).—The meteoric iron described, a specimen of special interest, was found in 1885, during

* The loss on ignition is 4.60, of which 2.48 is water.

the construction of a branch of the Northern Pacific Railroad, about 20 miles south-east of Jamestown, Stutsman Co., North Dakota. It weighs 4015 grams, and is of peculiar shape and appearance, in that it appears to be a thick scale blown off from the spherical surface of a large body. The iron is so malleable that it can be rolled out into thin ribbon in the cold, and it breaks like a soft, semi-solid material. The extreme malleability and peculiar fracture separate this iron from all others hitherto described. The concave side of the specimen is characterised by a vesicular structure not unlike that of certain furnace specimens. These cavities, which are distributed with some regularity in three more or less parallel zones across the shorter dimension of the surface, appear to have no connection with the pittings on the surface, and are different from anything hitherto observed in other meteoric irons. They suggest an evolution of gas from the material in process of cooling. This may have been the cause of the splitting off of the specimen from the original mass. A preliminary analysis of the iron gave the following results:—

Fe.	Ni.	P.	Cu.	Total.
90.24	9.75	0.05	trace	100.04

No trace of sulphur was detected. A point of interest in this iron is that it was found at the bottom of a slanting hole, rendering it probable that it belonged to a comparatively recent fall.

B. H. B.

Meteorite of Ochansk. By J. v. SIEMASCHKO (*Jahrb. f. Min.*, 1891, i, Ref. 47—48; from *Tschermak's Min. Mitth.*, 11, 87—90).—From the examination of a considerable number of fragments of the Ochansk meteorite, the author concludes that the division of meteorites is not effected instantaneously by explosion, but by the repeated separation of fragments. In this meteorite, the brecciated structure is highly developed. The melted iron met with in the outer layer of the meteorite occurs in the form of grains or plates. One of these plates treated with acid did not exhibit Widmannstätten lines. It had the following composition:—

Fe.	Ni.	Co.	P.	S.
79.12	11.38	trace	0.74	8.44

The most noteworthy point about this meteorite is the occurrence of yellow iron sulphide in pentagonal dodecahedra, as this is the first time that iron pyrites has been observed with certainty in a meteorite.

B. H. B.

Pipe Creek Meteorite. By A. R. LEDOUX (*Jahrb. f. Min.*, 1891, i, Ref. 50; from *Trans. N. York Acad. Sci.*, 8, 186—187).—This meteorite weighing 13½ kilos., was found in December, 1887, near Pipe Creek, 35 miles south-west of San Antonio, Texas. Analysis yielded:

Magnetic portion	30.89 per cent.
Non-magnetic portion	69.11 "

The magnetic portion gave :

Fe.	Ni.	Total.
90.94	9.00	99.94

and the non-magnetic portion, silicates and iron sulphide, gave—

SiO ₂ .	S.	CaO.	MgO.	P.	Fe ₂ O ₃ .
35.61	3.45	2.25	15.09	0.25	12.15

The analysis of a second fragment found at Waldon Ridge, Cumberland Gap, Tennessee, gave 93.86 per cent. of iron and 6.01 per cent. of nickel.
B. H. B.

Meteorite from Collescipoli. By G. TROTTARELLI (*Gazzetta*, 20, 611—615).—This meteorite, said to have fallen at Collescipoli on February 3rd, 1890, was shaped like a tortoise, and weighed about 4½ kilos.; it exploded on touching the ground, imbedding itself to the depth of half a metre. The surface was dark, dull, vitrified, covered with divergent striations, dotted over with shining particles, and pitted here and there. The interior was ash-coloured, with a granular structure, and contained numerous minute particles of metallic and nickeliferous iron, magnetic iron ore, and black nodules of ferric chromite and of pyrrhotite. When powdered, it emitted an odour resembling that of burning pyrites. Its sp. gr. in bulk is 3.71, in powder 5.313. Its composition is as follows:—

Volatile.	Na ₂ O.	SiO ₂ .	CaO.	Al ₂ O ₃ .	MgO.	Pd.
2.100	10.386	31.057	0.1169	0.9304	0.0186	0.7745
Mn.	Fe.	Cr.	Ni.	S.	O and loss.	
1.006	40.983	0.5616	1.544	7.679	2.8428	

and traces of phosphorus, lead, antimony, tin, potassium, lithium, sulphuric acid, and chlorine.
S. B. A. A.

Organic Chemistry.

The Relative Motion of Singly-bound Carbon Atoms. By A. EILOART (*J. pr. Chem.* [2], 43, 124—130; compare Abstr., 1888, 549; 1889, 261; 1890, 719, 899, 1083).—The author summarises this paper as follows:—(1.) There is no decisive proof that rotation occurs in the molecule of perchlorethane (compare Meyer, Abstr., 1890, 719). (2.) "The most favourable configuration" is incompatible with free rotation. (3.) Forms of a compound distinguished respectively by being capable and not being capable of rotation may exist, but we cannot distinguish such isomerides.
A. G. B.

Halogen Derivatives of Amylene (Trimethylethylene). By C. HELL and M. WILDERMANN (*Ber.*, 24, 216—223).—Chlorine acts

on amylene with development of much heat, and forms a mixture of chlorinated derivatives which was found to consist of 31 parts of chloramylene, C_5H_9Cl ; 44 parts of amylene dichloride, $C_5H_8Cl_2$; 10 parts of liquid trichloropentane, $C_5H_7Cl_3$; and a little tetrachloropentane, $C_5H_6Cl_4$. The first boils at $92-93^\circ$; the second at $130-133^\circ$ (760 mm., and at $28-29^\circ$ under a pressure of 12 mm.); the third at $174-180^\circ$ (760 mm., and at $63-65^\circ$ under a pressure of 12 mm.). These results confirm in the main those obtained by Bauer (*Zeitschr. Chem.*, 1866, 380, 667), but, unlike the latter, the authors have not obtained any solid trichloropentane, nor do they find that amylene chloride is the sole product at -17° .

Phosphorus pentachloride was found by Guthrie (this Journal, 1861, 136) to act on amylene with the formation of amylene dichloride. The authors find that chloramylenes are formed, and, under certain conditions, is trichloropentane also. If the action is allowed to take place at a low temperature, and the product at once poured on to ice, only the first two are obtained, and may be easily separated by fractional distillation; whereas if the product is allowed to become warm before pouring on to the ice, a mixture of all three compounds is obtained which it is exceedingly difficult to separate. Trichloropentane is formed both by the displacement of hydrogen in amylene dichloride and by the addition of chlorine to chloramylene, but is best prepared in a pure condition by the action of phosphorus pentachloride on the latter at 100° .

The formation of such a large proportion of chloramylene in the direct chlorination is probably due to the great heat developed in the reaction, which causes the elimination of hydrogen chloride from the amylene dichloride first formed. It follows also from the relative proportions of the products, that amylene dichloride loses hydrogen chloride more readily than it takes up another atom of chlorine by substitution, and that chlorine acts more readily on amylene than on chloramylene.

Bromine acts on amylene with the formation not only of amylene dibromide, as stated by Bauer (*loc. cit.*), but also of tribromopentane, tetrabromopentane, and isoamyl bromide; bromamylene is not formed in any appreciable quantity, probably owing to the fact that the heat of the reaction is not so great as with chlorine. *Tribromopentane* is an oily liquid which boils at $118-119^\circ$ (12 mm.), is volatile in a current of steam, although scarcely so with alcohol vapour, and is scarcely attacked by boiling alcoholic potassium cyanide. *Tetrabromopentane* boils at $148-156^\circ$ (12 mm.), and is also volatile in a current of steam.

By the action of bromine on amylene dibromide at 100° the above tribromo- and tetrabromopentane are obtained, together with higher brominated derivatives. A crystalline tribromopentane, melting at 207° , may be prepared, as already found by Bauer, by the addition of bromine to bromamylene, and a crystalline compound which may be identical with it is formed by the action of bromine on amylene dibromide in sunlight.

The action of bromine on amylene differs, therefore, from that of chlorine inasmuch as no bromamylene is formed, and the higher

brominated products are obtained solely by substitution from amylene dibromide.
H. G. C.

Cetyl Alcohol. By A. CLAUS and F. v. DREDFN (*J. pr. Chem.* [2], 43, 148—153).—Palmitaldehyde cannot be obtained by oxidising cetyl alcohol with chromic acid; the product of this reaction is not a single substance, as supposed by Friedau and by Dollfus (*Annalen*, 83, 23; 131, 287; compare Beilstein, 2nd ed., 1, 780), but a mixture of unaltered cetyl alcohol and palmitic acid (compare Krafft, *Abstr.*, 1880, 867).

Palmitic chloral, $C_{16}H_{32}Cl_2O$, is obtained by passing dry chlorine through a solution of cetyl alcohol in chloroform, first in the cold, and afterwards on the water-bath, until no more hydrogen chloride is evolved, and evaporating; it is a yellow, thick, transparent oil, becomes dark in air, has a pungent smell and sharp taste, and decomposes about 140° . The *hydrate*, $C_{16}H_{30}Cl_2O \cdot H_2O$, is best obtained by shaking an ethereal solution of the chloral with water and then evaporating the ether; it is a colourless, crystalline substance. The *alcoholate* is also a solid crystalline substance insoluble in water.

When cetyl alcohol is treated with nitric acid in the cold, cetyl nitrate is obtained, but if the action is allowed to proceed too violently, pimelic, sebacic, and suberic acids are formed. The action of nitric acid on palmitic and stearic acids has been studied, and will be treated of in a future communication.
A. G. B.

Inversion of Saccharose by Hydrochloric Acid. By A. BORNTRÄGER (*Chem. Centr.*, 1890, ii, 908—910; from *Zeit. Vereins Rübenzücker. Ind.*, 1890, 876—905).—The author's investigations consist in a series of comparative experiments made with a view of determining which of the several methods recommended for the inversion of cane-sugar is the best. By employing the French standard weight and inverting according to Clerget's method (16.35 grams dissolved in 100 c.c. of water, of which 50 c.c. with 5 c.c. of concentrated hydrochloric acid is heated on the water-bath at 68° during 10 minutes), the observed change was 134.35 at 20° . By allowing the inversion to take place in the cold, the change = 134.69 at 20° . By employing the methods recommended by Creydt (*Deuts. Zuck. Ind.*, 13, 807) and Wohl (*Zeits. Ver. Rub. Zuck. Ind.*, 25, 763—771), the author arrived at results corresponding with those of Herzfeld. Since, according to the method usually employed in Germany, the solution of 13.024 grams of sugar in 50 c.c. of water and 5 c.c. of hydrochloric acid is diluted, after inversion, to 100 c.c., and then polarised, the author subjected the inverted solution prepared by Clerget's method, and which then showed a reading equal to 134.35 at 20° , also to a like dilution, when the polariscope reading corresponded with a change of 132.5 at 20° .

By employing the German method, in which 26.048 grams of sugar is dissolved in 100 c.c. of water and 50 c.c. is inverted at ordinary temperatures with 5 c.c. of concentrated hydrochloric acid, the observed change of rotation was 134.98 at 20° . By inverting according to Clerget's method the change = 134.65 . If the solution is (as is

usual in Germany) diluted with water to 100 c.c. after inversion, the change = 132.8° at 20° , whereas if the solution is neutralised before diluting, the change = 134.20° at 20° .

By inverting the sugar solution, whether prepared with the French standard weight or the German, according to the method of Reichardt and Bittmann, the author found the change in rotation decidedly lower.

Among the newer methods proposed for the inversion of cane-sugar that of Herzfeld is to be recommended. 13.024 grams of the sugar is dissolved in 75 c.c. of water, 5 c.c. of 38 per cent. hydrochloric acid added, and the flask is then plunged into water of a temperature a little above 70° . The temperature of the sugar solution should rise to $68-70^\circ$ within 2—3 minutes, and it is retained at this temperature in the water-bath for five minutes longer. The solution is then cooled quickly, diluted to 100 c.c., and polarised at 20° . Pure saccharose should show a change in rotation of $132.34-132.70^\circ$ by this method.

The effect of neutralising the inverted sugar solution was found to be an increase in the polariscope reading. It was further found that the choice of base had no influence on the result, the following giving the same increase in the reading:—Sodium carbonate, sodium hydroxide, potassium hydroxide, calcium carbonate, barium hydroxide, and magnesium oxide.
J. W. L.

Solubility of Sugar in Mixtures of Alcohol and Water. By C. SCHEIBLER (*Ber.*, 24, 434—435).—In the author's paper on this subject (*Ber.*, 5, 343), the conclusion was drawn that solutions containing small quantities of alcohol are capable of dissolving more sugar than the water present can dissolve by itself. This conclusion is erroneous, and was brought about by an error in plotting out the curves, the fact being that all mixtures of water and alcohol dissolve less sugar than the water present is alone capable of dissolving.

H. G. C.

Gallisin, and its Method of Formation. By C. SCHEIBLER and H. MITTELMEIER (*Ber.*, 24, 301—305; compare Fischer, this vol., p. 412).—When commercial dextrose, prepared from starch, is dissolved in water (10 parts), the dextrose completely destroyed by fermentation with yeast, and the filtered solution then evaporated to a syrup, a non-fermentable, amorphous substance, named gallisin by Cobenzl and Schmitt (*Abstr.*, 1884, 981; 1885, 134), is obtained. This substance is wanting in all the properties of a definite chemical compound, and the formula $C_{12}H_{24}O_{10}$, assigned to it by Cobenzl, Rosenheck, and Schmitt, cannot be regarded as based on established facts; the evolution of gas, observed on heating at 100° gallisin prepared as described by Cobenzl and Schmitt, and purified with the aid of alcohol and ether, is due to the evolution of alcohol, from which the substance cannot be freed by keeping over sulphuric acid under reduced pressure.

Gallisin, purified by repeated precipitation by alcohol from its aqueous solution, is a colourless, amorphous, very hygroscopic substance; it is very readily soluble in water, the solution having a

neutral reaction, and a powerful reducing action on Fehling's solution. When its aqueous solution is heated at 100° for about an hour with phenylhydrazine acetate, and then allowed to cool, a considerable quantity of a yellow osazone is deposited. This compound, purified by recrystallisation from hot water, has the composition $C_{24}H_{38}N_4O_{11}$, and resembles closely the osazones of the bioses in appearance; it turns brown when kept over sulphuric acid, and is only sparingly soluble in ether and acetone, but more readily in hot alcohol. It softens at about 145° , melts at $152-153^{\circ}$, decomposes when heated above 200° , and is rather more readily soluble in hot water than the known isomeric osazones.

These experiments show that gallsin contains a sugar of the composition $C_{12}H_{22}O_{11}$, and as gallsin yields only dextrose on hydrolysis, this sugar is probably formed by the combination of 2 mols. of dextrose in such a way that the aldehyde group of one remains unchanged (compare Scheibler and Mittelmeier, *loc. cit.*). When chemically pure dextrose (50 grams) is heated with $2\frac{1}{2}$ per cent. sulphuric acid (500 c.c.) for 12 hours at 100° , the solution freed from acid and then heated with phenylhydrazine acetate, a large quantity of phenylglucosazone is deposited; if the hot solution is filtered, and then allowed to cool, a small quantity (about 0.2 gram) of an osazone, identical in properties with that described above, separates from the solution; this compound is doubtless identical with the isomaltosazone (compare Fischer, *loc. cit.*).
F. S. K.

Action of Potassium Permanganate on Starch. By C. J. LINTNER (*Zeit. ang. Chem.*, 1890, 546-548).—With the object of approaching the question of the constitution of the starch molecule in a new direction, the oxidising action of potassium permanganate on starch was studied. Since both maltose and dextrose are readily oxidised by permanganate, it was anticipated that the groups which are easily hydrolysed would be the first to be destroyed by oxidation, whilst those which yield dextrin would show greater resisting power. On following the progress of the reaction by the iodine test, the same series of colours was observed as in the action of acids or of diastase. Instead of dextrin, there was produced a series of gummy acids, precipitable by lead acetate and by baryta. The operation may be performed either by adding powdered potassium permanganate to a hot $2\frac{1}{2}$ per cent. starch paste, or by adding the ungelatinised starch, mixed to a milk with about 3 parts of water, to a $7\frac{1}{2}$ per cent. solution of permanganate at $60-70^{\circ}$. Much carbonic anhydride is evolved, and manganic dioxide precipitated. With 1 part of permanganate to 2 of starch, the product gives a reddish-violet reaction with iodine, and has, when purified, a specific dextrorotatory power $[\alpha]_D = 170-182.4$; with 4 of permanganate to 3 of starch, the reaction is reddish-brown (sp. rot. power = 153.1); with 2 of permanganate to 1 of starch, the product is no longer coloured by iodine (sp. rot. power = $131.2-154.3$). One of the products giving a violet colour with iodine was submitted to the action of sulphuric acid until the iodine reaction was no longer produced; it then gave a value 128.4 . A similar treatment with diastase gave 130.4 . This product would therefore

seem to be a single substance, whilst the others are mixtures. The method of purification employed consists in filtering from the manganese precipitate, neutralising with acetic acid, concentrating to one-third the bulk, precipitating with lead acetate, washing the precipitate with hot water, and decomposing it with hydrogen sulphide. The concentrated filtrate is then poured into absolute alcohol, and the curdy precipitate is washed with absolute alcohol and ether, dried in a vacuum over sulphuric acid, and finally at 100°. The products reduce Fehling's solution to a very small extent. With phloroglucinol and hydrochloric acid, also with orcinol and hydrochloric acid, they give no characteristic colour reactions, from which fact the absence of C_6 groups may be inferred. The elementary analysis of a product which was not coloured by iodine agreed with the formula $C_{12}H_{23}O_{11}, C_{12}H_{20}O_{10}$.

M. J. S.

Spermine. By W. MAJERT and A. SCHMIDT (*Ber.*, 24, 241—243; see also this vol., p. 415).—The authors have been enabled to carry out a direct comparison of spermine and piperazine, and find that although there is great similarity between the two bases and some of their salts, they are not identical, the bismuthiodides and the phosphates showing distinct differences. Piperazine bismuthiodide forms microscopic rectangular plates or rods, whilst spermine bismuthiodide crystallises in long, pointed needles, often united to feathery aggregates. Piperazine phosphate forms small, flat, four-sided tabular crystals, the angles of which are often cut off diagonally; spermine phosphate, on the other hand, crystallises in stellate aggregates of acute rounded pyramids.

Piperazine, in doses of 0.5—1.5 gram, passes through the human organism unchanged, and may be found in the urine in a very short time.

H. G. C.

Spermine. By A. POEHL (*Ber.*, 24, 359—360).—The author has recently prepared this base by a method resembling in principle that given by Schreiner (*Abstr.*, 1879, 72), and finds the properties agree fully with his description. The analysis of the platinumchloride, however, gave numbers which do not agree with Schreiner's empirical formula C_7H_5N , but with the formula $C_{10}H_{26}N_4$, and the analysis of the aurochloride confirmed this formula. Spermine can, therefore, be neither identical nor isomeric with piperazine.

H. G. C.

Amidoximes and Azoximes. By F. TIEMANN (*Ber.*, 24, 435—436).—The compound described by Jacoby as capronylcapramidoxime (*Abstr.*, 1886, 785) is in reality *isocapronamide*, or *isobutylacetamide*, and melts when pure at 120° (see Hofmann, *Abstr.*, 1884, 1114). All the substances obtained by Jacoby are derived from isocapronitrile, and should therefore have the prefix "iso-."

The substance described by Wurm as benzenylamidoximeoxalic acid, $NH_2 \cdot CPh \cdot N \cdot O \cdot CO \cdot COOH$ (*Abstr.*, 1890, 259), is *benzenylamidoxime oxalate*, $NH_2 \cdot CPh \cdot NOH, H_2C_2O_4$.

H. G. C.

Methylguanecil and Trimethylguanecil. By T. CURATOLO (*Gazzetta*, 20, 585—593).—*Methylguanecil*, $\text{NH}\cdot\text{C} \begin{smallmatrix} \text{NH}\cdot\text{CMe} \\ \text{NH}-\text{CO} \end{smallmatrix} \text{CH}$.

By the action of ethyl acetoacetate on guanidine carbonate in alcoholic solution, Behrend (*Abstr.*, 1886, 338—443) obtained a substance having the composition $\text{C}_5\text{H}_7\text{N}_3\text{O}$, and analogous to methyluracil. It is best prepared by heating guanidine carbonate with a slight excess of ethyl acetoacetate at $130\text{--}150^\circ$ for a few hours. The product crystallises from water in tufts of brilliant, white needles; when gently heated on platinum foil, it sublimes completely without melting; in a closed tube, it turns brown at $260\text{--}270^\circ$, and melts with complete decomposition at $292\text{--}294^\circ$. It has an alkaline reaction, dissolves moderately in boiling water, but only sparingly in cold water or boiling alcohol. It is readily soluble in warm ammonia, but on cooling the solution the base crystallises out in large prisms. It also dissolves freely in alcoholic solutions of potash or soda, forming the respective salts. The *sodium* salt, $\text{C}_5\text{H}_6\text{NaN}_3\text{O}$, forms a white, foliaceous mass mixed with shining scales. Methylguanecil is readily soluble in acids; the *hydrochloride*, $\text{C}_5\text{H}_7\text{N}_3\text{O}\cdot\text{HCl}$, crystallises in tufts of long white needles; the *platinochloride*, $(\text{C}_5\text{H}_7\text{N}_3\text{O})_2\cdot\text{H}_2\text{PtCl}_6$, crystallises in large, pale-red rhombohedra insoluble in a mixture of alcohol and ether; the *formate*, $\text{C}_5\text{H}_7\text{N}_3\text{O}\cdot\text{CH}_3\text{O}_2$, which crystallises in tufts of needles, dissolves in hot water and alcohol, and when heated at 125° splits up into formic acid and methylguanecil. The *acetate* forms amorphous nodules and decomposes at 270° .

Trimethylguanecil, $\text{NH}\cdot\text{C} \begin{smallmatrix} \text{NMe}\cdot\text{CMe} \\ \text{NMe}-\text{CO} \end{smallmatrix} \text{CH}$, is prepared by heating a mixture of methylguanecil and methyl iodide in molecular proportion with an excess of methyl alcohol for 2—3 hours at $130\text{--}140^\circ$, and decomposing the hydriodide formed with potash. It crystallises in needles, begins to decompose at 300° , and melts and partially sublimes at 320° . The *hydriodide*, $\text{C}_5\text{H}_6\text{Me}_3\text{N}_3\text{O}\cdot\text{HI}$, crystallises in silky needles, melts at $219\text{--}220^\circ$, and dissolves readily in hot water. Determinations of the molecular weight of the two bases were made by Raoult's method, with results moderately approximating to theory.

S. B. A. A.

Olefinic Constituents of Ethereal Oils. By F. W. SEMMLER (*Ber.*, 24, 201—211).—The preparation of geranaldehyde, $\text{C}_{10}\text{H}_{18}\text{O}$, has already been described (this vol., p. 30); it boils at $224\text{--}228^\circ$, under a pressure of 760 mm., and at $110\text{--}120^\circ$ under a pressure of 12 mm.; the sp. gr. is 0.1972 at $15^\circ/15^\circ$. The compound is optically inactive; the refractive index indicates the presence of two ethylene bonds, and this view is supported by the formation of a *tetrabromo*-additive compound which has not yet been obtained in crystals. Hydroxyl may be substituted for the bromine atoms, and the products thus obtained are being further investigated.

Orange oil appears to contain from 0.5 to 0.75 per cent. of oxygen; its sp. gr. is 0.8435 at $20^\circ/20^\circ$; on treatment with hydrogen sodium sulphite, a crystalline compound is formed; on decomposing this and distilling the oily product, geranaldehyde is obtained

together with a very small quantity of a lower boiling aldehyde. "Citral" is the technical term applied to an ethereal oil which is contained to the extent of 6—8 per cent. in lemon oil; this substance proves to be identical with geranaldehyde, which is also found in a number of other ethereal oils.

On heating geranaldehyde with hydrogen potassium sulphate for 20 minutes at 170° , and distilling the product in a current of steam, cymene, $C_{10}H_{14}$, is obtained, and is regarded as being formed by elimination of water from the aldehyde.

Coriander oil consists of terpenes and about 90 per cent. of another substance which is termed coriandrol, and may be readily separated by distillation under reduced pressure. *Coriandrol*, $C_{10}H_{18}O$, boils at 194 — 198° under a pressure of 760 mm., and at 85 — 90° under a pressure of 20 mm., the sp. gr. is 0.8679 at $20^{\circ}/20^{\circ}$, and the molecular refraction 49.07 ; this points to the existence of two ethylene unions in the compound. It combines with 2 molecules of bromine, and on treatment with silver oxide, a hydroxyl derivative is formed.

Linaloe oil appears to be a mixture of several compounds, but no terpenes could be detected. The principal constituent, which is termed *linalool*, boils at about 195 — 190° (? 185 — 190°), and has a sp. gr. 0.8702 at $20^{\circ}/20^{\circ}$; the molecular refraction is 49.33 ; the compound combines with 4 atoms of bromine and resembles geraniol.

A sample of "German melisse oil" gave a compound with sodium hydrogen sulphite; this was decomposed in a current of steam; the resulting product has the formula $C_{10}H_{18}O$, and boils at 204 — 209° ; the sp. gr. is 0.8681 at 15° , and the molecular refraction 48.59 . It combines directly with 2 atoms of bromine. On treating the compound $C_{10}H_{18}O$ with silver oxide, the corresponding acid, $C_{10}H_{16}O_2$, is obtained, which is liquid; the *silver salt* is white. On oxidation, the aldehyde yields isovaleric acid.

The above compound $C_{10}H_{18}O$ is identical with a technical product termed "citronellone" and with a compound with the same name prepared by Gladstone and Wright; it is also probably the same as the citronellie aldehyde of Dodge (compare Abstr., 1890, 231).

The author applies the term "olefinic camphenes," to compounds of the formulæ $C_{10}H_{18}O$, $C_{10}H_{16}O$, $C_{10}H_{14}O$. These, which are always open chain alcohols, aldehydes, or ketones, have a sp. gr. of 0.86 to 0.90 at $20^{\circ}/20^{\circ}$, and a higher refractive power than the isomeric compounds with closed chains.

J. B. T.

Derivatives of Acetal and Acetone. By W. AUTENRIETH (*Ber.*, 24, 159—166).—*Chlorethylidene diethyl ether*, $CH_2Cl \cdot CH(OEt)_2$, is prepared by the action of sodium ethoxide on the dichlorinated derivative of the ethyl ether, and boils at 156 — 158° .

Thiophenyl acetal, $PhS \cdot CH_2 \cdot CH(OEt)_2$, is obtained by boiling the preceding compound with sodium phenyl sulphide; it is a colourless, viscid liquid, has an aromatic odour, and boils at 273° ; a cherry-red coloration is produced on heating with concentrated sulphuric acid, whilst traces of phenyl mercaptan are formed by the action of alkalis or hydrochloric acid. The yield is quantitative. All attempts to pre-

pare thionaphthene by the action of dehydrating agents were unsuccessful; potassium permanganate also causes decomposition.

Thioethylacetal, $\text{EtS}\cdot\text{CH}_2\cdot\text{CH}(\text{OEt})_2$, prepared from chloracetal and sodium ethyl sulphide, is a yellow liquid which boils at $168\text{--}170^\circ$, and has a powerful odour.

Phenoxyacetal, $\text{PhO}\cdot\text{CH}_2\cdot\text{CH}(\text{OEt})_2$, is prepared by heating sodium phenoxide and chloracetal in a sealed tube for two days at 160° ; on pouring into water, a heavy, colourless, oily liquid separates which boils at $254\text{--}256^\circ$. With bromine-water, a *bromo-derivative* is formed, crystallising in small, white needles, and melting at 84° .

On treating chloracetone in the cold with alcoholic solution of sodium phenyl sulphide, a compound is obtained of the formula $\text{PhS}\cdot\text{CH}_2\cdot\text{COMe}$, which the author proposes to term *thiophenylacetone*, instead of acetylthiophenyl ether, or acetylphenyl sulphide as heretofore. The *phenylhydrazone*, $\text{PhS}\cdot\text{CH}_2\cdot\text{COMe}\cdot\text{N}_2\cdot\text{HPh}$, is deposited from alcohol in colourless crystals melting at $86\text{--}87^\circ$. No indole derivative could be obtained.

Thioethylacetone, $\text{EtS}\cdot\text{CH}_2\cdot\text{COMe}$, is prepared in a similar manner to the phenyl derivative, and is a pale-yellow, viscid liquid boiling at $170\text{--}172^\circ$. The *phenylhydrazone* is unstable and melts at $55\text{--}57^\circ$.

Phenyl bisulphide is the only substance that could be obtained by the action of ethyl chloroacetoacetate on sodium phenyl sulphide. Hantzsch's results are thus confirmed. J. B. T.

Isonitrostearic Acid. By A. CLAUS and O. PFEIFFER (*J. pr. Chem.*, [2], 43, 161—176).—*Isonitrostearic acid*, $\text{C}_{18}\text{H}_{33}(\text{NO}_2)\text{O}_2$, is obtained by adding, at intervals of 4—5 hours, fuming nitric acid of sp. gr. 1.48 (250—300 grams in all) to a boiling solution of stearic acid (100 grams) in glacial acetic acid ($1\frac{1}{2}$ litres); the heating is continued for 2 or 3 days, until a portion of the liquid does not become turbid on cooling from separation of unaltered stearic acid, and the liquid is then poured into a large quantity of cold water. The new acid is thus separated as a yellow oil which, after being washed with hot water and separated from any remaining stearic acid by slow evaporation of its alcoholic solution, solidifies to a yellowish-white, opaque, buttery mass; it dissolves in most solvents, except water and light petroleum; its melting point has not been accurately determined; it does not volatilise with steam at 110° .

Isonitrostearic acid is bibasic. The *normal potassium salt*, $\text{K}_2\text{C}_{18}\text{H}_{31}\text{NO}_4$, obtained by adding potassium hydroxide to an emulsion of the acid in water until it is neutral to phenolphthalein and evaporating, is a transparent, red mass, sparingly soluble in alcohol. By acting on an alcoholic solution of the acid with potassium hydrogen carbonate, a *double salt*, $\text{K}_2\text{C}_{18}\text{H}_{31}\text{NO}_4\cdot\text{KHCO}_3$, is obtained, as well as the normal potassium salt. The *normal sodium salt* forms a yellowish-red powder, with $\frac{1}{2}$ mol. H_2O ; it dissolves easily in water. Attempts to obtain the ammonium salt were unsuccessful, as a deep seated reaction takes place between the acid and ammonia. The *barium*, *strontium*, and *calcium* salts were obtained by double decomposition of the alkali salts. By adding copper acetate to an aqueous solution of one of the alkali salts, a mixture

of 1 mol. of the *acid copper salt*, $(C_{18}H_{33}NO_4)_2Cu$, with 2 mols. of the *normal copper salt*, $C_{18}H_{33}NO_4Cu$, is precipitated; by treating the precipitate with chloroform, the former salt is dissolved to a dark-green liquid, and remains as a dark-green, amorphous mass, when the solvent is evaporated, whilst the latter salt remains undissolved by the chloroform as a bulky, bright-green precipitate; the normal salt, which is also obtained when ether is added to a chloroform solution of the acid salt, is insoluble in all simple solvents. *Ethyl isonitrostearate* is obtained by passing dry hydrogen chloride through an alcoholic solution of the acid, and subsequently adding water; it is a heavy oil which explodes at 110° .

Experiments on the reduction of isonitrostearic acid have not as yet led to very definite results; consequently nothing is known of its structure, although its behaviour is more in accord with that of an iso- than with that of a primary nitro-compound. A. G. B.

Turkey Red Oil. By SCHEURER-KESTNER (*Compt. rend.*, 112, 158—160).—The author has examined the sulphonated acid prepared from castor oil by the action of monohydrated sulphuric acid. It has a complex composition, but the greater part consists of a ricinoleosulphonic acid, in which the sulphonic group is united to oxygen and not to carbon (Benedikt and Ulzer). This sulphonic acid is hydrated and stable, but loses its water at 120° , and becomes insoluble. The oil also contains fatty acids formed by the decomposition or alteration of the sulphonic acid, their proportion varying with the conditions. They are polymerised acids, but the condensation does not proceed so far as stated by Juillard, the highest polymeride being diricinoleic acid. The difference is due to the fact that Juillard added sodium chloride to the products, and this in presence of sulphuric acid liberated hydrochloric acid, which is a powerful polymerising agent. The author employed sodium sulphate as the precipitating salt.

The sulphonic acid tends to give yellowish shades, whilst the polymeric acid tends to give carmine shades with a bluish tint.

C. H. B.

Hydroxypyruvic Acid, a Product of Decomposition of Cellulose. By W. WILL (*Ber.*, 24, 400—407).—By the action of aqueous soda on a solution of collodion wool in alcoholic ether, the mixture becomes warm, and all solid substance is taken up by the alkaline solution. When the latter is acidified, carbonic anhydride and oxides of nitrogen are evolved, and a gelatinous precipitate separates, which solidifies to a gummy, brittle mass, insoluble in water, but soluble in alcohol and alkalis. It is identical with the substance described by Eder (*Abstr.*, 1880, 373) as cellulose dinitrate, but is in reality no longer a derivative of cellulose, as it does not yield the latter when treated with ferrous chloride, and decomposes on boiling with water, evolving hydrogen cyanide.

If the alkaline collodion solution be kept at 20° for 24—30 hours, a point is found at which acids no longer cause any precipitate. The solution reduces alkaline copper solution, which has led former investigators to assume the presence of sugars, but the results given

below show this to be incorrect. If the solution is acidified with dilute sulphuric acid, warmed gently to remove oxides of nitrogen, and a mixture of phenylhydrazine hydrochloride and sodium acetate added, a compound separates at 80° which has the properties of an osazone. It crystallises from hot benzene in pale-yellow, prismatic crystals, melts at 205° with evolution of gas, when quickly heated, and has the composition $C_{15}H_{14}N_4O_2$. It would therefore appear to have the constitution

In agreement with this formula, it is found to be a strong monobasic acid; the *sodium* salt, $C_{14}H_{13}N_4\cdot COONa$, crystallises in pale yellow, lustrous needles, and melts at 231° with decomposition; the *potassium* salt closely resembles this and melts at 233° with decomposition; the *ammonium* salt forms very slender, pale-yellow needles, melting at 200° , and the *calcium* salt pale-yellow needles which begin to decompose at 100° , with evolution of a carbamine odour. The *ethyl* salt crystallises in long, brownish-yellow needles and melts at 149° .

An attempt to convert the osazone into the corresponding "osone" by Fischer's method was unsuccessful, just as in the case of the osazone of glyoxal. The mother substance of the osazone was therefore prepared directly from the alkaline collodion solution; this was first acidified with sulphuric acid, the excess of the latter removed by barium nitrate, the filtrate precipitated with lead acetate, and the lead salt washed and decomposed with hydrogen sulphide. The solution on evaporation gave off carbonic anhydride, oxides of nitrogen, formic and hydrocyanic acids, and the residue, in addition to the acid yielding the above osazone, also contained oxalic acid; the latter is not, however, found in the freshly prepared solution. The mixture was evaporated to dryness, and heated until no more nitrogen remained in the residue, which was then dissolved in water, precipitated with calcium carbonate, and the filtrate precipitated a second time with lead acetate. The acid prepared from the lead salt forms a syrup which becomes solid and brittle on cooling. It has a strongly acid, astringent taste, is readily soluble in water, and is precipitated in flakes by alcohol and ether; it reduces ammoniacal copper and silver solution, and yields salts which are for the most part soluble in water. The aqueous solutions of the acid and its salts are slightly levorotatory. The *calcium* salt, $(C_5H_3O_4)_2Ca + 8H_2O$, is a granular precipitate, which retains 4 mols. H_2O at 110° , and only loses the latter at 180° , undergoing further decomposition at the same time. The *strontium* salt, $(C_5H_3O_4)_2Sr + 4H_2O$, is similar, and the *cadmium* salt is a white compound, soluble in water.

The analyses of the salts confirm the formula $C_5H_3O_4$; there are, however, two acids of this composition capable of yielding an osazone of the above constitution, namely, $CHO\cdot CH(OH)\cdot COOH$ and $OH\cdot CH_2\cdot CO\cdot COOH$, which stand to one another in the same relation as dextrose to levulose. The acid is not oxidised by bromine-water, and is unaltered on boiling with lime and baryta-water; these properties agree best with the second of these formulæ, and the acid

is therefore probably *hydrozypyruvic acid*. It shows all the reactions of an alcohol, yielding a benzoyl compound, &c. H. G. C.

Action of Ammonia and of Amines on Ethyl Acetosuccinate and its Homologues. By W. O. EMERY (*Annalen*, 260, 137—160).—By treating ethyl acetosuccinate with ammonia, Conrad and Epstein obtained a compound which they named ethyl amidacetosuccinate, $\text{NH}_2\cdot\text{CMe}\cdot\text{C}(\text{COOEt})\cdot\text{CH}_2\cdot\text{COOEt}$ (Abstr., 1888, 253). This substance, which the author names *ethyl α -amidethylidenesuccinate*, can also be prepared by dissolving ethyl acetosuccinate in an alcoholic solution of ammonia, saturated at 0° , and keeping the solution for 24 hours at the ordinary temperature; it separates from alcohol in large, transparent, rhombic crystals, $a : b : c = 0.51504 : 1 : 0.60033$, melts at 62° , and is readily soluble in ether, alcohol, and chloroform, but rather more sparingly in carbon bisulphide, and almost insoluble in cold water. The *acetyl* derivative,

is produced when the ethereal salt is heated at $155\text{--}160^\circ$ with acetic anhydride for several hours; it is a thick, yellow liquid, of sp. gr. 1.12873 at $20^\circ/4^\circ$, and boils at $175\text{--}176^\circ$ (about 11 mm.).

The *lactam* $\begin{matrix} \text{NH}\cdot\text{CMe} \\ \text{COC}-\text{H}_2 \end{matrix} > \text{C}\cdot\text{COOEt}$ is obtained when ethyl α -acetyl-amidethylidenesuccinate is distilled slowly under reduced pressure, or heated at $145\text{--}150^\circ$ until alcohol is no longer given off. It crystallises from ether in colourless needles, melts at $133\text{--}134^\circ$, boils at 195° (about 12 mm.), and is readily soluble in alcohol, but only sparingly in ether and carbon bisulphide. It crystallises unchanged from water, combines with bromine in carbon bisulphide solution, and yields a deliquescent sodium derivative when treated with sodium ethoxide in alcoholic ethereal solution. The *acetyl* derivative, $\text{C}_{10}\text{H}_{13}\text{NO}_4$, is formed in small quantities when the lactam is heated at $155\text{--}160^\circ$ with acetic anhydride; it separates from ether, in which it is sparingly soluble, as a colourless, crystalline powder, and melts at $141\text{--}142^\circ$.

A *lactam*, which has probably the constitution $\begin{matrix} \text{NMe}\cdot\text{CMe} \\ \text{CO}-\text{CH}_2 \end{matrix} > \text{C}\cdot\text{COOEt}$ is obtained when ethyl acetosuccinate is treated with anhydrous methylamine, either alone, or in alcoholic or ethereal solution, at the ordinary temperature, and the product distilled under a pressure of 11 mm. It separates from carbon bisulphide and ether, in which it is very readily soluble, in colourless crystals, melts at 42° , and boils at 160° (11 mm.); it is not converted into an acetyl-derivative by acetic anhydride at $155\text{--}160^\circ$.

A *lactam* of the composition $\text{C}_{10}\text{H}_{15}\text{NO}_3$ can be obtained from ethyl acetosuccinate and ethylamine in like manner; it crystallises in colourless needles, melts at $75\text{--}76^\circ$, boils at 165° (14 mm.), and resembles the preceding compound in its other properties.

The *lactam* $\text{C}_{11}\text{H}_{17}\text{NO}_3$, prepared from ethyl acetosuccinate and propylamine in a similar manner, crystallises in colourless needles,

melts at 50°, boils at 172° (14 to 15 mm.), and resembles the two preceding compounds in its behaviour with solvents.

The *lactam*, $C_{12}H_{15}NO$, formed by distilling the reaction-product of isobutylamine and ethyl acetosuccinate, crystallises in needles, melts at 68°, and boils at 175° (about 15 mm.). The compound $C_{11}H_{14}NO$, obtained from amylamine and ethyl acetosuccinate in like manner, crystallises from carbon bisulphide in plates, melts at 51–52°, and boils at 188° (16 mm.).

All the alkylated lactams described above turn yellow on exposure to the air, and are resinified by a boiling solution of barium hydroxide, but the compounds obtained by treating ethyl acetosuccinate and ethyl phenylacetosuccinate with ammonia are very stable as regards their behaviour with barium hydroxide.

A *lactam* of the composition $C_9H_{11}NO$ is obtained in crystals when ethyl methylacetosuccinate is mixed with alcoholic ammonia, saturated at 0°, and after keeping for 48 hours at the ordinary temperature, the solution slowly evaporated; it crystallises from ethyl acetate in small, colourless prisms melting at 127°.

A compound melting at 147–149° is formed when ethyl phenylacetosuccinate is treated with alcoholic ammonia (compare Weltner, Abstr., 1885, 793); analyses of this substance left its composition undetermined, but when it is heated at 160° for some time, it is converted into the *lactam* of ethyl α -amidoethylidenephylsuccinate. This compound crystallises from hot ethyl acetate in colourless needles, melts at 127–128°, and is readily soluble in alcohol and ether, but rather more sparingly in carbon bisulphide and ethyl acetate; its constitution is represented by the formula

Combination of Malic Acid with Alkaline Phosphomolybdates. By D. GERNEZ (*Compt. rend.*, 112, 226–229).—Measurements of the rotatory powers of solutions of malic acid with various proportions of the white alkaline phosphomolybdates of the type $3M_2O \cdot P_2O_5 \cdot 5MoO_3$ indicate in the case of the sodium and ammonium salts compounds containing respectively four equivalents of malic acid to one of the phosphomolybdate, and two equivalents of acid to three of phosphomolybdate. The potassium salt does not behave quite in the same manner, the only compound definitely indicated being one containing two equivalents of the acid and one of the phosphomolybdate. C. H. B.

Ethyl Ethoxyoxalacetate. By W. WILHELMUS and M. SCHMIDT (*Ber.*, 24, 432–434).—By the action of sodium ethoxide on a mixture of ethyl oxalate and ethyl ethoxyacetate, the sodium compound of ethyl ethoxyoxalacetate is formed,

This does not crystallise out on remaining, and is therefore at once

decomposed by water, and the ethyl ethoxyoxalacetate extracted with ether. The latter is a colourless, somewhat thick oil, which boils at 155—156° (17 mm.), and is sparingly soluble in water and miscible with alcohol and ether. Its alcoholic solution is coloured deep violet by ferric chloride, and it gives a bluish-green copper salt on the addition of cupric acetate. It unites with phenylhydrazine with elimination of water, and the resulting hydrazone appears to behave in a similar manner to that of ethyl oxalacetate (Abstr., 1888, 1178).

H. G. C.

Synthesis of Alkyltricarballic Acids and other Polycarboxylic Fatty Acids. By K. ATWERS (*Der.*, 24, 307—314).—Ethyl sodiomalonate combines directly with various ethereal salts of unsaturated acids, the reaction taking place very readily. Ethyl crotonate and ethyl sodiomalonate, for example, yield the compound $\text{COOEt}\cdot\text{CHNa}\cdot\text{CHMe}\cdot\text{CH}(\text{COOEt})_2$, from which β -methylglutaric acid, $\text{COOH}\cdot\text{CH}_2\cdot\text{CHMe}\cdot\text{CH}_2\cdot\text{COOH}$, identical with the compound (m. p. 85—86°) prepared by Kommenos (Abstr., 1884, 422) is obtained on hydrolysis.

Ethereal salts of tricarballic acid and its homologues can be easily prepared by treating ethyl fumarate with ethyl sodiomalonate and its homologues; the product is in this case a compound of the constitution $\text{COOEt}\cdot\text{CHNa}\cdot\text{CH}(\text{COOEt})\cdot\text{CR}(\text{COOEt})_2$, which, on hydrolysis, is converted into an acid having the constitution $\text{COOH}\cdot\text{CH}_2\cdot\text{CH}(\text{COOH})\cdot\text{CHR}\cdot\text{COOH}$. Tricarballic acid and its *methyl* (m. p. 180°), *ethyl* (m. p. 147—148°), *propyl* (m. p. 151—152°), and *isopropyl* derivatives were prepared in this way; these acids are all readily soluble in water and alcohol, but only sparingly in ether, and very sparingly in benzene and light petroleum. A good yield of the crude substituted tricarballic acid is obtained in every case, but the product is very difficult to purify, probably because it is mixed with stereochemically isomeric compounds.

When tricarballic acid is treated with acetic chloride, it loses 1 mol. H_2O , being converted into a compound melting at 131°, the constitution of which has not yet been determined.

A tetracarboxylic acid of the constitution

is obtained when ethyl sodiomalonate is treated with ethyl aconitate, and the product, which has, doubtless, the constitution

submitted to hydrolysis; the same acid is formed when the condensation product of ethyl fumarate and ethyl ethenyltricarboxylate, a substance which must have the constitution

is hydrolysed. It crystallises very readily, melts at 189°, and is probably identical with the acid (m. p. 185°) obtained by Bischoff (Abstr., 1888, 1061) from ethyl butanehexacarboxylate.

F. S. K.

Action of Ethyl β -Bromopropionate on Ethyl Malonate and Ethyl Acetoacetate. By W. O. EMERY (*Ber.*, 24, 282—286).—*Ethyl carboxyglutarate*, $\text{COOEt}\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}(\text{COOEt})_2$, is obtained, together with a much smaller quantity of ethyl pentanetetetracarboxylate when ethyl β -bromopropionate is boiled with an alcoholic solution of ethyl sodiomalonate. It is a colourless liquid of sp. gr. 1.0808 at $20^\circ/4^\circ$, and boils at 161° (12 to 13 mm.); when hydrolysed with alcoholic potash, it yields carboxyglutaric acid as a thick syrup.

Ethyl 1:3:3:5-pentanetetetracarboxylate,

is a colourless oil of sp. gr. 1.1084 at $20^\circ/4^\circ$; it boils at 215° (13 mm.).

1:3:5-Pentanetricarboxylic acid,

is obtained when ethyl pentanetetetracarboxylate is hydrolysed with alcoholic potash, and the syrupy acid, obtained in this way, boiled with concentrated hydrochloric acid until the evolution of carbonic anhydride is at an end; it crystallises in colourless needles and melts at 106 — 107° . The silver salt, $\text{C}_8\text{H}_5\text{O}_6\text{Ag}_3$, is colourless.

Ethyl α -acetylglutarate can be obtained by treating ethyl α -bromopropionate with ethyl sodioacetoacetate; it has a sp. gr. of 1.07115 at $20^\circ/4^\circ$, and boils at 162° under a pressure of 11 mm. It reacts with ammonia and with amines, yielding amido-derivatives of ethyl α -ethylideneglutarate; the latter can be converted into lactams with elimination of alcohol.

F. S. K.

Derivatives of Levulosecarboxylic Acid. By G. DÜLL (*Ber.*, 24, 348—351).—The author has already described an improved method for preparing levulosecarboxylic acid (*Abstr.*, 1890, 595).

The ammonium salt of levulosecarboxylic acid is formed when levulosecarboxylic acid is dissolved in the least quantity of water, saturated with ammonia, and alcohol cautiously added to the solution; it crystallises in beautiful, prismatic crystals on allowing the solution to remain over sulphuric acid.

Tetrahydroxybutanetricarboxylic acid,

is prepared by warming levulosecarboxylic acid (10 grams) with dilute nitric acid (1:2, 20 grams) on the water-bath at 40° for 24 hours and evaporating the liquid at 60 — 70° . The syrupy mass thus obtained is converted into the calcium salt, from which the acid is liberated by shaking it up with dilute sulphuric acid (1:10); an equal bulk of strong alcohol is then added, the mixture allowed to remain for a time, filtered, and the alcoholic solution evaporated in a vacuum over sulphuric acid to a syrup. It crystallises in colourless tablets, becomes opaque on remaining over sulphuric acid, softens at 140° , and melts completely at 146 — 147° . When working with large quantities of calcium salt, the syrupy acid crystallises with difficulty to a soft, white mass, consisting of long, slender needles. The author supposes this to be a lactone; as, when a neutral solution is allowed to remain for a time, it becomes acid. The

calcium salt, $(C_7H_7O_{10})_2Ca_3 + 6H_2O$, is purified by dissolving it in dilute hydrochloric acid, shaking with animal charcoal, and then adding sodium acetate to the warm solution until a slight precipitate remains; on cooling, the normal calcium salt separates as a crystalline mass. The *mon-acid potassium* salt, $C_7H_5O_{10}K_2$, is especially characteristic, and is obtained on evaporating an aqueous solution of the acid, two-thirds neutralised with potash, in a vacuum over sulphuric acid, in beautiful, large, prismatic crystals, and is precipitated from its aqueous solution by alcohol in microscopic, oblique prisms. The di-acid potassium salt and the normal cadmium, zinc, and strontium salts were also prepared.

The *phenylhydrazide* crystallises from 50 per cent. acetic acid in long, slender, yellow needles, is insoluble in cold water, alcohol, and glacial acetic acid, dissolves in concentrated sulphuric acid with a violet colour; it begins to decompose at 200° , and then carbonises to a hard, black mass. Analysis showed that two phenylhydrazine residues were contained in the molecule.

By heating the acid to a temperature slightly above its melting point, only a small quantity of carbonic anhydride was evolved. The melt contained the unaltered acid; neither saccharic, isosaccharic, metasaccharic, mucic acid, nor any other acid could be detected.

E. C. R.

Constitution of Thiocarbamide. By L. STORCH (*Monatsh.*, 11, 452—471).—The author has endeavoured to obtain from thiocarbamide, by the action of oxidising agents, a bisulphide of the constitution $NH:C(NH_2)\cdot S\cdot S\cdot C(NH_2)\cdot NH$ (compare Maly, *Abstr.*, 1890, 1399). The formation of such a compound would lead to the conclusion that thiocarbamide is a mercaptan, having the constitution $NH:C(SH)\cdot NH_2$, and not the symmetrical diamide $NH_2\cdot CS\cdot NH_2$. The oxidation was conducted in acid solutions with iodine, potassium permanganate, potassium chlorate, nitrous acid, and hydrogen peroxide respectively, and in every case the bisulphide was formed. The best yield was obtained when the thiocarbamide (5.5 grams) was dissolved in a mixture of water (100 c.c.) and nitric acid of sp. gr. 1.22 (110 c.c.) and the solution cooled in ice and treated with potassium permanganate (253.5 c.c. of a 0.6619 normal solution), the nitrate of the base, $C_2S_2N_4H_6(HNO_3)_3$, separated in almost insoluble prisms (yield 114—123 per cent. of the thiocarbamide employed). The new compound is gradually decomposed by water with evolution of gas at ordinary temperatures, and cannot be kept for any length of time in the dry state; its aqueous solution does not become coloured when treated with ferric chloride or copper sulphate, but gives a precipitate of silver sulphide on warming with silver nitrate; and its formation favours the view that thiocarbamide must be represented, at least in acid solution, as a mercaptan. When the oxidation is effected in presence of oxalic acid, an acid oxalate, $C_2S_2N_4H_6\cdot 2C_2H_4O_6\cdot \frac{1}{2}H_2O$, is formed.

G. T. M.

Conversion of Alkylthiosinamines and Alkylallylsemithiocarbazides into Isomeric Bases. By C. AVENARIUS (*Ber.*, 24, 260—271).—By the action of potassium thiocyanate on bromethyl-

amine hydrobromide, Gabriel (Abstr., 1889, 848; 1890, 127) obtained a new base, which has one of the following constitutional formulæ:—

The corresponding derivatives containing aromatic radicles were then obtained by Prager (Abstr., 1890, 159) by an intramolecular change from aromatic allylthiocarbamides. The author has investigated the action of hydrochloric acid at 100° on the corresponding alkylallylthiocarbamides, and finds that the reaction takes place in a similar manner.

The substituted allylthiocarbamides or thiosinamines were prepared by the action of the amines on allylthiocarbimide. *Methylthiosinamine*, $\text{NHMe·CS·NH·C}_3\text{H}_5$, is a crystalline mass, melting at 46°, and sparingly soluble in water, readily in alcohol, ether, and benzene; *ethylthiosinamine*, $\text{NHEt·CS·NH·C}_3\text{H}_5$, forms colourless plates melting at 41°; *propylthiosinamine*, $\text{NHPr}^a\text{·CS·NH·C}_3\text{H}_5$, crystallises in thin plates melting at 61°, whilst *amylthiosinamine* could only be obtained as an oil. Of the disubstituted thiosinamines, diethylthiosinamine has already been obtained by Gebhardt (Abstr., 1885, 383); *piperylthiosinamine*, $\text{C}_5\text{H}_{10}\text{N·CS·NH·C}_3\text{H}_5$, could only be obtained as an oil.

The molecular interchange takes place on heating with hydrochloric acid at 100°, and probably proceeds in the following manner:—

Methylpseudothiosinamine, $\begin{array}{c} \text{CHMe·S} \\ | \\ \text{CH}_2\text{—N} \end{array} > \text{C·NHMe}$, is crystalline, melts at 57°, and boils without decomposition at 228°, and yields a *picrate* melting at 147°, and an oily hydrochloride. *Ethylpseudothiosinamine*, $\text{C}_4\text{H}_7\text{NS·NHEt}$, crystallises from light petroleum in slender needles, melts at 63°, and boils at 230°. Its *hydrochloride* is also liquid, whilst the *picrate* forms slender, golden-yellow needles melting at 143°. *Propylpseudothiosinamine*, $\text{C}_4\text{H}_7\text{NS·NHPr}^a$, is a yellow oil which has a strongly basic odour and boils at 237°. Its *platinochloride* and *picrate* crystallise well, the latter melting at 123°. *Amylpseudothiosinamine*, $\text{C}_4\text{H}_7\text{NS·NH·C}_5\text{H}_{11}$, has an extremely unpleasant odour, melts at 32° and boils at 267°.

Diethylpseudothiosinamine, $\text{C}_4\text{H}_7\text{NS·NEt}_2$, is a colourless oil which has also an unpleasant odour, and boils at 226°. Its *platinochloride* melts at 160°, and its *picrate* at 99°. *Piperylpseudothiosinamine*, $\text{C}_4\text{H}_7\text{NS·NC}_5\text{H}_{10}$, is a yellowish oil which boils at 277°, is very sparingly soluble in water, and yields a *picrate* melting at 112°. It is an extremely stable base, and is not altered by sodium in boiling amyl alcohol solution or by phosphonium iodide at 200°. It combines

with methyl iodide forming the *methiodide*, $C_4H_7NS \cdot NC_2H_5 \cdot MeI$, a crystalline, hygroscopic substance which melts at 67° , and is extremely soluble in water. By the action of silver oxide, it yields an oil free from halogen, which is probably $C_4H_7NS \cdot NC_2H_5 \cdot MeOH$, and has an odour resembling that of the lobster. On oxidation, piperylpseudothiosinamine is converted into β -methyltaurine, showing that the sulphur atom causes the closing of the chain.

In order to ascertain whether the alkylated pseudothiosinamines have a constitution corresponding with the first or second of the formulæ given above for the unalkylated base, ethylpseudothiosinamine was treated with ethyl iodide; the diethyl compound obtained was identical with that described above, and therefore contains both ethyl groups combined with the same nitrogen atom. The alkylated bases, as well as the aromatic derivatives obtained by Prager, must, therefore, have the constitution represented by the second formula.

The substituted allylsemithiocarbazides undergo a similar intramolecular change when heated with hydrochloric acid. The following semithiocarbazides have been prepared:—phenylallylsemithiocarbazide, $C_6H_5 \cdot NH \cdot CS \cdot N \cdot H_2Ph$, melting at 118° (see also Dixon, *Trans.*, 1890, 262); *orthotolylallylsemithiocarbazide*, which forms slender needles melting at 105° ; *paratolylallylsemithiocarbazide*, crystallising in small, white needles and melting at 128° ; and β -*naphthylallylsemithiocarbazide*, melting at 155° .

The molecular interchange was carried out in a manner similar to that of the thiosinamines. *Phenylpropylenepseudo-semithiocarbazide*, $C_6H_5NS \cdot N \cdot H_2Ph$, crystallises in yellowish plates, melts at 93° , and yields β -methyltaurine on oxidation; its *hydrochloride* forms stellate groups of pink crystals and melts at 202° , whilst the sparingly soluble *picrate* melts at 167° . *Orthotolylpropylenepseudo-semithiocarbazide* also forms a pink *hydrochloride*, but the free base could not be obtained in crystals. The *paratolyl* compound crystallises from alcohol in slender needles melting at 133° , and the β -*naphthyl* compound forms a flocculent precipitate which, after recrystallisation from alcohol, melts at 160° .

H. G. C.

Action of Ethyl Oxalate on Acetothiënone. By A. ANGELI (*Ber.*, 24, 232—233).—Like benzophenone and pyrrol methyl ketone (*Abstr.*, 1890, 1156, 1243), acetothiënone unites with ethyl oxalate in presence of sodium ethoxide, forming the ethyl salt of acetothiënone-oxalic acid, $C_6H_5 \cdot CO \cdot CH_2 \cdot CO \cdot COOEt$, which separates from light petroleum in large, yellow crystals. It melts at 42° , gives an intense bluish-violet coloration with isatin and sulphuric acid, and is resolved by alcoholic potash into acetothiënone and oxalic acid. Its alcoholic solution gives, with cupric acetate, a copper compound crystallising in pale-green needles; ferric chloride gives an intense red coloration.

It yields compounds with aniline and phenylhydrazine resembling those obtained from the corresponding benzoyl and pyrrolyl compounds. With hydroxylamine, it forms a substance crystallising in long, colourless needles, the constitution of which is probably represented by one of the following formulæ:—

H. G. C.

Biophen. By L. H. LEVI (*Chem. Centr.*, 1890, ii, 949—950; from *Technology Quarterly*, 3, No. 2).—Just as thiophen is prepared by the action of phosphorus trisulphide on succinic acid, so also should a closed-chain compound containing two atoms of sulphur be formed by the action of phosphorus trisulphide on thiodiglycollic acid. By heating a mixture of 5 grams of thiodiglycollic acid and 10 grams of phosphorus trisulphide in 15—20 c.c. of ether in a sealed tube for two hours at 170°, a compound of the formula $\text{S} \begin{array}{c} \text{CH} \cdot \text{CH} \\ \parallel \quad \parallel \\ \text{CH} \cdot \text{CH} \end{array} \text{S}$ is formed, which the author has named *biophen*. The liquid contained in the sealed tube is washed in a separating funnel with potash, dried with calcium chloride, and the ether distilled off, after which the biophen remains as an oil. It boils at 165—170°. With sulphuric acid and isatin, it gives the indophenin reaction.

Acetobienone is prepared by the action of acetic chloride in the presence of aluminium chloride; it is an oil which boils at 300° with decomposition. The *phenylhydrazide*, $\text{C}_6\text{H}_5\text{H}_3\text{CMe} \cdot \text{N}_2\text{HPh}$, melts at 125°. *Phenyl bienyl ketone*, $\text{C}_6\text{H}_5\text{H}_3\text{COPh}$, is prepared in a corresponding manner to the acetyl derivative; it is a dark-brown oil, soluble in alcohol and ether, and boiling at 241°. *Nitrophenyl bienyl ketone*, $\text{C}_{11}\text{H}_7\text{S}_2\text{O}_2\text{N}$, is prepared by the action of nitric acid of sp. gr. 1.62 on the last-named compound, under efficient cooling; it melts at 112°.

J. W. L.

Discrimination between Allylbenzene and Propenylbenzene Derivatives by means of their Dispersive Powers. By R. NASINI (*Rend. Acad. Lincei*, 6, ii, 299—301).—The author claims that Eykman's method of distinguishing allylbenzene from propenylbenzene derivatives (*Abstr.*, 1890, 748) rests on Gladstone's observations (*Trans.*, 1884, 241) and his own (*Rend. Acad. Lincei*, i, i; *Abstr.*, 1885, 210 and 1097).

S. B. A. A.

Lupeol. By A. LUKIBERNIK (*Ber.*, 24, 183—186).—The term lupool is applied to a compound obtained from the husks of *Lupinus luteus* seeds. These are extracted with ether, and the residue remaining after evaporation of the solvent is hydrolysed with alcoholic potash and dissolved in water; on treatment of the solution with ether, the lupeol dissolves, and crystallises on evaporation. It is insoluble in water, but readily dissolves in chloroform, benzene, and light petroleum; from dilute alcohol, it is deposited in long, colourless needles which melt at 204°.

Lupeol has the formula $\text{C}_{28}\text{H}_{48}\text{O}$, and therefore contains two atoms of hydrogen less than cholesterol; its rotatory power is $[\alpha]_D = +27^\circ$; a brown coloration is produced by adding concentrated sulphuric acid to a chloroform solution, whilst the addition of acetic anhydride and two drops of concentrated sulphuric acid yields a red coloration which changes after some time to intense violet-red. The *benzoate*,

$C_{26}H_{41} \cdot OBz$, which may be conveniently employed to obtain pure lupeol, crystallises from ether in lustrous, transparent prisms melting at 250° . The *acetate*, $C_{26}H_{41} \cdot OAc$, is deposited from dilute alcohol in feathery groups of needles melting at 230° .

On treatment with bromine dissolved in chloroform, a *bromo-derivative*, $C_{26}H_{41}BrO$, is formed, crystallising in small, colourless, nodular aggregates and melting at 150° . J. B. T.

Phenoxyethylamine and Paracresoxyethylamine. By R. SCHREIBER (*Ber.*, 24, 189—196; compare C. Schmidt, *Abstr.*, 1890, 373).—*Benzoylphenoxyethylamine*, $OPh \cdot CH_2 \cdot CH_2 \cdot NHBz$, crystallises from very dilute acetic acid in slender, colourless needles, and melts at 93° . The *acetyl derivative* melts at 78° .

Bromethyl cresyl ether, $CH_3Br \cdot CH_2 \cdot O \cdot C_6H_4Me$, is prepared by the action of sodium ethoxide on ethylene bromide and cresol; it crystallises from dilute alcohol, melts at 40° , and boils at $254-255^{\circ}$ without decomposition.

On heating it with potassium phthalimide at 220° , *paracresoxyethylphthalimide*, $C_6H_4Me \cdot O \cdot C_2H_4 \cdot N \cdot C_6H_4O_2$, is formed, and is deposited from alcohol in pale-yellow crystals which melt at 135° ; the yield is 80 per cent. of the theoretical.

Cresoxyethylphthalamic acid, $C_6H_4Me \cdot O \cdot C_2H_4 \cdot NH \cdot CO \cdot C_6H_4 \cdot COOH$, is prepared by dissolving the preceding compound in dilute potash and precipitating with hydrochloric acid; after purification, it is obtained in silvery white crystals melting at 137° . The *silver salt* is white and crystalline. On heating the acid or imide with hydrochloric acid, and treating the product with potassium hydroxide, *paracresoxyethylamine*, $C_6H_4Me \cdot O \cdot CH_2 \cdot CH_2 \cdot NH_2$, is formed; it is a colourless liquid boiling at $242-243^{\circ}$ under a pressure of 779 mm.; on exposure to the air, a solid *carbonate* is obtained. The *hydrochloride* crystallises from alcohol in needles or plates, and melts at 240° . The *picrate*, *platinchloride*, and *aurochloride* are all crystalline; the *nitrite* appears to be stable. The *benzoyl derivative* crystallises from alcohol, benzene, or glacial acetic acid in long, slender needles, and melts at 134° .

Paracresoxyethylcarbamide, $C_6H_4Me \cdot O \cdot C_2H_4 \cdot NH \cdot CO \cdot NH_2$, crystallises from alcohol in needles and melts at 158° . On treating cresoxyethylphthalimide with fuming nitric acid at low temperatures, *dinitrocresoxyethylphthalimide*,

is formed, crystallising from alcohol in lustrous, yellow plates, and melting at 88° . By the action of baryta-water, the nitro-groups are eliminated, and the product appears to undergo further decomposition.

Dinitroparacresol is obtained by the action of nitric acid on bromethyl cresyl ether. On heating the ether with aniline, *cresoxyethylaniline*, $C_6H_4Me \cdot O \cdot CH_2 \cdot CH_2 \cdot NHPh$, is formed; this crystallises from alcohol in small, lustrous plates, and melts at 55° . The *hydrochloride* is crystalline.

Imidoethyl cresyl ether, $NH(CH_2 \cdot CH_2 \cdot O \cdot C_6H_4Me)_2$, is prepared by

the action of alcoholic ammonia on the brominated ether, and crystallises from alcohol in stellate groups of needles melting at 49—50°. The *hydrochloride* melts at 217°. On heating the ether with alcoholic potash, *ethylene tolyl ethyl ether*, $C_6H_4Me \cdot O \cdot CH_2 \cdot CH_2 \cdot OEt$, is obtained as a colourless liquid boiling at 243—244°. With sodium methoxide, the corresponding *methyl ether*, $C_6H_4Me \cdot O \cdot CH_2 \cdot CH_2 \cdot OMe$, is formed; this resembles the preceding compound, and boils at 230°. The *phenyl ether*, $C_6H_4Me \cdot O \cdot CH_2 \cdot CH_2 \cdot OPh$, prepared with sodium phenoxide, crystallises from alcohol in large, colourless plates, and melts at 99°.

Ethylene dicresyl ether, $C_3H_4(O \cdot C_6H_4Me)_2$, is formed by the action of potassium cyanide or dimethylaniline on bromethyl cresyl ether.

J. B. T.

* **Diazo-compounds of the Aromatic Series.** By G. ODDO (*Gazzetta*, 20, 631—654).—When diazobenzene chloride is gradually added to sodium ethoxide at the ordinary temperature with continual agitation, an energetic reaction takes place, accompanied by a rapid evolution of nitrogen and a strong odour of aldehyde; on steam-distilling the product, alcohol, aniline, and diphenyl pass over. If the product is diluted with water and directly distilled, aniline and ammonia are found in the distillate. The reaction is probably represented by the equation $5PhN_2Cl + 5NaOEt = PhNH_2 + NH_3 + 2C_{12}H_{10} + 5NaCl + 5Me \cdot COH + 4N_2$. 5 grams of aniline and 3 grams of diphenyl were obtained from 38 grams of aniline taken for diazotisation. Sodium methoxide acts like the ethoxide.

Diazobenzene chloride is not affected by methyl iodide in the cold, but on heating, much phenol and resinous products are formed, together with a very small quantity of iodobenzene. When, however, methyl iodide is slowly added to a cold mixture of the diazo-salt with the zinc-copper couple, nitrogen is evolved, and on steam-distilling the product, iodobenzene passes over; 20 grams of this compound were thus obtained from 18 grams of aniline. On treating diazobenzene chloride (0.4 mol.) at a low temperature with bromoform (0.4 mol.) and the zinc-copper couple (0.9 mol.), bromobenzene (14 grams) was obtained in like manner. An equal yield of bromobenzene may be had with one-third the above amount of bromoform if the reaction is carried out in a reflux apparatus. When diazobenzene chloride is treated with chloroform and the zinc-copper couple, a complicated reaction takes place, chlorobenzene and diphenyl being formed.

β -Bromonaphthalene is best prepared by the following modification of Gattermann's method (*Abstr.*, 1890, 970). β -Diazonaphthalene bromide (from 14.3 grams of β -naphthylamine) is gradually added to a mixture of potassium bromide (36 grams), water 100 grams, and moist copper powder (30 grams), previously heated to 50—70°, and the whole heated in a reflux apparatus for 15 minutes and then steam-distilled. The yield is 46—48 per cent. when the naphthylamine is thoroughly diazotised. The zinc-copper couple has an action similar to that of the moist copper powder, but the yield is small.

Double Decompositions of Diazo-compounds.—If diazobenzene chloride (1 mol.) is treated with a hot solution of potassium bromide (2 mols.) in water, bromobenzene is formed, together with much resin and traces of phenol. A larger yield is obtained by slowly introducing potassium nitrite into a hot aqueous solution of aniline, hydrochloric acid, and potassium bromide. β -Bromonaphthalene can also be formed by the latter method, the yield being about 10 per cent. of the β -naphthylamine used. By adding diazobenzene chloride to a hot solution of potassium cyanide, benzonitrile is formed (1 to 1.5 grams from 9 grams of aniline); with a hot solution of potassium nitrite, nitrobenzene is obtained. These reactions may be represented by the equation $\text{PhN}_2\text{Cl} + \text{KX}' = \text{PhX}' + \text{KCl} + \text{N}_2$ [$\text{X}' = \text{Br}, \text{CN}, \text{NO}_2, \text{\&c.}$]. On the other hand, if potassium nitrite is added to a mixture of aniline, hydrogen bromide, and sodium chloride, no chlorobenzene, and only traces of bromobenzene are formed.

Dinitroparamidoazobenzene, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{N}_2\cdot\text{C}_6\text{H}_3(\text{NO}_2)\cdot\text{NH}_2$, is prepared by adding a solution of potassium nitrite (8.5 grams) drop by drop to a hot solution of paranitraniline (13.8 grams) in hydrofluoric acid (100 c.c. of 33 to 40 per cent.), and precipitating the liquid portion of the product with water. It crystallises from alcohol in small, yellowish or brownish-red tufts, melts with partial decomposition at $210\text{--}215^\circ$, dissolves very sparingly in alcohol, ether, benzene, and chloroform, moderately in acetic acid, and very freely in solutions of alkaline hydroxides. The alkaline solutions are red, the intensity of the colour diminishing with the molecular weight of the alkali; the red coloration is more intense in alcoholic solutions. On neutralising the solution with an acid, it becomes yellow. In the preparation of this compound, a quantity of nitrophenol is formed, and, if the hydrofluoric acid used is dilute, this is the only product.

Dinitrometamidoazobenzene, prepared in like manner to the preceding compound, crystallises in minute, bright-red, rectangular prisms, melts at $193\text{--}195^\circ$, dissolves sparingly in alcohol, benzene, ether, and chloroform, but very freely in alkalis. The *acetyl* derivative melts at 145° . As bye-products in the preparation of this compound, there are obtained (a) a quantity of *metanitraniline hydrofluoride*, which crystallises from alcohol in light flakes and melts at $185\text{--}190^\circ$; (b) a small amount of ill-defined, reddish-brown crystals, melting at $183\text{--}185^\circ$, of a substance probably isomeric with the azo-compound.

The author considers that the preceding experiments, in connexion with Sandmeyer's and Gattermann's results, indicate that the general conditions for the double decomposition of diazo-compounds by inorganic salts, with elimination of the diazo-group, are that the inorganic and the diazo salt should be of the same character, and that the radicle combined with the diazo-group should be more electronegative than that contained in the inorganic salt. In concluding, the author discusses some of his results from a thermochemical point of view.

S. B. A. A.

Stability of Diazo-compounds in Aqueous Solution. By R. HINCH (Ber., 24, 324–326).—A solution of diazo-orthotoluene in

phenol decomposes much more easily than a similar solution of diazoparatoluene. Aqueous solutions of the diazo-compounds behave in a similar manner. The author determines quantitatively the relative stability of diazo-compounds in the following way.

Aniline (9.3 grams), orthotoluidine and paratoluidine (10.7 grams), metaxylydine (12.1 grams), and sulphanilic acid (17.3 grams) are severally dissolved in water (700 c.c.) and hydrochloric acid (30 c.c.), and then diazotised with nitrite (7.2 grams), dissolved in water, and the solution made up to 1 litre. A solution of sodium naphthol-sulphonate (Schaeffer's salt) is made to correspond with the diazo-solution. The diazo-solutions are then allowed to remain at the ordinary temperature, and the amount of decomposition estimated from time to time as follows:—25 c.c. of the naphthol solution is mixed with a few drops of ammonia and some salt, and the diazo-solution run in from a burette as long as any dye is formed. The results obtained show that the introduction of a methyl group in the para-position into diazobenzene greatly increases the stability, whilst a methyl group in the ortho-position lessens the stability. Metaxylydine stands between orthotoluidine and paratoluidine as regards the stability of its diazo-compound, whilst diazoparaxylydine is more easily decomposed than diazo-orthotoluene. Experiments on the stability of diazobenzene solutions under different conditions showed that the best way to prevent decomposition was to keep the solution cold; the addition of acid prevents decomposition to some extent; sodium acetate and alkalis have no appreciable effect.

E. C. R.

Dry Decomposition of Diazoamido-compounds. By F. HEUSLER (*Annalen*, 260, 227—250).—When diazoamidobenzene (1 mol.) is mixed with liquid paraffin (8—10 parts) and then very gradually heated to 150°, slow decomposition ensues with evolution of nitrogen (1 mol.); the products are benzene, aniline, diphenyl, paramidodiphenyl, and orthamidodiphenyl. The *acetyl* derivative of paramidodiphenyl melts at 171°, that of the ortho-compound at 119°.

The diazoamido-derivatives of paratoluidine and parachloraniline seem to yield, under the same conditions, decomposition products analogous to those obtained from diazoamidobenzene, but the formation of diphenyl-derivatives could not be determined with certainty.

When benzenediazobenzylamide is heated with paraffin in the manner described above, it is decomposed into benzene, benzylamide, small quantities of diphenyl, and benzylideneaniline; the formation of the last-named compound is shown by the fact that when the mixture of decomposition products is treated with hydrochloric acid, benzaldehyde and aniline are obtained.

In studying the decomposition of benzenediazopiperidide, a considerable quantity (250—300 grams) of the dry compound is gradually heated in a large flask, and the decomposition products passed through a Linnemann's dephlegmator, to which is attached a condenser; the temperature of dissociation is about 225—230°, but in order to complete the decomposition, the temperature must finally be raised to about 250°. The residue consists of diphenyl (10 per

cent. of the theoretical quantity) and tarry matters; the distillate contains benzene (52 per cent. of the theoretical quantity), piperidine, small quantities of aniline, and a basic substance which the author names isopiperidine.

Isopiperidine is a thick, sticky liquid, with a strong, narcotic odour, and miscible with water in all proportions; it seems to have the composition $C_8H_{11}N$, but there are several facts which tend to show that it is a mixture. On distillation under the ordinary pressure, it passes over between 260° and 290° , and even on repeated fractionation, a liquid of constant boiling point cannot be obtained. All the salts, except the platinochloride, which crystallises in ruby-red needles, are very hygroscopic, and cannot be obtained in a pure condition for analysis. Isopiperidine reacts with acetic anhydride and with benzoic chloride, yielding oily products, and it combines very energetically with methyl iodide with formation of a very hygroscopic additive compound; benzyl chloride and phenyl cyanate combine with the base very readily, the products being oils; diazobenzene chloride converts it into a yellow, solid compound which very readily resinifies. When isopiperidine is treated with carbon bisulphide in ethereal solution, a yellow substance, which seems to have the composition $2C_{10}H_{13}N_2CS_2$, is precipitated; this compound is decomposed when warmed, either alone or with dilute sulphuric acid, with evolution of hydrogen sulphide. Isopiperidine has powerful reducing properties, gives the carbylamine reaction, and its hydrochloride is partially decomposed by sodium nitrite in the cold; with aqueous solutions of formaldehyde and acetaldehyde it gives colourless, seemingly amorphous precipitates which are soluble in acids, but are reprecipitated by alkalis.

Benzenediazodimethylamide, $Ph \cdot N_2 \cdot NMe_2$, can be obtained in a pure condition by treating an alkaline solution of dimethylamine with diazobenzene chloride, extracting the precipitated oil with ether, and fractionating the dried product under reduced pressure. It is a yellowish, highly refractive liquid, boils at $113-114^\circ$ (12 mm.), and has a sp. gr. of 1.032 at 18° ; when dropped on to sand heated to 253° , it is decomposed into benzene, diphenyl, dimethylamine, and small quantities of a liquid base which was not investigated.

F. S. K.

Action of Phosphorus Pentachloride on Oxyazo-derivatives. By R. PAGANINI (*Ber.*, 24, 365—369; compare this vol., p. 301).—*Paratoluene-azochlorobenzene*, $C_6H_4Me \cdot N_2 \cdot C_6H_4Cl$, is prepared by the action of phosphorus pentachloride on paratoluene-azophenol, and crystallises from alcohol in long, orange-yellow needles melting at $149-150^\circ$; it is very sparingly soluble in concentrated hydrochloric acid, insoluble in alkalis, and on sublimation forms large, yellow plates.

Paratoluene-azophenyl phosphate, $PO(O \cdot C_{10}H_{11}N_2)_2$, is formed together with the preceding compound; it is insoluble in alcohol, but crystallises from acetone in long, lustrous needles, melts at 140° , and is readily hydrolysed by alcoholic potash.

Orthotoluene-azophenol, $C_6H_4Me \cdot N_2 \cdot C_6H_4 \cdot OH$, is obtained by treating

orthotoluidine hydrochloride with nitrous acid, and adding an alkaline solution of phenol; the solution is cooled, and the compound precipitated with carbonic anhydride; after purification, it crystallises from benzene in thick, orange-yellow needles, melts at 101° , and is soluble in dilute ammonia.

Phenoldiazorthotoluene, $\text{OH}\cdot\text{C}_6\text{H}_3(\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\text{Me})_2$, is separated from the previous compound by treatment with dilute ammonia, in which it is very sparingly soluble; it crystallises from alcohol in thin, slender, brownish-red needles, and melts at $116\text{--}117^{\circ}$ with decomposition.

Orthotoluene-azochlorobenzene, $\text{C}_6\text{H}_4\text{Me}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\text{Cl}$, is prepared in a similar manner to the para-derivative, and crystallises from alcohol in small, yellow needles melting at $143\text{--}144^{\circ}$.

Orthotoluene-azophenyl phosphate, $\text{PO}(\text{O}\cdot\text{C}_{17}\text{H}_{11}\text{N}_2)_3$, is sparingly soluble in cold alcohol, and crystallises from acetone in long, orange-needles melting at 116° .

Metatoluene-azophenol is prepared in a similar manner to the ortho-compound, and crystallises from alcohol in yellow cubes melting at 141° . On treatment with phosphorus pentachloride, a compound is obtained in small quantity, which crystallises from alcohol in yellow needles melting at 65° , and is probably *metatoluene-azochlorobenzene*, $\text{C}_6\text{H}_4\text{Me}\cdot\text{N}_2\cdot\text{C}_6\text{H}_4\text{Cl}$.

J. B. T.

Sulphur Derivatives of Amidoximes. By F. TIEMANN (*Ber.*, 24, 369—377).—Compounds free from sulphur are obtained by the action of hydroxylamine on thiocarbimides.

Carbon bisulphide reacts with amidoximes according to the equation

these compounds, which may be termed *amidosulphimes of dithiocarbamid-sulphinic acids*, are very unstable, and on treatment with hydrochloric acid yield amidine hydrochlorides, carbonic anhydride, hydrogen sulphide, and sulphur; on heating the above compounds alone, however, stable derivatives are obtained containing the group $\text{RC}_2\text{N}_2\text{HS}_2$; the same substances, together with amidino thiosulphates, are also formed by heating the sulphinic acid derivatives in air. The constitution of the complex $\text{RC}_2\text{N}_2\text{HS}_2$ is probably represented by one or other of the formulæ $\text{R}\cdot\text{C}\begin{smallmatrix} \text{N}\cdot\text{S} \\ \diagup \quad \diagdown \\ \text{N} \end{smallmatrix}\text{C}\cdot\text{SH}$; $\text{R}\cdot\text{C}\begin{smallmatrix} \text{N}\cdot\text{S} \\ \diagup \quad \diagdown \\ \text{NH} \end{smallmatrix}\text{CS}$.

On heating with hydrochloric acid at 150° , decomposition takes place according to the equation $\text{RC}_2\text{N}_2\text{HS}_2 + 4\text{H}_2\text{O} + 2\text{HCl} = \text{R}\cdot\text{COOH} + \text{CO}_2 + 2\text{NH}_4\text{Cl} + \text{H}_2\text{S} + \text{S}$; on oxidation, 2 mols. combine together with elimination of 1 mol. of hydrogen, and by the action of reducing agents the original compound is regenerated; this behaviour appears to be most readily explained by the first formula, and it is proposed to term the substances *azosulphimcarbohydrosulphides*, in order to show the analogy with the azoximes.

On heating benzenylphenylthiouamidoxime in chloroform solution

with phenylthiocarbimide, water is eliminated, and a compound is formed which is probably *benzenylazosulphimeranilide*,

it does not yield aniline on treatment with hydrochloric acid, and is completely unacted on by carbon bisulphide.

Benzenylparatolylthiouramidoxime yields a corresponding product when heated a little above its boiling point. J. B. T.

Action of Hydroxylamine, Ethoxylamine, and Benzyl-oxyamine on Thiocarbimides. By L. VOLTMER (*Ber.*, 24, 378—385; compare preceding abstract).—*Phenylhydroxythiocarbamide*, $\text{NHPh} \cdot \text{CS} \cdot \text{NH} \cdot \text{OH}$, is prepared by mixing together phenylthiocarbimide and hydroxylamine in molecular proportions; after about 20 minutes, the mixture is well shaken, and allowed to remain for 20 hours at a temperature below 0° ; the crystals which form are separated and washed with chloroform. The compound melts at 106° with evolution of gas, and gives a dark-violet coloration with ferric chloride; it cannot be recrystallised, but dissolves readily in potash, and is precipitated unchanged by acids. No salts could be isolated. When boiled with alcohol, or when fused, sulphur is eliminated and phenylecyanamide is formed; the same change takes place slowly at ordinary temperatures.

Phenylethoxythiocarbamide, $\text{NHPh} \cdot \text{CS} \cdot \text{NH} \cdot \text{OEt}$, is obtained from phenylthiocarbimide and ethoxylamine in a similar manner to the preceding compound, and crystallises from alcohol in colourless, strongly refractive, prismatic plates melting at 103° . The compound is comparatively stable, it gives no coloration with ferric chloride, and when boiled in alcoholic solution, phenylecyanamide, alcohol, and sulphur are formed. *Phenylmethoxythiocarbamide*, $\text{NHPh} \cdot \text{CS} \cdot \text{NH} \cdot \text{OMe}$, prepared from phenylthiocarbimide and methoxylamine, crystallises from alcohol in lustrous needles, and melts at 115° ; the yield is very small.

Phenylbenzyloxythiocarbamide, $\text{NHPh} \cdot \text{CS} \cdot \text{NH} \cdot \text{O} \cdot \text{CH}_2\text{Ph}$, crystallises from alcohol in prisms melting at 115° .

Orthotolylhydroxythiocarbamide, $\text{C}_6\text{H}_4\text{Me} \cdot \text{NH} \cdot \text{CS} \cdot \text{NH} \cdot \text{OH}$, is prepared from orthotolylthiocarbimide and hydroxylamine; it is deposited from chloroform in long, slender needles, melts at 92° , and yields an intense violet coloration with ferric chloride.

Orthotolylcyanamide, $\text{C}_6\text{H}_4\text{Me} \cdot \text{NH} \cdot \text{CN}$, is formed by the decomposition of the preceding compound either at the ordinary temperature or on boiling in solution, but is best prepared by the action of hydroxylamine on orthotolylthiocarbimide at higher temperatures; it crystallises from ether in rhombic plates, melts at 77° , and is readily soluble in alcohol, chloroform, and alkalis, but rather more sparingly in acids. The silver salt decomposes on exposure to light.

Orthotolylbenzyloxythiocarbamide, $\text{C}_6\text{H}_4\text{Me} \cdot \text{NH} \cdot \text{CS} \cdot \text{NH} \cdot \text{O} \cdot \text{CH}_2\text{Ph}$, is deposited from alcohol in crystals, melts at 125° , and closely resembles the corresponding phenyl derivative.

a-Naphthylhydroxythiocarbamide, $\text{C}_{10}\text{H}_7 \cdot \text{NH} \cdot \text{CS} \cdot \text{NH} \cdot \text{OH}$, crystallises

from alcohol in lustrous plates, melts at 116° , and gives a dark bluish-green coloration with ferric chloride. *α -Naphthylecyanamide*, $C_{10}H_7 \cdot NH \cdot CN$, is obtained by heating an alkaline solution of the preceding compound, and crystallises from alcohol in aggregates of slender needles melting at 135° ; the addition of a little potash to an alcoholic solution causes a blue fluorescence. The *silver salt* is white. On heating the amide with hydrochloric acid, a compound is formed which is indifferent towards alkalis and dilute acids, and crystallises in slender needles melting at $209-210^{\circ}$. *α -Naphthylbenzylthiocarbamide*, $C_{10}H_7 \cdot NH \cdot CS \cdot NH \cdot O \cdot CH_2Ph$, melts at $132-133^{\circ}$. No additive product could be obtained from allylthiocarbimide and hydroxylamine.

Phenylbenzylthiocarbamide, $NHPh \cdot CO \cdot NH \cdot O \cdot CH_2Ph$, is prepared by the action of benzylhydroxylamine on phenyl isocyanate in molecular proportion; on the addition of light petroleum to its solution in benzene, it crystallises in long needles melting at 106° . The compound is very stable, and requires heating for a considerable time with hydrochloric acid before decomposition takes place; it is readily soluble in alcohol, ether, and chloroform, but more sparingly in hot water.

J. B. T.

Action of Carbon Bisulphide on Benzenylamidoxime and Parahomobenzenylamidoxime. By G. CRAYEN (*Ber.*, 24, 385—393; compare Schubart, *Abstr.*, 1890, 49).—*Benzenylamidodisulphide benzenylsulphimeditthiocarbamate*,

is prepared by heating carbon bisulphide with dilute alcoholic solution of benzenylamidoxime for 3—4 hours in a reflux apparatus. After remaining for 2—5 days at the ordinary temperature, the crystals which form are separated, and purified by washing with benzene, light petroleum, and ether; they melt at $134-136^{\circ}$ with decomposition, and cannot be recrystallised.

By treatment with hydrochloric acid or soda, benzenylamidine is formed; on heating at 100° in air, *benzenylazosulphimedicarbohydro-sulphide*, $CPh \begin{smallmatrix} \text{N} \cdot \text{S} \\ \diagdown \quad \diagup \\ \text{N} \end{smallmatrix} \text{C} \cdot SH$, and *benzenylamidine thiosulphate*,

are obtained; the former is soluble in alcohol, and crystallises in needles melting at 162° . The compound, which has previously been prepared by Schubart (*loc. cit.*), yields salts with metals, the *mercury derivative* being the most characteristic. The above thiosulphate is deposited from water, on the addition of acetone, in small, lustrous plates melting at 222° .

Benzenylazosulphimedicarboisulphide,

is prepared by the oxidation of the hydrosulphide with nitric acid, chromic anhydride, or potassium permanganate; it is sparingly soluble in alcohol or ether, and crystallises in concentric needles

melting at 120°. The hydrosulphide is regenerated on treatment with sodium amalgam and alcohol.

Benzenylazosulphimecarbothioethyl ether, $\text{CPh} \begin{smallmatrix} \text{N} \cdot \text{S} \\ \diagdown \quad \diagup \\ \text{N} \end{smallmatrix} \text{C} \cdot \text{SEt}$, obtained by the action of ethyl iodide and sodium ethoxide on the hydrosulphide, crystallises from dilute alcohol, and melts at 49°. The corresponding *benzyl ether*, $\text{PhC} \begin{smallmatrix} \text{N} \cdot \text{S} \\ \diagdown \quad \diagup \\ \text{N} \end{smallmatrix} \text{C} \cdot \text{S} \cdot \text{CH}_2\text{Ph}$, melts at 79°.

Parahomobenzenylamidcsulphine parahomobenzenylsulphimedithiocarbamate, $\text{C}_6\text{H}_4\text{Me} \cdot \text{C}(\text{NSH}) \cdot \text{NH} \cdot \text{CSSH} \cdot \text{NH}_2 \cdot \text{C}(\text{C}_6\text{H}_4\text{Me}) \cdot \text{NSH}$, is prepared in a similar manner to the benzenyl derivative; it is very unstable, cannot be recrystallised, and is immediately decomposed when heated. By the action of hydrochloric acid, *parahomobenzenylamidine hydrochloride*, $\text{C}_6\text{H}_4\text{Me} \cdot \text{C}(\text{NH}) \cdot \text{NH}_2 \cdot \text{HCl}$, is formed; this crystallises in colourless prisms melting at 212°. The *platinochloride* melts at 225°.

Parahomobenzenylazosulphimecarbohydrosulphide

is obtained from the mother liquors of the above dithiocarbamate by treatment with hydrochloric acid, and has been previously prepared by Schubart. The *ethyl ether*, $\text{C}_6\text{H}_4\text{Me} \begin{smallmatrix} \text{N} \cdot \text{S} \\ \diagdown \quad \diagup \\ \text{N} \end{smallmatrix} \text{C} \cdot \text{SEt}$, crystallises from ether in large, transparent plates melting at 37°.

Parahomobenzenylazosulphimecarbabisulphide,

is formed by the oxidation of the hydrosulphide with nitric acid, and crystallises from benzene, on the addition of absolute alcohol, in slender, white needles melting at 169°.

Parahomobenzenylamidine parahomobenzenylazosulphimecarbohydrosulphide, $\text{C}_6\text{H}_4\text{Me} \begin{smallmatrix} \text{N} \cdot \text{S} \\ \diagdown \quad \diagup \\ \text{N} \end{smallmatrix} \text{C} \cdot \text{SH} \cdot \text{H}_2\text{N} \cdot \text{C}(\text{NH}) \cdot \text{C}_6\text{H}_4\text{Me}$, is deposited from the mother liquors of the amidosulphimesulphimate in colourless, well-developed crystals which melt at 172°. On treatment with hydrochloric acid, the compound is decomposed into the amidine hydrochloride and the hydrosulphide, and it may be directly prepared from these components.

J. B. T.

Condensation Products from Thiouramidoximes. By H. KOCH (*Ber.*, 24, 394—399).—Benzenylphenylthiouramidoxime, $\text{NOH} \cdot \text{CPh} \cdot \text{NH} \cdot \text{CS} \cdot \text{NHPh}$, is colourless, and melts at 172°, instead of 163°, as stated by Krüger. When heated in chloroform solution with two molecular proportions of phenylthiocarbimide for 10 hours in a reflux apparatus, *benzenylazosulphimecarbamilide*,

is formed; this crystallises from alcohol in small, white plates, and melts at 174°. On heating it with hydrochloric acid in a sealed tube at

150—160°, it yields sulphur, hydrogen sulphide, aniline, ammonia, and benzoic acid.

Benzenylazosulphimecarboparabromanilide,

is prepared by treating the anilide with bromine in glacial acetic acid solution; after precipitation with water, the product crystallises from alcohol in small, white plates; when heated, it decomposes without melting. The constitution of the compound is shown by the formation of parabromacetanilide on hydrolysis and subsequent treatment with glacial acetic acid.

Benzenylazosulphimecarbonitrosoanilide, $\text{CPh} \begin{array}{c} \text{N} \cdot \text{S} \\ \diagup \quad \diagdown \\ \text{N} \end{array} \text{C} \cdot \text{NPh} \cdot \text{NO}$, is prepared by treating the azosulphime, in glacial acetic acid solution, with sodium nitrite; it crystallises in yellow needles, melts at 190° with decomposition, and gives the nitroso-reaction with phenol and sulphuric acid. The *acetanilide*, $\text{CPh} \begin{array}{c} \text{N} \cdot \text{S} \\ \diagup \quad \diagdown \\ \text{N} \end{array} \text{C} \cdot \text{N} \cdot \text{AcPh}$, is formed by heating the anilide with acetic anhydride, and melts at 196°.

Benzenylparatolylthiouramidoxime, $\text{NOH} \cdot \text{CPh} \cdot \text{NH} \cdot \text{CS} \cdot \text{NH} \cdot \text{C}_6\text{H}_4\text{Me}$, prepared from benzylamidoxime and paratolylthiocarbimide, is purified by solution in benzene, and precipitation with light petroleum; it melts at 67°, and readily decomposes.

Benzenylazoximecarboparatoluidide, $\text{CPh} \begin{array}{c} \text{N} \cdot \text{O} \\ \diagup \quad \diagdown \\ \text{N} \end{array} \text{C} \cdot \text{NH} \cdot \text{C}_6\text{H}_4\text{Me}$, is prepared by heating benzenylamidoxime with paratolylthiocarbimide, and crystallises from alcohol in small plates melting at 135°.

Benzenylallylthiouramidoxime, $\text{NOH} \cdot \text{CPh} \cdot \text{NH} \cdot \text{CS} \cdot \text{NH} \cdot \text{C}_3\text{H}_5$, is obtained in a similar manner to the preceding compound; on the addition of light petroleum to its solution in benzene, it crystallises out in slender, silky needles melting at 71°. All attempts to obtain condensation compounds from it were unsuccessful. J. B. T.

Reduction of Aromatic Amides. By A. HUTCHINSON (*Ber.*, 24, 173—178; compare E. Fletcher, *Abstr.*, 1890, 597).—Aromatic amides containing the carboxyl group linked to the benzene nucleus are readily reduced to the corresponding alcohol by the action of sodium amalgam in acid solution, a certain quantity of resinous matter being also formed. The amides examined were those of orthotoluic acid, salicylic acid, parahydroxybenzoic acid, and paramethoxybenzoic acid.

With the carboxyl group in the side chain, a different result is obtained; thus phenylacetamide is unaltered, and cinnamide yields phenylpropionamide.

The behaviour of phenylacetamide, phenylpropionamide, and salicylamide in alkaline solution is the same as in acid solution.

Paramethoxybenzamide in alkaline solution, in addition to the products just mentioned, yields considerable quantities of anisole.

Benzamide yields benzyl alcohol, resinous matter, and about 7 per cent. of *dihydrobenzamide*, $\text{C}_6\text{H}_7 \cdot \text{CONH}_2$, crystallising from water or

alcohol in silvery, lustrous plates, and melting at 152—153°. This compound is unaffected by nascent hydrogen. When treated with alkalis it is hydrolysed; the *dihydrobenzoic acid* thus formed melts below 100°, and is readily soluble in water.

Orthotoluidamide behaves exactly like benzamide; *orthodihydrotoluamide*, $C_6H_4Me \cdot CONH_2$, crystallises from water, and melts at 155—156°. The corresponding *acid* melts at 68°, and is volatile with steam. J. B. T.

Nitro- and Amido-derivatives of Phenylacetamide. By A. PUGGOTTI (*Gazzetta*, 20, 593—600).—The author has previously described (this vol., p. 59) the formation of phenylacetamide by the action of concentrated sulphuric acid on benzonitrile; the following derivatives have now been examined.

Paranitrophenylacetamide, $NO_2 \cdot C_6H_4 \cdot CH_2 \cdot CONH_2$, is prepared by introducing phenylacetamide in small quantities at a time into a well-cooled mixture of an equal weight of nitric acid and twice its weight of sulphuric acid, allowing it to remain for a few hours, and pouring it into an excess of water. After purification, it crystallises from boiling alcohol in colourless, acicular prisms, melts at 197—198°, dissolves freely in hot water and acetic acid, but only very sparingly in ether, benzene, and cold water. On boiling with dilute sulphuric acid, it is converted into paranitrophenylacetic acid melting at 150—151°.

Metanitrophenylacetamide is prepared by evaporating at the ordinary temperature the mother liquors obtained in the preparation of the preceding compound. It crystallises in microscopic, hexagonal pyramids, melts at 109—110°, and dissolves freely in cold water and in benzene. On boiling it with a solution of sodium hydroxide, ammonia is evolved, and sodium metanitrophenylacetate remains.

Paramidophenylacetamide, prepared by reducing the corresponding nitro-derivative with ammonium sulphide, crystallises in glistening scales, melts at 153—154°, dissolves readily in cold alcohol and warm water, but only sparingly in benzene.

Paracetamidophenylacetamide, $NHAc \cdot C_6H_4 \cdot CH_2 \cdot CONH_2$, prepared by heating a mixture of the preceding compound with acetamide in molecular proportion at 160—170°, forms a white, amorphous powder, melts at 235°, and dissolves sparingly in boiling water. On boiling with dilute sulphuric acid, it is converted into the sulphate of paramidophenylacetic acid. S. B. A. A.

Derivatives of Cinnamaldehyde. By A. NAAR (*Ber.*, 24, 244—252).—Chlorine acts on cinnamaldehyde in chloroform solution in a manner similar to bromine (*Abstr.*, 1884, 1343), forming the additive compound $CHPhCl \cdot CHCl \cdot COH$, which, however, loses hydrogen chloride very readily, forming *α -chlorocinnamaldehyde*, $CHPh \cdot CCl \cdot COH$. It is best prepared by boiling an acetic acid solution of the dichloride with potassium acetate, and crystallises from a mixture of ether and light petroleum in large, lustrous, rhombic crystals melting at 34—36°. Its *oxime*, $CHPh \cdot CCl \cdot CH \cdot NOH$, crystallises in long plates melting at 157—159°; its *hydrazone*,

$\text{CHPh}:\text{CCl}:\text{CH}:\text{N}_2\text{HPh}$, in narrow, yellow plates melting at 160° , and becoming brown in the air, and the compound with dimethylparadiamidobenzene, $\text{CHPh}:\text{CCl}:\text{CH}:\text{N}:\text{C}_6\text{H}_4:\text{NMe}_2$, in orange-yellow needles, which are decomposed by heating with acids.

α -Bromocinnamaldehyde, $\text{CHPh}:\text{CBr}:\text{CH}:\text{N}:\text{OH}$, crystallises in nacreous plates melting at 135 – 136° , and the dimethylparadiamidobenzene compound in yellow scales melting at 253 – 255° .

Both α -chlorocinnamaldehyde and α -bromocinnamaldehyde are readily acted on by nitric acid, with simultaneous formation of ortho- and para-derivatives. *Paranitrochlorocinnamaldehyde*,

crystallises in yellow needles melting at 145° , which may be separated from the ortho-compound by their insolubility in ether. The *oxime* crystallises from alcohol in yellowish needles melting at 213 – 215° ; the *hydrazone* in cinnabar-red plates melting at 179° ; and the dimethylparadiamidobenzene compound in dark-brown needles melting at 185° . *Orthonitrochlorocinnamaldehyde* forms yellowish needles melting at 112 – 113° ; the *oxime* crystallises in a similar manner, and melts at 191° ; the *hydrazone* forms yellowish plates, which become brown in the air, and melts at 140 – 141° , whilst the dimethylparadiamidobenzene compound forms reddish-brown prisms melting at 128 – 130° . The corresponding ortho- and para-nitro-bromocinnamaldehydes have been already described (*loc. cit.*). Their *oximes* form yellow needles melting at 161 – 162° and 205 – 207° respectively, and the dimethylparadiamidobenzene compounds crystallise in lustrous, bronze-coloured needles, both melting at 172 – 173° .

By the oxidation of α -chlorocinnamaldehyde, the corresponding α -chlorocinnamic acid, $\text{CHPh}:\text{CCl}:\text{COOH}$, melting at 138 – 139° , is formed; it has already been frequently prepared. It gives a characteristic barium salt $(\text{C}_6\text{H}_4\text{ClO}_2)_2\text{Ba} + \text{H}_2\text{O}$, which crystallises from hot water in lustrous plates. *Paranitrochlorocinnamaldehyde* yields the corresponding acid with chromic acid, but is converted into *paranitrobenzoic acid* on further oxidation. *Orthonitrochlorocinnamic acid*, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{CCl}:\text{COOH}$, is obtained in a similar manner, and crystallises from water in lustrous needles melting at 201 – 202° ; it is completely destroyed by further oxidation. The brominated derivatives behave in a similar manner; *orthonitro- α -bromocinnamic acid*, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{CBr}:\text{COOH}$, forms slender, colourless needles, and melts with decomposition at 211 – 212° .

Metanitrocinnamaldehyde is also acted on by chlorine forming an additive product, which readily loses hydrogen chloride yielding *metanitro- α -chlorocinnamaldehyde*, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CH}:\text{CCl}:\text{COH}$. This crystallises from alcohol in pale-yellow plates melting at 112° ; its *oxime* forms yellowish needles which melt at 185 – 186° , its *hydrazone* pale-yellow scales melting at 154 – 156° , and the dimethylparadiamidobenzene derivative, obtuse, brown needles melting at 225 – 227° . The corresponding *metanitro- α -bromocinnamaldehyde* and its *hydrazone* have been prepared by Kinkelin (Abstr., 1885, 791); the *oxime* crystallises in pale-yellow needles melting at 199 – 200° , and the dimethylparadiamidobenzene compound in reddish-brown prisms

melting at 145—147°. *Metanitrochlorocinnamic acid* and *metanitrobromocinnamic acid* are obtained by the oxidation of the aldehydes, and crystallise in colourless, matted needles melting at 205—207° and 211—213° respectively.

H. G. C.

Aromatic Alkyl Ketones and their Oxidation by Potassium Permanganate. By A. CLAUS (*J. pr. Chem.* [2], 43, 138—147; compare Abstr., 1890, 769, 979; this vol., p. 199).—*Paracymylglyoxylic acid* [$\text{Me} : \text{COOH} : \text{Pr} = 1 : 2 : 4$] is obtained by slowly oxidising paracymylglyoxylic acid (this vol. p. 199) with acid solution of potassium permanganate, and separating the product by sublimation with steam as soon as possible to prevent further oxidation; it crystallises in small, colourless needles, melts at 69° (uncorr.), and sublimes.

Metaxylyl ethyl ketone [$\text{Me} : \text{COEt} : \text{Me} = 1 : 2 : 5$] is a colourless, aromatic, refractive liquid which boils at 238—239° (uncorr.). It dissolves in most solvents except water, is slightly volatile with steam, and does not solidify at -10° . The *phenylhydrazide* forms colourless leaflets which melt at 126° (uncorr.) and dissolve in hot water, alcohol, ether, and glacial acetic acid.

Metaxylylglyoxylic acid [$\text{Me}_2 : \text{CO} \cdot \text{COOH} = 1 : 5 : 2$] (Abstr., 1886, 463), obtained by oxidising the ketone with permanganate, crystallises in long, flat prisms (with $\frac{1}{2}$ mol. H_2O) when hydrochloric acid is added to a hot dilute aqueous solution of its salts, and can be recrystallised in the same form (with $\frac{1}{2}$ mol. H_2O) from a mixture of chloroform and light petroleum; these crystals melt at 53—54° (uncorr.). But if hydrochloric acid is added to the solution of the salt in the cold, the glyoxylic acid separates as an oil which soon solidifies to a crystalline mass melting at 85° (uncorr.). The *barium* salt crystallises with 2 mols. H_2O ; the *calcium* salt with 2 or 4 $\frac{1}{2}$ mols. H_2O , according to the conditions; the *sodium* salt crystallises from aqueous alcohol with 6 mols. H_2O , and from water with 1 $\frac{1}{2}$ mols.; the *potassium* salt crystallises with 1 mol. H_2O from water, and with varying amounts of H_2O from aqueous alcohol. When reduced with sodium amalgam, this acid yields *metaxylylglycollic acid* [$\text{Me}_2 : \text{CH}(\text{OH}) \cdot \text{COOH} = 1 : 5 : 2$]; it crystallises from hot water in colourless, transparent rhombohedra, and from a mixture of chloroform and light petroleum in leaflets; it melts at 119° (uncorr.), and sublimes in small, lustrous rhombohedra.

Paraxylyl ethyl ketone has been already described (Abstr., 1887, 253); its oxidation does not produce paraxylyl- β -ketonic acid (*loc. cit.*), but paraxylylglyoxylic acid (Abstr., 1885, 1136), the so-called β -ketonic acid previously obtained being probably a mixture of the glyoxylic acid with xylylcarboxylic acid. Paraxylylglycollic acid (paraxylylhydroxyacetic acid, *loc. cit.*) crystallises in lustrous, colourless needles and prisms which melt at 114° (uncorr.), and dissolve in hot water, alcohol, ether, chloroform, and glacial acetic acid.

A. G. B.

Bromonitrobenzoic Acids. By A. CLAUS and W. SCHEULEN (*J. pr. Chem.* [2], 43, 200—207; compare Abstr., 1888, 594; 1889, 987, 988).—*Metabromoparanitracetanilide* [$\text{Br} : \text{NO}_2 : \text{NH}_2\text{Ac} =$

3 : 4 : 1], obtained by nitrating metabromacetanilide, crystallises in broad, nearly colourless needles. *Metabromorthonitracetanilide* [Br : NO₂ : NH₂Ac = 3 : 6 : 1], which is obtained at the same time, forms colourless needles and melts at 139°; it dissolves in chloroform and ether, whereby it is separated from the metapara-compound.

Metabromoparanitraniline [Br : NO₂ : NH₂ = 3 : 4 : 1], obtained by de-acetylising the acetanilide with sulphuric acid, crystallises in lustrous, yellow, stellate needles; it melts at 172° (uncorr.), and is soluble in alcohol, but insoluble in chloroform, benzene, light petroleum, and, nearly so, in water.

Metabromoparunitrobenzonitrile [Br : NO₂ : CN = 3 : 4 : 1], obtained by means of the diazo-compound, forms colourless needles, and melts at 104° (uncorr.); it dissolves easily in benzene and in hot water.

Metabromoparunitrobenzoic acid [Br : NO₂ : COOH = 3 : 4 : 1], obtained by heating the nitrile with sulphuric acid, crystallises in long, colourless needles, melts at 197° (uncorr.), and dissolves sparingly in cold water, but freely in other solvents. The *sodium*, *potassium* (with 2 mols. H₂O), *barium* (with $\frac{1}{2}$ mol. H₂O), *lead* (with 1 mol. H₂O), *silver*, and *copper* salts are described.

Parabromorthonitrobenzonitrile [Br : NO₂ : CN = 4 : 2 : 1] crystallises in yellowish needles, melts at 99° (uncorr.), sublimes without decomposition, and dissolves in hot water and other solvents.

Parabromorthonitrobenzoic acid [Br : NO₂ : COOH = 4 : 2 : 1] crystallises in large, lustrous, transparent, colourless, columnar needles which melt at 163° (uncorr.), and dissolve freely in most solvents, except cold water. The *sodium*, *potassium*, *ammonium*, *calcium* (with 2 mols. H₂O), *barium*, *lead* (with 1 mol. H₂O), *copper* (with 7 mols. H₂O), and *silver* salts are described.

Parabromorthumidobenzoic acid [Br : NH₂ : COOH = 4 : 2 : 1] crystallises in long, colourless, strongly refractive needles which melt at 222° (uncorr.), and are easily soluble in alcohol, ether, and chloroform. The *barium* (with 1 mol. H₂O), *calcium* (with $\frac{1}{2}$ mol. H₂O), and *silver* salts are described.

A. G. B.

New Mode of Formation of Benzoic Anhydride. By G. MINUNNI and L. CABERTI (*Gazzetta*, 20, 655—656).—A mixture of freshly-distilled benzoic chloride (50 grams) and fused and powdered sodium nitrite (150 grams) is heated for about 12 hours on the water-bath, the product extracted with dry ether, and freed from traces of benzoic acid by rapidly washing with a very dilute solution of sodium carbonate, and then with distilled water. The crude product is very pure. When dried in a vacuum, it melts at 42—43°. The yield is 74 per cent. Acetic chloride similarly treated with sodium nitrite is largely resinified: a small amount of acetic anhydride may, however, be extracted. The reaction is probably $2\text{BzCl} + 2\text{NaNO}_2 = \text{Bz}_2\text{O} + 2\text{NaCl} + \text{N}_2\text{O}_3$.

S. B. A. A.

New Method for Obtaining Aromatic Carboxylic Acids. By H. FREY and M. HOROWITZ (*J. pr. Chem.* [2], 43, 113—124).—The

aromatic hydrocarbon is heated with a fatty acid, zinc chloride, and phosphorus oxychloride.

Toluene (1 part), glacial acetic acid (2 parts), and granulated zinc chloride (2 parts) are heated in a reflux apparatus at 105–110°; when the zinc chloride has dissolved, phosphorus oxychloride (1 part) is added by degrees through the condenser, the flask being shaken meanwhile; the temperature is now raised to 115–120° and kept at that until the mixture has become greenish-black and ceases to evolve large bubbles of hydrogen chloride. The product is then mixed with much water, whereby a resin is separated from which the paratoluic acid is extracted with 5 per cent. aqueous soda; the yield is 30–35 per cent. of the toluene. Methyl tolyl ketone (Abstr., 1882, 970) is obtained at the same time, but only in small quantity, unless the heating is discontinued while much hydrogen chloride is coming off; the product is then distilled with steam and the ketone extracted from the distillate by ether. Methyl chloride is evolved during the reaction, and the authors are thus led to the following explanation:—

- (1.) $C_6H_5Me + Me \cdot COOH = C_6H_5Me \cdot COMe + H_2O.$
- (2.) $C_6H_5Me \cdot COMe + POCl_3 = C_6H_5Me \cdot CO \cdot POCl_2 + MeCl.$
- (3.) $C_6H_5Me \cdot CO \cdot POCl_2 + 3H_2O = C_6H_5Me \cdot COOH + H_3PO,$
 $+ 2HCl.$

By the same method, metaxylene and acetic acid yielded orthoparaxylic acid [$COOH : Me_2 = 1 : 2 : 4$], which was found to melt at 122°, thus confirming Kekulé and Hepp, and controverting others who give the melting point as 126°; on nitration, it yielded a dinitroxylic acid melting at 197°. Orthoparadimethylacetophenone (b. p. 224–225° under a pressure of 715 mm.; compare Claus, Abstr., 1886, 463) can also be prepared (25 per cent.) by this method; a tribromoderivative melting at 69° was obtained.

Paraxylene yielded the xylic acid [$COOH : Me_2 = 1 : 2 : 5$] melting at 132° (Abstr., 1882, 187), and orthoxylene the acid [$1 : 3 : 4$] melting at 163°. These and other experiments show that the method is a general one. A. G. B.

Cumarone. By D. BIZZARRI (*Gazzetta*, 20, 607–611).—Cumarone, prepared by the dry distillation of cumarilic acid with lime according to Fittig and Ebert's method (Abstr., 1883, 474), is a colourless liquid boiling at 169°, which powerfully resists the action of heat and reagents. It is not altered by heating to redness with quicklime and ammonium chloride. It is not affected by aqueous or alcoholic ammonia, even after prolonged heating at 140°; aniline alone has no action on it, even after heating for 40 hours at 230–250°, but the addition of sulphuric acid effects a condensation of the two compounds—a reddish resin being formed. When heated with aniline and zinc chloride at 220°, a brown mass is formed consisting of various impure products, a reddish-yellow, semitransparent resin—probably Kraemer and Spilker's paracumarone, and, lastly, a compound crystallising from benzene in pale yellowish plates

soluble in alcohol and ether and giving in alcoholic solution a yellow *picrate* and a white, flocculent *hydrochloride*. The latter darkens on exposure to the air, and has approximately the composition of amidophenanthrene hydrochloride.

When the crystals are dissolved in concentrated sulphuric acid, nitrous fumes passed into the solution, and the product thrown into boiling absolute alcohol, aldehyde is evolved, and the residue contains a small quantity of phenanthrene. If the crystals are directly oxidised by chromic acid, amidophenanthraquinone is obtained.

S. B. A. A.

Condensation Products of Anilidoglutaric Acid. By A. REISSERT (*Ber.*, 24, 314—320).—Some time ago the author described two substances, namely, pyranilpyrrolactone and phenylketoxydimethylanilidotetrahydropyridinecarboxylic lactone, which he obtained by heating anilidoglutaric acid at 170—180° until the evolution of gas was at an end (compare *Abstr.*, 1888, 694; 1889, 1174). Anschütz (*Abstr.*, 1890, 774) came to the conclusion that pyranilpyrrolactone is identical with citraconanil, because when anilidoglutaric acid is distilled under reduced pressure, it yields citraconanil only. The author has repeated his experiments, and finds that the two substances described by him are in fact obtained when anilidoglutaric acid is heated at 170—180°, but that they are not definite chemical compounds. Pyranilpyrrolactone is a mixture of citraconanil and the second condensation product of anilidoglutaric acid. Pyranilpyrrolactonic acid (*loc. cit.*) is a mixture of mesaconanilic acid with the acid (m. p. 150°) previously described (*loc. cit.*).

Phenylketoxydimethylanilidotetrahydropyridinecarboxylic lactone is simply anilidoglutaranil, so that the names and constitutional formulæ assigned to all the derivatives of this compound, which have been previously described, must be altered.

F. S. K.

Metadinitrodiphenyldisulphine. By A. EKBOM (*Ber.*, 24, 335—338).—*Metadinitrodiphenyldisulphine*, $\text{NO}_2\cdot\text{C}_6\text{H}_4\cdot\text{SO}\cdot\text{SO}\cdot\text{C}_6\text{H}_4\cdot\text{NO}_2$, is obtained by heating metanitrobenzenesulphonic chloride, dissolved in acetic acid, with the calculated quantity of hydriodic acid (sp. gr. = 1.5) for $2\frac{1}{2}$ hours on the water-bath. The product is treated with water, the precipitate washed with alcohol, and then crystallised from alcohol. The yield is about 50 per cent. of that required by theory. It crystallises in rhombohedral prisms or beautiful needles, melts at 124°, is easily soluble in acetic acid and hot alcohol, sparingly in cold alcohol and light petroleum, and insoluble in water. When heated in acetic acid solution on the water-bath with hydriodic acid (sp. gr. = 1.5), or with sulphurous acid, it is reduced to metadinitrodiphenyl bisulphide. The latter crystallises from alcohol in needles or rhombic tablets, and melts at 84°.

E. C. R.

Substituted Sulphones. By W. AUTENRIETH (*Ber.*, 24, 166—172; compare E. Stuffer, this vol., p. 180).—*Thioethylacetone ethylmercaptole*, $\text{SEt}\cdot\text{CH}_2\cdot\text{CMe}(\text{SEt})_2$, is obtained by the action of hydrogen chloride on a mixture of thioethylacetone (1 mol.) with ethyl mercaptan (2 mols.); it is a yellow, oily liquid which decomposes on

distillation. On treatment with potassium permanganate, the corresponding trisulphone, $\text{SO}_2\text{Et}\cdot\text{CH}_2\cdot\text{CMe}(\text{SO}_2\text{Et})_2$, is formed, from which the author was unable to prepare a methyl derivative.

Thiophenylacetonedithylmercaptole, $\text{SPh}\cdot\text{CH}_2\cdot\text{CMe}(\text{SEt})_2$, from thiophenylacetone and ethyl mercaptan, is a yellow, viscid liquid which cannot be distilled. The trisulphone, $\text{SO}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CMe}(\text{SO}_2\text{Et})_2$, solidifies with difficulty, crystallises from alcohol in lustrous plates, melts at $127\text{--}128^\circ$, and is insoluble in water. On heating it with normal potash solution for three hours in a reflux apparatus, the three sulphone groups are eliminated.

Thioethylacetonediphenylmercaptole, $\text{SEt}\cdot\text{CH}_2\cdot\text{CMe}(\text{SPh})_2$, from thioethylacetone and phenyl mercaptan, resembles the preceding compounds; no trisulphone could, however, be obtained from it.

Thiophenylacetonediphenylmercaptole, $\text{SPh}\cdot\text{CH}_2\cdot\text{CMe}(\text{SPh})_2$, prepared from thiophenylacetone and phenyl mercaptan, crystallises from alcohol in cubic crystals, melts at $54\text{--}55^\circ$, and dissolves readily in ether, but is insoluble in water. No corresponding trisulphone could be obtained.

Chloracetonedithylmercaptole, $\text{CH}_2\text{Cl}\cdot\text{CMe}(\text{SEt})_2$, is formed by the action of chloracetone on ethyl mercaptan. It is a colourless oil which is volatile with steam, and on oxidation yields *diethylsulphone-chlorodimethylmethane*, $\text{CH}_2\text{Cl}\cdot\text{CMe}(\text{SO}_2\text{Et})_2$; this crystallises from water in small, white, lustrous plates, melts at $78\text{--}79^\circ$, and is readily soluble in alcohol, ether, or chloroform; by treatment with potash, it is completely hydrolysed; the chlorine atom appears to be very firmly linked in the molecule, since all attempts to replace it have hitherto been unsuccessful. J. B. T.

Phenylsulphoneacetone-mercaptole. By R. OTTO and A. RÖSSING (*Ber.*, 24, 234—237).—It has already been shown by R. and W. OTTO (*Abstr.*, 1888, 262) that phenylsulphoneacetone is converted by treatment with thiophenol in presence of a dehydrating agent into phenylsulphoneacetonediphenylmercaptole,

By the oxidation of the latter with potassium permanganate, an insoluble product is obtained, which appears to consist of *thiophenyl-diphenylsulphonepropane*, $\text{SO}_2\text{Ph}\cdot\text{CH}_2\cdot\text{CMe}(\text{SPh})\cdot\text{SO}_2\text{Ph}$. It is a granular, crystalline compound melting at $148\text{--}149^\circ$, and sparingly soluble in alcohol. On further oxidation, it is converted into benzenesulphonic acid, which is therefore also found in large quantity in the original oxidation product.

Aqueous potash quickly converts the mercaptole into methylphenylsulphone, thiophenol, and acetic acid, but it is not attacked by reducing agents in acid solution. H. G. C.

Benzenesulphonates of Aromatic Radicles. By M. GORODITSKY (*Ber.*, 24, 416—418).—Benzenesulphonic chloride acts on dilute alkaline solutions of phenols in the same manner as on other hydroxy-compounds (this vol., pp. 49, 202), forming salts of benzenesulphonic acid. *Phenyl benzenesulphonate*, $\text{C}_6\text{H}_5\cdot\text{SO}_3\text{Ph}$, obtained from phenol,

forms colourless crystals, and melts at 35—36° (see also following abstract). It is a very stable compound, and is not attacked by an acetic acid solution of hydrogen chloride at 160°, and only with difficulty by hot alcoholic potash.

β-Naphthyl benzenesulphonate, $C_{10}H_7SO_2 \cdot C_6H_5$, prepared from *β*-naphthol, also forms colourless crystals, and melts at 105—107°. *Oymyl benzenesulphonate*, $C_6H_5 \cdot SO_2 \cdot C_6H_4 \cdot Me \cdot Pi$, is a pulverulent precipitate, but may be obtained from hot alcohol in needles melting at 55—56°. *Resorcinyl phenylsulphonate*, $C_6H_4(O \cdot SO_2Ph)_2$, crystallises from hot alcohol in needles, and melts at 67—70°; the *quinol* derivative, $C_6H_4(O \cdot SO_2Ph)_2$, forms pale, yellowish crystals, and melts at 120—121°; the *pyrogallol* and *phloroglucinol* derivatives, $C_6H_3(O \cdot SO_2Ph)_3$, both separate from alcohol in colourless crystals melting at 140—142° and 115—117° respectively. All these compounds are soluble in hot alcohol, benzene, chloroform, and carbon bisulphide, but only dissolve sparingly in ether. H. G. C.

Benzenesulphonates of Aromatic Radicles. By R OTTO (*Ber.*, 24, 643—644).—In connection with Georgescu's paper on this subject (preceding abstract), the author points out that five years ago he obtained phenyl benzenesulphonate and some of its homologues, and published an account of their chemical and crystallographical properties (*Abstr.*, 1886, 883). H. G. C.

Aromatic Sulphonamic Acids. By W. TRAUBE (*Ber.*, 24, 360—364; compare *Abstr.*, 1890, 1137).—On adding 1 molecular proportion of aniline to a solution of chlorosulphonic acid in chloroform, aniline chlorosulphonate is probably formed: the further addition of aniline causes the production of aniline phenylsulphonamate. This substance is also obtained, together with aniline sulphate, by the action of fuming sulphuric acid on aniline at low temperatures; it thus appears probable that the formation of sulphanilic acid is preceded by that of phenylsulphonamic acid.

Barium dibromophenylsulphonamate, $(C_6H_4Br_2 \cdot NH \cdot SO_2)_2Ba$, is prepared by the action of bromine-water on barium phenylsulphonamate, and crystallises from dilute ammonia; on treatment with acids, it yields dibromaniline and sulphuric acid.

Sulphanilide, $SO_2(NHPh)_2$, was the only compound that could be obtained by the action of phosphorus pentachloride or phosphorus oxychloride on phenylsulphonamic acid; it is very sparingly soluble in water, but dissolves in alkalis, and is not affected by acids.

Ammonium methylphenylsulphonamate, $NMePh \cdot SO_2NH_4$, is prepared from chlorosulphonic acid and methylaniline in the manner already described (*loc. cit.*); the *potassium salt* forms a crystalline powder.

Ammonium diphenylsulphonamate is very unstable.

Ammonium β-naphthylsulphonamate is deposited from water in colourless crystals which slowly become red on exposure to air.

Diethylsulphonamic acid, $N(C_2H_5)_2 \cdot SO_2H$, is prepared from chlorosulphonic acid and diethylamine; it crystallises from alcohol, and melts at 98°. The compound is not affected by boiling with water or

dilute acids, but is decomposed by concentrated acids. The stability of the sulphonamic acids is therefore decreased by the presence of aromatic groups; compounds containing two aromatic radicles decompose even in alkaline solution, whilst those with only one yield crystalline salts. J. B. T.

Orthodinitrodiphenyl and Orthodiamidodiphenyl. By E. TAUBER (*Ber.*, 24, 197—201).—2:6'-*Orthodinitrodiphenyl*, $C_{12}H_8(NO_2)_2$ [$(NO_2)_2 = 2:2'$], is prepared by the action of ethyl nitrite on metadinitrobenzidine hydrochloride; it crystallises from alcohol in straw-coloured needles, melts at 124° , and is readily soluble in benzene and glacial acetic acid, but only very sparingly in light petroleum. On reduction with tin and hydrochloric acid, *orthodiamidodiphenyl*, $C_{12}H_8(NH_2)_2$, is formed, crystallising from dilute alcohol in small, colourless needles, and melting at 81° ; in small quantities, it may be distilled without composition. The *hydrochloride* and *sulphate* are crystalline, and readily soluble in water or dilute alcohol.

The amide yields a *tetraso*-derivative, which has only very feeble tinctorial properties; on boiling the chloride with water, a substance is obtained which is probably impure diphenylene oxide.

The *diacetyl derivative* of diamidodiphenyl crystallises from absolute alcohol in small, colourless prisms melting at 161° .

Carbazole is obtained by heating orthodiamidodiphenyl with six parts of dilute (25 per cent.) sulphuric acid in a sealed tube for 15 hours at 200° ; an equivalent quantity of 15 per. cent. hydrochloric acid may also be employed. J. B. T.

Carbazole. By G. MAZZARA (*Ber.*, 24, 278—281).—*Benzoylcarbazole*, $C_{15}H_9N \cdot COPh$, is formed when carbazole is heated with excess of benzoic chloride at 160 — 170° for two hours. It crystallises from boiling alcohol in greenish needles, melts at 98.5° , is volatile with steam, and is moderately easily soluble in ether, but only sparingly in benzene and light petroleum; it dissolves in glacial acetic acid yielding a green solution, and is decomposed by alcoholic potash into carbazole and benzoic acid. It is not acted on by phenylhydrazine in boiling alcoholic solution, but hydroxylamine, under the same conditions, decomposes it, and carbazole is produced. The *nitro*-compound, $NO_2 \cdot C_{15}H_9N \cdot COPh$, can be prepared by gradually adding nitric acid of sp. gr. 1.48 (18 grams), to a lukewarm glacial acetic acid solution of benzoylcarbazole (9 grams), and then heating the mixture on the water-bath for a few minutes. It crystallises from boiling glacial acetic acid in yellow plates, melts at 181° , and is soluble in warm ether and benzene, but only sparingly in alcohol and light petroleum; it is not acted on by boiling potash, but boiling 6 per cent. alcoholic potash slowly converts it into *nitrocarbazole*, $C_{15}H_9N_2O_2$. This compound crystallises from boiling alcohol in plates, melts at 210° to a red liquid, and is only sparingly soluble in warm glacial acetic acid, chloroform, and benzene, and almost insoluble in ether and light petroleum. F. S. K.

Carbazole Syntheses. By A. BLANK (*Ber.*, **24**, 306).—Carbazole is formed in considerable quantity when the vapour of orthamidodiphenyl is passed over heated lime. Amidocarbazole, $\begin{matrix} \text{NH}_2\cdot\text{C}_6\text{H}_3 \\ \text{C}_6\text{H}_4 \end{matrix} > \text{NH}$, can be obtained from diphenylene in like manner; it crystallises from water in small, slender needles melting at 238°. F. S. K.

Condensation of Unsaturated Hydrocarbons with Phenols.
Tetrahydronaphthylphenol. By W. KOENIGS (*Ber.*, **24**, 179—181; compare this vol., p. 208). *Tetrahydronaphthylphenol*, $\text{C}_{10}\text{H}_{11}\cdot\text{C}_6\text{H}_4\cdot\text{OH}$, is prepared by the action of equal parts of concentrated sulphuric acid and glacial acetic acid on a mixture of phenol and dihydronaphthalene; after purification, the compound crystallises from a mixture of ether and light petroleum, or from dilute alcohol, in aggregates of needles; it melts at 129—130° with previous softening, and boils at 320° without decomposition. It is readily volatile with steam at 160°, but more slowly at 100°; no characteristic coloration is obtained with ferric chloride; the yield is 70 per cent. of the dihydronaphthalene employed.

The phenol may also be obtained by the action of sulphuric acid alone, but the product appears to be less pure. The *sodium salt* is formed as a flocculent, crystalline precipitate on cooling a solution of the phenol in soda. The *benzoyl* derivative crystallises from absolute alcohol, and melts at 107—108°. J. B. T.

Picryl- α - and β -naphthylhydrazines, and α -Dinitrophenyl- α , and β -naphthylhydrazines and their Derivatives. By C. WILLGERMIDT and F. SCHULZ (*J. pr. Chem.* [2], **43**, 177—189).—The picrylnaphthylhydrazines are prepared by the action of alcoholic solutions of picryl chloride on the naphthylhydrazine (obtained after E. Fischer, *Abstr.*, 1886, 554), or its hydrochloride (equal mols.); they exist in a stable and an unstable form.

Picryl- α -naphthylhydrazine.—The *red* or *stable* modification of this compound is obtained if the reaction is assisted by heat, and crystallises, as the mixture cools, in short, dark-brown prisms; it can be purified by washing with water. It decomposes at 176°, dissolves in most organic solvents, and is indifferent in its behaviour to acids and alkalis. The *yellow* or *unstable* modification is amorphous, and is formed if the reaction takes place in the cold; it must be quickly filtered, and dried on a porous plate, as it rapidly changes into the red modification if left in the mother liquor, and even more quickly when heated with solvents; when heated by itself, the change occurs at 140°.

Picryl- β -naphthylhydrazine.—Both modifications are obtained in the same way as those of the α -compound. The *red*, or *stable*, modification crystallises in red prisms which decompose at 175°; it is sparingly soluble in alcohol and ether, but easily in chloroform, glacial acetic acid, benzene, and acetone. The *yellow*, or *unstable*, modification is amorphous, and so unstable that it is impossible to prepare it quite free from the red modification, into which it passes, when heated

alone at 100°, or with solvents. It is suggested that these stable and unstable forms are stereochemical isomerides.

Picrylazonaphthalenes are obtained by adding the corresponding hydrazines to a warm solution of excess of chromic acid in acetic acid; the mixture is then poured into water, and the precipitate washed with water. *Picryl- α -azonaphthalene* crystallises from glacial acetic acid in red-yellow needles which melt and decompose at 226°; it dissolves sparingly in benzene and alcohol. *Picryl- β -azonaphthalene* crystallises in dull-red needles, melts at 205° with decomposition, and dissolves easily in glacial acetic acid, but sparingly in alcohol and benzene.

Dinitronitrosophenyl- α -azonaphthalene is obtained by heating picryl- α -naphthylhydrazine with glacial acetic acid in a reflux apparatus, until the colour of the crystals, which separate on cooling, is quite yellow; it forms yellow needles, melts at 232°, and dissolves easily in benzene, but more sparingly in glacial acetic acid and alcohol.

Dinitronitrosophenyl- β -azonaphthalene, similarly prepared, crystallises in yellow leaflets, melts at 245° with decomposition, and dissolves easily in glacial acetic acid, but more sparingly in alcohol, ether, and benzene; it dissolves in strong sulphuric acid with a brilliant dark-blue colour, which becomes greenish-yellow on dilution with water.

Dinitrosanitrophenyl- α -azonaphthalene is prepared by heating picryl- α -naphthylhydrazine with alcohol in a sealed tube, for 2—3 hours at 120°, dissolving the product in benzene, and decolorising with animal charcoal; it crystallises in slender, yellowish-brown needles, melts at 210°, and is moderately soluble in benzene and glacial acetic acid, but less so in alcohol.

Dinitrosanitrophenyl- β -azonaphthalene is obtained by heating picryl- β -naphthylhydrazine with alcohol in a reflux apparatus for 14 hours; it melts at 231° with partial decomposition, and dissolves in hot glacial acetic acid and benzene, but hardly at all in alcohol.

Orthoparadinitrophenyl- α -naphthylhydrazine is obtained by dissolving phenyl- α -naphthylhydrazine (4 grams), in alcohol, adding α -dinitrochlorobenzene (2.56 grams), and heating in a reflux apparatus for $\frac{1}{2}$ — $\frac{3}{4}$ hour; the crystalline mass which separates on cooling is purified by heating with dilute hydrochloric acid. It crystallises from benzene in long, narrow, red prisms, melts at 181°, and dissolves sparingly in alcohol.

Orthoparadinitrophenyl- β -naphthylhydrazine, similarly prepared, crystallises in short, reddish-yellow prisms, melts at 188° with decomposition, and dissolves sparingly in alcohol and benzene, but more freely in glacial acetic acid, in which it is unstable.

Orthoparadinitrophenyl- α -azonaphthalene, obtained by heating the corresponding naphthylhydrazine with excess of chromic acid in acetic acid and pouring the mixture into water, crystallises in slender, reddish-brown needles, melts at 190°, and dissolves sparingly in alcohol, and more freely in glacial acetic acid and benzene.

Orthoparadinitrophenyl- β -azonaphthalene, similarly prepared, crystallises in reddish-yellow needles, melts at 178°, and dissolves in glacial acetic acid.

Orthoparanitronitrosophenyl- α -azonaphthalene is prepared by heating orthoparadinitrophenyl- α -naphthylhydrazine with glacial acetic acid in a reflux apparatus for two hours; it crystallises in green needles, melts at 201° , and dissolves in glacial acetic acid and benzene, but only sparingly in alcohol.

Orthoparanitronitrosophenyl- β -azonaphthalene, similarly obtained, crystallises in yellow needles, melts at 225° , and dissolves in glacial acetic acid, but only sparingly in alcohol and benzene.

Orthoparadinitrosophenyl- α -azonaphthalene is obtained by heating orthoparadinitrophenyl- α -naphthylhydrazine with alcohol in a sealed tube for six hours at 120° , cooling, and heating the crystals with glacial acetic acid and animal charcoal; it is yellow, amorphous, and melts at 162° .

Orthoparadinitrosophenyl- β -azonaphthalene is prepared in a similar manner; after long heating with glacial acetic acid, it forms microscopic, yellow needles; it melts at 178° , and dissolves in glacial acetic acid and benzene, but only sparingly in alcohol.

The molecular weights of the foregoing compounds have been checked by Raoult's method. A. G. B.

Action of Hydriodic Acid on 1—3'-Nitronaphthalenesulphonamide. By A. EKBOM (*Ber.*, 24, 329—335).—The action of hydriodic acid on 1—3'-nitronaphthalenesulphonamide is similar to its action on the 1—4'-compound (*Abstr.*, 1890, 994).

Amidonaphthalenesulphonamide [$\text{NH}_2 : \text{SO}_2\text{NH}_2 = 1 : 3'$] is prepared by heating nitronaphthalenesulphonamide with excess of hydriodic acid (sp. gr. = 1.5) and red phosphorus for seven hours; the product is dissolved in alcohol, treated with sulphurous acid, and ammonia added until an alkaline reaction is obtained, when the amide is precipitated as a yellow, crystalline compound. It crystallises from alcohol in slender, silky needles, melts at 218 — 219° with carbonisation, and is easily soluble in hot alcohol, sparingly in cold, and insoluble in water. The *hydrochloride*, obtained by dissolving the amide in hydrochloric acid, crystallises in scales. The *hydriodide* crystallises from concentrated alcoholic hydriodic acid in beautiful, pale-yellow needles. The *sulphate* crystallises in prisms. *Acetamidonaphthalenesulphonamide* is obtained by treating the above compound with excess of acetic anhydride; it crystallises from alcohol in small aggregates consisting of radiating, light-red needles, and melts at 238 — 239° . An attempt to prepare the diacetyl compound by heating amidonaphthalenesulphonamide in a sealed tube with excess of acetic anhydride for 2½ hours at 156° failed. The author draws attention to the fact that Cleve obtained a monacetyl derivative from the 1 : 3 and 1 : 2'-amidonaphthalenesulphonamides and a diacetyl derivative from the 1 : 4-compound, and that he has obtained a diacetyl derivative from the 1 : 4'-compound. Hence if the group SO_2NH_2 be in a β -position, a monacetyl compound is obtained; if it be in an α -position, a diacetyl-compound is formed.

1 : 3'-Diamidodinitrophenyl bisulphide, $\text{NH}_2\cdot\text{C}_{10}\text{H}_6\cdot\text{S}\cdot\text{S}\cdot\text{C}_{10}\text{H}_6\cdot\text{NH}_2$, is prepared by treating 1 : 3' nitronaphthalenesulphonamide with excess of hydriodic acid (sp. gr. = 1.96), and when the reaction is ended,

boiling the mixture gently for three hours. The product is dissolved in alcohol, treated with sulphurous acid and ammonia, and the precipitate washed with water and crystallised from alcohol several times. It crystallises in pale-yellow needles, melts at 166° , and is easily soluble in alcohol, ether, benzene, and acetic acid, sparingly in light petroleum, and insoluble in water. The same bisulphide was obtained by reducing the dinitrodinaphthyl bisulphide from the β -acid (Abstr., 1888, 698) with hydriodic acid and phosphorus. The *hydrochloride*, $\text{NH}_2\cdot\text{C}_{10}\text{H}_6\cdot\text{S}\cdot\text{S}\cdot\text{C}_{10}\text{H}_6\cdot\text{NH}_2\cdot 2\text{HCl}$, is obtained as a white precipitate on adding hydrochloric acid to an alcoholic solution of the diamide; on boiling with water, it is decomposed into hydrochloric acid and diamidodinaphthyl bisulphide. The *hydriodide* is obtained in yellow needles on concentrating an alcoholic solution of the diamide, saturated with hydriodic acid. *Diaceto-diamidodinaphthyl bisulphide*, obtained by treating diamidodinaphthyl bisulphide with excess of acetic anhydride, crystallises from acetic acid in colourless, microscopic needles, and melts at 276° with carbonisation.

When 1 : 3'-nitronaphthalenesulphonamide and 1 : 3'-diamidodinaphthyl bisulphide are treated with excess of hydriodic acid (sp. gr. = 1.96), and the mixture boiled briskly for 3—4 hours, a product is obtained, somewhat easily soluble in alcohol, which, after treatment with ammonia, forms a viscid, evil-smelling substance; the author assumes it to be β -amidothionaphthol.

E. C. R.

Action of Ethyl Formate on Camphor. By L. CLAISEN (*Chem. Centr.*, 1890, ii, 878—880; from *Sitzber. math.-naturw., Abt. bayr. Akad. Wiss.*, 1890, 445—479).—*Formylcamphor*, the preparation of which has been already described (Abstr., 1888, 692 and 1889, 619), melts at 76 — 78° , boils at 240 — 243° under 760 mm. pressure, and at 138° under 28 mm. pressure. It behaves as a fairly strong acid and liberates acetic acid from its salts; ferric chloride produces a dark violet-red coloration in its alcoholic solution; the *ferric salt* is nearly black, crystalline, insoluble in water, soluble in alcohol, ether, benzene, and chloroform forming a dark red solution; the *copper salt*, $(\text{C}_{11}\text{H}_{18}\text{O}_2)_2\text{Cu} + 2\text{C}_{11}\text{H}_{18}\text{O}_2$, melts at 126° and crystallises from light petroleum in silky, lustrous needles.

Acetylformylcamphor, $\text{C}_9\text{H}_{14}\text{C} \begin{smallmatrix} \text{C}:\text{CH}\cdot\text{OAc} \\ \text{CO} \end{smallmatrix}$, melts at 60— 62° and boils at 175 — 177° ; it gives no coloration with ferric chloride.

Ethylformylcamphor, $\text{C}_9\text{H}_{14}\text{C} \begin{smallmatrix} \text{CH}:\text{CH}\cdot\text{OEt} \\ \text{CO} \end{smallmatrix}$, is a colourless oil, which boils at 266 — 268° under 760 mm. pressure, sp. gr. 1.006 at 15° ; it is insoluble in water and dilute alkalis. With ferric chloride, it produces no coloration (unless decomposed), and is decomposed by hydrogen bromide into alcohol and formylcamphor.

Benzylformylcamphor, $\text{C}_9\text{H}_{14}\text{C} \begin{smallmatrix} \text{C}:\text{CH}\cdot\text{O}\cdot\text{C}_6\text{H}_5 \\ \text{CO} \end{smallmatrix}$, melts at 45 — 46° , and boils at 222 — 224° under a pressure of 16 mm. *Anilidoformyl-*

camphor, C_9H_{14} $\begin{smallmatrix} \text{C:CH}\cdot\text{NHPH} \\ | \\ \text{CO} \end{smallmatrix}$, melts at 156—159°, and is prepared

by the action of aniline either on a methyl alcohol solution of formylcamphor or on ethylformylcamphor. *Methylanilidoformyl-*

camphor, C_9H_{14} $\begin{smallmatrix} \text{C:CH}\cdot\text{NMePh} \\ | \\ \text{CO} \end{smallmatrix}$, melts at 124° and separates from its

solution in chloroform and light petroleum in beautiful crystals of the rhombic system, $a : b : c = 0.792 : 1 : 0.7535$. The *monhydrazone* of camphorquinone melts at 169—170°.

From a consideration of the properties and reactions of formylcamphor, the author considers that it has the formula

Menthone appears to react with ethyl formate in a similar manner to camphor. J. W. L.

Influence of Solvents on the Rotatory Powers of Camphols and Isocamphols: Chloral Borneolates. By A. HALLER (*Compt. rend.*, 112, 143—146).—The rotatory power of laevogyrate α -camphol is independent of the nature of the solvent, except in the case of methyl alcohol, when it is below its normal value; the effect of various solvents in the case of laevogyrate isocamphol varies with their nature, but is the same for members of a homologous series.

Chloral borneolates are obtained by direct union of borneol and anhydrous chloral at the ordinary temperature. The α -compounds crystallise, but the products from isocamphol and $+\alpha-\beta$ -borneol are viscous and do not crystallise even at 15°. All the compounds have the formula $CCl_2\cdot CH(OH)\cdot OC_{10}H_{17}$, and are decomposed by boiling water into camphols and chloral hydrate. Their rotatory powers in a benzene solution containing half a gram-molecule per litre were as follows:—

	Melting point.	Molecular rotatory power.
Dextrogyrate chloral α -borneolate (cryst.).....	55—56°	+30.13°
Laevogyrate chloral α -borneolate (cryst.).....	55—56	—30.13
Racemic chloral borneolate ($-\alpha + \alpha$) cryst.	55—56	0.0
Laevogyrate chloral isoborneolate or β -borneolate.....	—	—56.40°
Chloral $-\beta + \alpha$ -borneolate from in- active $-\beta + \alpha$ -camphol.....	—	—22.12

The differences between the various derivatives are of the same order as in the case of the bornylphenyl-urothanes. It is clear that the orientation of the elements of the group $H\cdot\dot{C}\cdot OH$ exerts an important influence on the rotatory power and other physical properties of these additive compounds. C. H. B.

Digitonin and Digitogenin. By H. KILIANI (*Ber.*, 24, 339—347).—The author has shown in a former communication (*Abstr.*, 1890, 996), that pure commercial digitalin, when heated with dilute hydrochloric acid, gives, besides dextrose and galactose, a large quantity of digitogenin, $C_{15}H_{24}O_8$.

Digitonin is best obtained from commercial digitalin by extraction with 85 per cent. alcohol. Digitalin (1 part) is dissolved in 85 per cent. alcohol (4 parts) at 50—60° and the solution allowed to crystallise slowly. The crude product thus obtained is dissolved in 12 times its weight of boiling alcohol (85 per cent.), heated for two minutes with animal charcoal, and filtered: by rubbing the sides of the beaker as the solution cools, the product is obtained in nodular aggregates of slender needles. The crystals are, however, more compact and the product purer if the solution is allowed to cool very slowly without rubbing the sides of the beaker. Digitonin crystallises easily from 85 per cent. alcohol, whilst from stronger alcohol it is only obtained in the amorphous state, begins to soften at 225°, is completely melted at 235°, and is lævo-rotatory; for a 2.8 per cent. solution in 75 per cent. acetic acid, $[\alpha]_D = -50^\circ$. The amorphous digitonin of Schmiedeberg dissolved in cold water in all proportions; the crystalline substance is sparingly soluble in water; on heating, it dissolves more easily, but does not crystallise on cooling, and the solution always shows an opalescence. With concentrated sulphuric acid, it gives a red solution; the addition of a drop of bromine-water greatly intensifies the reaction. Concentrated hydrochloric acid gives a colourless solution which, after a time or on heating, turns yellow and then red. Heated with dilute hydrochloric acid under the same conditions as were before given for digitalin, it yields nearly the calculated quantities of digitogenin, dextrose, and galactose. The digitogenin obtained in this way was identical in every respect with that formerly obtained from digitalin.

Derivatives of Digitogenin.—When digitogenin is heated in a sealed tube with concentrated hydriodic acid and red phosphorus, a large quantity of a resin containing iodine is formed; but neither methyl nor ethyl iodide.

Acetyldigitogenin, $C_{15}H_{22}O_8Ac$, is obtained by heating digitogenin (1 part) with anhydrous sodium acetate (1 part) and acetic anhydride (6 parts) in a reflux apparatus for one hour, and pouring the bright red solution in a fine stream into a large quantity of water. It crystallises from a small quantity of absolute alcohol in beautiful needles, melts at 178°, and is extremely soluble in warm alcohol, ether, and acetic acid. Instead of sodium acetate, sulphuric acid can be employed as a condensing agent: when zinc chloride is employed, amorphous compounds which were not examined are obtained. The author points out that the formation of a monacetyl derivative from digitogenin, does not agree with the production of two sugars from digitonin, which latter fact points to the existence of two hydroxyl groups in digitogenin.

Digitogenin on oxidation yields, according to the conditions, three acids, which the author names respectively, digitogenic, oxydigitogenic, and digitic acids.

Digitogenic Acid, $C_{14}H_{22}O_4$, is prepared by slowly adding chromic acid (0.7 part dissolved in 1.4 parts of water and 7 parts of acetic acid) to a solution of digitogeuin (1 part) in acetic acid (30 parts). As soon as all the chromic acid is reduced, an equal volume of water is added, and the mixture repeatedly extracted with ether. The ethereal solution is allowed to remain for 24 hours, poured off from the deposit which is formed, the ether distilled off, and the acid residue evaporated on the water-bath until a crystalline crust forms on the liquid; the product crystallises after 12 hours. The yield amounts to 60 per cent. of the digitogenin employed. It crystallises from absolute alcohol in colourless needles or thin prisms, begins to melt at 146° , and is completely melted at 150° , becomes strongly electric when rubbed, tastes extremely bitter, and is easily soluble in chloroform and hot glacial acetic acid, less easily in 50 per cent. acetic acid, more sparingly in cold alcohol and ether, and insoluble in water; when heated with water, it melts. When moistened with dilute alcohol, it has a distinctly acid reaction. It dissolves easily in alkali hydroxides and carbonates. The *magnesium salt* ($C_{14}H_{20}O_4$) $_2$ Mg, prepared by adding an excess of dilute magnesium nitrate (1 : 10) to a very dilute neutral solution of the acid, separates as a crust consisting of aggregates of minute needles on allowing the mixture to remain for 24 hours. The *calcium salt* is similar to the magnesium salt. The bye-products of the oxidation with chromic acid probably contain formaldehyde or formic acid, as no evolution of carbonic anhydride was observed. The mother liquors contained a small quantity of an aldehydic or ketonic compound and a large quantity of an acid of high molecular weight which yields no crystalline derivatives.

Oxydigitogenic acid, $2C_{14}H_{20}O_4 + H_2O$, is prepared by dissolving digitogenic acid (1 part) in potash (1 : 10) (10 parts), diluting the solution to 100 parts, and adding a solution of potassium permanganate (1 : 50). When the oxidation is finished, the solution is decolorised with a few drops of alcohol, filtered, one-third the weight of 93 per cent. alcohol added, and the acid precipitated with 50 per cent. acetic acid. In this way it is obtained crystallised in nodular aggregates of needles, which begin to melt at 250° ; it is very sparingly soluble in alcohol and acetic acid, and becomes strongly electric when rubbed. The yield amounts to 70 per cent. of the digitogenic acid employed. The *magnesium salt*, ($C_{14}H_{18}O_4$) $_2$ Mg, is very sparingly soluble and crystallises in aggregates of small needles.

Digitic acid, $C_{10}H_{16}O_4$, is formed, together with oxydigitogenic acid, by the oxidation with permanganate of digitogenic acid dissolved in 3 parts of potash. When the oxidation is ended, the solution is decolorised with a few drops of alcohol, filtered, $\frac{1}{4}$ the weight of 93 per cent. alcohol added, and the acids precipitated with hydrochloric acid; the precipitate, which consists of oxydigitogenic acid mixed with some digitic acid, is filtered off rapidly; the filtrate after a time deposits most of the digitic acid in aggregates of beautiful needles. If, however, a separation of the two acids is not obtained in this way, they are dissolved in potash, the solution diluted until it contains 1 per cent. of acid, and fractionally precipitated with hydro-

chloric acid, when oxydigitogenic acid is precipitated first. A separation by fractional crystallisation from alcohol and acetic acid is not possible, although the solubility of the two acids is very different. Digitric acid melts at 192° , dissolves easily in alcohol, chloroform, and acetic acid, and crystallises readily from boiling 50 per cent. alcohol, but not from strong alcohol. The *barium* salt, $(C_{10}H_{16}O_4)_2Ba + 6H_2O$, prepared by adding barium chloride to a solution of the potassium salt, crystallises in nodular aggregates, and is somewhat sparingly soluble in water. The *potassium* salt also crystallises well and is extremely soluble in water.

If the acid is dissolved in decinormal potash in the proportion, $C_{10}H_{16}O_4 : 1KOH$, and phenolphthalein and a few drops of alkali are added, the red colour remains both when the solution is allowed to stand and when heated : hence the acid is not a lactone.

The author reserves the theoretical consideration of the results for a future communication. E. C. R.

Hydrocotoïn, a Constituent of Coto-Bark. By G. CIAMICIAN and P. SILBER (*Ber.*, 24, 299—301).—The molecular weight of hydrocotoïn (compare Jobst and Hesse, *Abstr.*, 1880, 325) was determined by Raoult's method, with results which agreed well with those required by a compound of the molecular formula $C_{15}H_{14}O_4$. Quantitative experiments, carried out as described by Zeisel, showed that hydrocotoïn contains two methoxy-groups, $C_{15}H_{12}O_2(OMe)_2$.

Methylhydrocotoïn, $C_{15}H_{14}O(OMe)_3$, is formed when hydrocotoïn is heated at 100° with methyl iodide and a solution of potash in methyl alcohol; it separates from alcohol in small, colourless needles, melts at 113° , and is readily soluble in ether and hot alcohol, but insoluble in water and alkalis.

When hydrocotoïn is heated with alcoholic potash in sealed tubes, it is decomposed, the products being probably a phenol-like substance and benzoic acid; its constitution may possibly be represented by the formula $COPh \cdot C_6H_2(OMe)_2 \cdot OH$. F. S. K.

Cochineal-Carmine. By F. LAFAR (*J. pr. Chem.* [2], 43, 130—133; compare *Abstr.*, 1885, 1076).—The sample of which the following is an analysis was purchased as "Carminnakerat"; it was a fine, loose powder, of full tone and warmth, and dissolved completely in ammonia. Liebermann's method of analysis (*Abstr.*, 1885, 1076) was followed. The sample contained 0.4 per cent. of sulphur and 3.49 per cent. of nitrogen; its proximate percentage composition was:—

H_2O lost at 110° .	Ash.	Nitrogenous matter.	Colouring matter (by difference).
15.50	6.87	23.26	54.37

The percentage composition of the ash (8.14 per cent. of the dried colour) was:—

CuO .	SnO_2 .	Al_2O_3 .	CaO .	MgO .	Na_2O .	K_2O .
0.35	0.14	40.48	44.20	0.61	5.40	3.20
P_2O_5 .	SiO_2 .	Fe_2O_3 .	CO_2 (by difference).			
2.71	0.60	trace		2.31		

The molecular ratio of $\text{Al}_2\text{O}_3 : (\text{CaO} + \text{MgO})$ is 1 : 2.044; Liebermann found it to be 1 : 1.972. A. G. B.

Synthetical Pyridine Bases of the β -Series. By C. STOEHR (*J. pr. Chem.* [2], 43, 153—156; compare this vol., p. 219).—The β -methylpyridine obtained from glycerol (this vol., p. 219) contains pyridine and β -ethylpyridine. By fractionating the crude mixture of bases, about 10 per cent. of pyridine first distils over (b. p. 115° ; m. p. of mercuriochloride 177 — 178°), the β -methylpyridine being contained in the fraction 140 — 146° , from which it is obtained pure by conversion into the mercuriochloride; it boils at 144 — 145° (corr.), and its sp. gr. at $0^\circ/4^\circ$ is 0.9751, that of the β -methylpyridine from strychnine being 0.9756. The melting point (201 — 202°) of the platinochloride cannot be made to agree with that given by Ladenberg (compare *loc. cit.*), but this salt forms asymmetric crystals, the investigation of which leaves no doubt as to their identity with the product obtained by Groth and Hjortdahl. The identity of the synthetical β -methylpyridine with that obtained from strychnine (this vol., p. 86) is thus established. The β -ethylpyridine was also isolated by means of its mercuriochloride; it melts at 165° (corr.), and its sp. gr. at $0^\circ/4^\circ$ is 0.9585, that of the β -ethylpyridine obtained from brucine (this vol., p. 87) being 0.9590; the two bases are thus identical. β -Ethylpyridine is only slightly soluble in cold water, and practically insoluble in hot water; it has a stronger smell than the lower homologues; by oxidation with permanganate, it yields nicotinic acid (m. p. 230 — 231°). The platinochloride melts with decomposition at 208° ; the mercuriochloride forms short prisms which melt without decomposition at 131 — 132° . The aurochloride and the picrate were obtained. A. G. B.

Tinctorial Properties of Nitrosoxyquinolines. By S. V. КОСТА-НЕЦКИ (*Ber.*, 24, 150—156).—3 : 4-Nitrosoparoxyquinoline has decided tinctorial powers, giving a green colour with iron mordants, and a brick-red with cobalt mordants, thus showing an analogy to 1 : 2-nitrosonaphthol. By the action of nitrous acid on orthoxyquinoline, two nitroso-derivatives are formed; the first, 1 : 4-nitrosoparoxyquinoline, is already known, and has no tinctorial properties; the second compound is much more readily soluble in water, and yields green and brownish-red "lakes" with iron and cobalt salts respectively. Amidorthohydroxyquinoline may be obtained from the corresponding nitroso-compound by reduction with stannous chloride; the sulphate crystallises with 2 mols. H_2O .

1 : 4-Nitroorthohydroxyquinoline, $\text{OH} \cdot \text{C}_6\text{NH}_4\text{NO}_2$, is prepared by the action of nitric acid on the nitroso-derivative; it crystallises from alcohol in small, yellow needles, melts at 173° , and is identical with the substance obtained from nitrothoxyquinolinecarboxylic acid. The compound dyes green with iron mordants, and yellow with aluminium mordants. The corresponding nitroparhydroxyquinoline has no tinctorial properties.

Dinitroorthohydroxyquinoline,

obtained by boiling the nitroso-derivative with nitric acid, is already known, and has only feeble tinctorial properties. J. B. T.

Quinolinedihydroximes. By S. v. KOSTANECKI and M. RUFCHER (*Ber.*, 24, 156—159).—1:4-*Quinolinedioxime*, $C_9NH_5(NO)_2$, is prepared by the action of hydroxylamine hydrochloride on nitrosoorthoquinoline, and is deposited from dilute alcohol in small crystals which gradually decompose at 200° . It is soluble in soda and in sodium carbonate with a pale-yellow colour; it yields a stable, intense green "lake" with iron salts, but with cobalt salts inferior brown shades are formed. The *diacetate*, $C_9NH_5(NOAc)_2$, crystallises from glacial acetic acid, on the addition of water, in white needles which melt at 160° with decomposition.

A corresponding *dioxime* may be obtained from nitrosoparoxyquinoline by the action of hydroxylamine; it crystallises from alcohol in small needles and decomposes at 190° . A brown colour is formed with normal iron salts, but the tinctorial properties of the compound are only feeble. On boiling with dilute alkalis or with acetic anhydride, *quinoline dioxime anhydride*, $C_9NH_5 \begin{smallmatrix} N \\ \diagup \\ N \end{smallmatrix} > O$, is formed; this crystallises from dilute alcohol in long, strongly refractive needles, melts at 134° , and is readily volatile with steam.

J. B. T.

Substitution Products of Isoquinoline. By A. EDINGER and E. BOSSUNG (*J. pr. Chem.* [2], 43, 190—200).—*Isoquinoline dibromide*, $C_9NH_7Br_2$, is obtained by slowly dropping a solution of the calculated quantity of bromine in ether or chloroform into the same solvent containing isoquinoline suspended in it; the yellowish substance thus precipitated melts at 82° (uncorr.). The *hydrobromide*, $C_9NH_7Br_2 \cdot HBr$, is prepared by dissolving isoquinoline in an excess of aqueous hydrogen bromide and evaporating; it forms red crystals, which are unstable and melt between 130° and 135° .

Bromisoquinoline, C_9NH_6Br , is obtained by heating either of the preceding salts in an oil-bath at 180 — 200° , adding sodium hydroxide solution, and distilling with steam; the distillate is mixed with nitric acid and evaporated until the *bromisoquinoline nitrate* crystallises; the aqueous solution of this salt is then decomposed with ammonia, when the base separates as a thick, colourless oil which gradually crystallises; it melts at 40° , and boils at 280 — 285° . The *platinochloride* crystallises with 2 mols. H_2O ; the *methiodide* melts at 233° ; the *methochloride* melts at 82° , and yields an anhydrous *platinochloride*. *Bromisoquinoline benzyl chloride* is prepared by heating the base with benzyl chloride for two hours in a tube at 140° ; it melts at 115° ; its *platinochloride* is anhydrous. That the bromine atom is in the pyridine ring is evident from the fact that when bromisoquinoline is oxidised with potassium permanganate in alkaline solution, it yields a *bromopyridinedicarboxylic acid* which melts at 237° ; its *barium salt* was obtained.

Nitrobromisoquinoline is obtained by dissolving bromisoquinoline (10 grams) in nitric acid of sp. gr. 1.52 (50 grams) and adding

sulphuric acid of sp. gr. 1.84 (50 grams) while stirring and cooling. The mixture is allowed to stand until a portion of it gives no odour of isoquinoline when warmed with soda, and is then poured into water; the yellow flocks which separate are washed, dissolved in alcohol, and the solution decolorised with animal charcoal. It crystallises in white needles which melt at 173° (uncorr.), and dissolve sparingly in cold alcohol; when strongly heated, it sublimes in yellow leaflets, otherwise, in white needles. The *platinochloride* crystallises in tables; the *methiodide* forms reddish-yellow needles, and melts at 262° ; the *methochloride* is more soluble than the methiodide, and crystallises in yellow needles which melt at 183° ; its *platinochloride* was obtained.

On adding ammonia to the aqueous liquid from which the yellow flocks have separated (see above), a second *nitrobromisoquinoline* is obtained in white flocks; after crystallisation from alcohol, it melts at 158° , and dissolves in hot water, alcohol, and glacial acetic acid. Bromisoquinoline cannot be converted into a nitro-derivative by nitric acid alone, even when heated with it.

Amidobromisoquinoline is obtained from the nitro-compound melting at 173° by treating it with hydrochloric acid and stannous chloride in alcohol, and may be purified by sublimation; it melts at 136° , and dissolves in hot water, ether, chloroform, alcohol, and glacial acetic acid, and with a red colour in mineral acids; its *platinochloride* is described; its *methiodide* crystallises in red needles, and melts at 243° .

Dibromisoquinoline is prepared by diazotising the amido-compound in the presence of cuprous bromide; 6 grams of amidobromisoquinoline are dissolved in 180 grams of water containing 6 grams of sulphuric acid, 14 c.c. of a freshly prepared 15 per cent. solution of sodium nitrite are added, and the mixture poured slowly into a boiling solution (2 litres) of cuprous bromide in aqueous hydrobromic acid; when the reaction is completed, the solution is mixed with sodium hydroxide, distilled with steam, and the white flocks which pass over are crystallised from alcohol. It melts at 138° , and dissolves fairly easily in hot water, alcohol, ether, glacial acetic acid, and mineral acids.

A. G. B.

New Class of Organic Bases. By C. STÖHR (*J. pr. Chem* [2], 43, 156–160).—Besides the pyridine bases previously described (this vol., p. 579), the author has obtained by the action of ammonium salts on glycerol (this vol., p. 219) a new series of bases having the general formula $C_nH_{2n-4}N_2$; they are analogous in properties to the pyridine bases, and are isomeric with the aromatic diamines and hydrazines, the ketines, pyrimidines, and pyridazines; they may be regarded as homologues of the diamine $C_4H_8N_2$.

The only member of this series which has been properly investigated is $C_6H_8N_2$; it is a clear, strongly refractive liquid boiling at $153.5\text{--}154^{\circ}$ (corr.) without decomposition. It has all the properties of a pyridine base, but is equally soluble in hot and cold water; it becomes hot on the addition of water; it is volatile in steam, and is precipitated from its aqueous solution by potash; its odour is very similar to that of the pyridine bases of higher mole-

cular weight, and resembles that of nicotine. Its sp. gr. at $0^{\circ}/4^{\circ}$ is 1.0079. The *hydrochloride* is very soluble and hygroscopic; it sublimes on the water-bath. The *aurochloride*, $C_6H_8N_2 \cdot H \cdot AuCl_4 \cdot \frac{1}{2}H_2O$, crystallises in brilliant, lustrous, long, broad, brittle needles, which are sparingly soluble in cold water. The *platinochloride*,

forms lustrous crystals of the colour of potassium dichromate, and is freely soluble in water; when heated in aqueous solution, a heavy, yellow, crystalline powder, consisting of the salt $(C_6H_8N_2)_2PtCl_4$, is deposited, and from the filtrate from this the salt $(C_6H_8N_2)_2HClPtCl_4$ separates in lustrous, golden-yellow crystals. The *mercuochloride* forms brilliant, rhombohedral crystals, and is sparingly soluble. With methyl iodide, a crystalline *ammonium iodide* was obtained. When oxidised with permanganate, the base yields a sparingly soluble, nitrogenous acid, which melts at $250-251^{\circ}$ with blackening; the silver and copper salts are sparingly soluble, and in aqueous solution the acid gives a red coloration with ferrous sulphate, which is permanent when heated.

The base, $C_6H_8N_2$, was also isolated; it boils at 178.5° (corr.); its sp. gr. at $0^{\circ}/4^{\circ}$ is 0.9852; it is volatile with steam and miscible with water. The *platinochloride*, *aurochloride*, and *mercuochloride* were obtained.

The author suggests the formula $N \begin{smallmatrix} \text{CH} \cdot \text{CH} \\ \text{CH} \cdot \text{CH} \end{smallmatrix} N$ for $C_4H_4N_2$; this, however, is identical with the formula for the ketine derivatives.

A. G. B.

New Base, $C_6H_{12}N_2O$, from Epichlorhydrin and Phenylhydrazine. By F. GERHARD (*Ber.*, 24, 352-357).—By boiling epichlorhydrin with twice its weight of phenylhydrazine, Balbiano obtained as final products a mixture of aniline and phenylhydrazine, and explains the reaction by supposing that the phenylhydrazine first forms the additive compound $C_6H_{12}N_2O$, which then reacts with the phenylhydrazine hydrochloride, $C_6H_{12}N_2O + PhNH \cdot NH_2HCl = PhNH_2 + NH_4Cl + H_2O + C_6H_5N_2Ph$. The author has prepared this intermediate compound, and from its behaviour concludes that it has the constitution $OH \cdot CH \begin{smallmatrix} \text{CH}_2 \cdot NH \\ | \\ \text{CH}_2 \cdot NPh \end{smallmatrix}$. It is prepared as follows:

—Epichlorhydrin (1 part) and phenylhydrazine (1.5 parts) are allowed to remain in ethereal solution. At a temperature below 15° , phenylhydrazine hydrochloride is slowly precipitated, the reaction being ended in about 14 days. On evaporating the filtered ethereal solution, a crystalline mass is obtained, which is purified by crystallisation from ether and carbon bisulphide, and finally from benzene. The new base crystallises from ether in hard, nacreous prisms, melts at $103-104^{\circ}$, is easily soluble in warm water, ether, alcohol, chloroform, and hot carbon bisulphide, and slowly turns yellow on exposure to light. By boiling with phenylhydrazine hydrochloride in benzene solution on the oil-bath, decomposition easily takes place, and the products are the same as those obtained by

Balbiano, namely, aniline and phenylpyrazole (the latter gave a platinum salt melting at 173°). The *platinochloride*,

obtained by adding a concentrated hydrochloric acid solution of platinic chloride, crystallises in beautiful, yellowish-red prismatic crystals, melts at 156° with decomposition, and is easily soluble in warm water and dilute alcohol, insoluble in ether.

The new base is easily acted on by oxidising agents. Nitric acid gives a violet coloration, which turns brown with excess of acid, or if left for a time. Chromic acid gives a bright red coloration. Potassium permanganate is reduced. With ferric chloride and hydrochloric acid, it gives a beautiful wine-red coloration. On reduction with sodium and absolute alcohol, phenylhydrazine is formed. The *acetyl* compound, $\text{N}_2\text{PhH}\cdot\text{C}_6\text{H}_5\text{OAc}$, is formed by boiling the base with acetic anhydride. E. C. R.

Constitution of Nicotine. By F. BLAU (*Ber.*, 24, 326—329).—The author has prepared α - β -dipiperidyl and compared it with hexahydronicotine obtained from nicotine by Liebrecht (*Abstr.*, 1886, 161): he finds that these two compounds are not identical.

α - β -Dipyridyl was prepared from metaphenylenediamine by converting it into phenanthroline and dipyridyldicarboxylic acid. The corrected boiling point of the substance is 295.5 — 296.5° .

α - β -Dipiperidyl is obtained from the above compound by reducing it first with sodium and alcohol, as described by Ladenburg, then with sodium and amyl alcohol, as described by Bamberger. It distils at 268 — 270° , and the distillate solidifies to a crystalline mass which melts at about 30° ; but on account of the hygroscopic nature of the substance the melting point is only approximate. The *hydrochloride* is easily soluble in water, very sparingly so in alcohol. The *platinochloride* is easily soluble in water, but not hygroscopic, and somewhat sparingly soluble in alcohol. The *aurochloride* is not so soluble in water, crystallises well, melts at 202° , and decomposes at 210° . Liebrecht's so-called dipiperidyl from nicotine is liquid, and yields an aurochloride melting at 131 — 132° . α - β -Dipiperidyl yields a well crystallised compound with carbon bisulphide, and also a nitroso-compound.

From a consideration of the boiling points of the dipiperidyls at present known, the author is inclined to think Liebrecht's hexahydronicotine does not belong to the dipiperidyl series. He is at present engaged in the preparation of $\beta\beta$ -dipiperidyl, and the examination of the behaviour of hexahydronicotine on further reduction.

E. C. R.

Isocinchonine. By O. HESSE (*Annalen*, 260, 213—226; compare Comstock and Koenigs, *Abstr.*, 1887, 1124).—Isocinchonine, $\text{C}_{19}\text{H}_{22}\text{N}_2\text{O}$, is formed when commercial cinchonine sulphate (30 grams) or the free base is dissolved in concentrated sulphuric acid (150 grams), the solution heated at 60 — 80° for six hours, and then kept for 24 hours at the ordinary temperature; the solution is

diluted, gradually mixed with excess of soda, and extracted with ether; on concentrating the ethereal extract, small quantities of hydrocinchonine and apocinchonine are deposited in crystals, and on further evaporation, there remains an oily residue which gradually solidifies, and from which pure isocinchonine can be obtained by repeated recrystallisation from ether, or by converting the base into the hydrochloride. Isocinchonine crystallises from ether in compact, colourless, anhydrous prisms, melts at 125° , volatilises at a high temperature, and is moderately easily volatile with steam; it is readily soluble in alcohol, ether, acetone, chloroform, and light petroleum, but insoluble in water and alkalis. Its alcoholic solution turns red litmus blue, but has no action on phenolphthaleïn paper; an absolute alcoholic solution of the base is laevorotatory, and at 15° $[\alpha]_D = -53.7^{\circ}$ when $p = 1$, and $[\alpha]_D = -55.6^{\circ}$ when $p = 3$. The *hydrochloride*, $C_{19}H_{22}N_2O \cdot HCl + H_2O$, prepared by neutralising the base with dilute hydrochloric acid, crystallises in hexagonal prisms, and loses its water at $140-150^{\circ}$, the anhydrous salt melting at 201° ; it is readily soluble in hot water, and moderately easily in alcohol and chloroform, but only sparingly in cold water, and insoluble in ether; its rotatory power at 15° in aqueous solution is $[\alpha]_D = -68.6$ when $p = 1$, and $[\alpha]_D = -71.2^{\circ}$ when $p = 2$, but the addition of hydrochloric acid to the solution diminishes the rotatory power. The *platinochloride*, $(C_{19}H_{22}N_2O)_2 \cdot H_2PtCl_6 + 3H_2O$, prepared by adding sodium platinochloride to an aqueous solution of the hydrochloride, is a pale yellow, sparingly soluble compound. The *acid platinochloride*, $C_{19}H_{22}N_2O \cdot H_2PtCl_6 + 2H_2O$, is precipitated on adding platinic chloride to an aqueous solution of the hydrochloride, but the yellow, amorphous compound thus produced readily loses 1 mol. H_2O , changing into a crystalline salt; the latter forms orange needles, and is rather sparingly soluble in hydrochloric acid, and almost insoluble in cold water. The *aurochloride*, $C_{19}H_{22}N_2O \cdot 2HAuCl_4$, is obtained as a yellow, amorphous precipitate on adding auric chloride to an aqueous solution of the hydrochloride; it is sparingly soluble in cold water. The *mercurochloride*, $C_{19}H_{22}N_2O \cdot HHgCl_2$, crystallises in small, concentrically grouped needles. The *normal sulphate*, $(C_{19}H_{22}N_2O)_2 \cdot H_2SO_4 + 6H_2O$, crystallises in prisms, and is readily soluble in alcohol and water; the *acid sulphate*, $C_{19}H_{22}N_2O \cdot H_2SO_4 + 4H_2O$, crystallises in needles, and is readily soluble in hot, but only moderately easily in cold, water. The *oxalate*, $(C_{19}H_{22}N_2O)_2 \cdot H_2C_2O_4$, *thiocyanate*, *hydriodide* (with 1 mol. H_2O), and the zinc double salt, $C_{19}H_{22}N_2O \cdot 2HCl \cdot ZnCl_2$, crystallise in needles.

When "pure" commercial cinchonine acid sulphate is boiled with dilute sulphuric acid as described by Jungfleisch and Léger (Abstr., 1888, 380), small quantities of apocinchonine and cinchonigine are formed, but cinchonibine and the two hydroxy-bases described by Jungfleisch and Léger are not produced; cinchonifine and cinchoniline are probably identical with hydrocinchonine and apocinchonine respectively, and cinchonigine is identical with isocinchonine.

When cinchonine sulphate is treated with sulphuric acid and oxalic acid at $125-130^{\circ}$ as described by Caventou and Girard, it yields hydrocinchonine, isocinchonine, and a base which is probably identical

with that formed by heating cinchonine oxalate with sulphuric acid; it would seem, therefore, that in this reaction some of the cinchonine is converted into cinchonine.

F. S. K.

Veratrine. By S. STRANSKY (*Monatsh.*, 11, 482—485).—The alkaloid dissolves readily in most solvents, such as xylene, glycerol, aniline, acetone, chloroform, and amyl alcohol. On distillation with alcoholic potash, commercial veratrine gave rise to the two bases cevidine and veratroïne; angelic and veratric acids were simultaneously formed, and the latter identified both by its melting point (179.5°) and by a combustion. When distilled with aqueous potash, the yellow, resinous mixture of bases furnished methylamine, recognised by its forming the characteristic platinochloride, and a yellow oil having an odour resembling that of the homologues of pyridine. The author has also investigated the behaviour of veratrine when distilled with zinc dust and when oxidised with potassium permanganate. In the former case, no recognisable product was obtained; in the latter traces of oxalic acid were formed (compare Bosetti, *Arch. Pharm.*, 1883, 81, and Ahrens, *Abstr.*, 1890, 1448).

G. T. M.

A Double Salt of Cocaine. By W. MÜLLER (*Chem. Centr.*, 1890, ii, 818; from *Pharm. Zeit.*, 35, 522).—On adding cocaine hydrochloride to a solution of mercuric chloride (1 : 50), a milkiness soon forms which gradually increases to a voluminous precipitate. It is the double salt $C_{17}H_{21}NO_4 \cdot HCl \cdot HgCl_2 + 2H_2O$, sparingly soluble in cold water, somewhat more soluble in alcohol; it forms slender crystals, and melts at 124° . If heated with hydrochloric acid in the absence of air, benzoic acid, methyl benzoate, and ecgonine hydrochloride are formed. After agitating the aqueous solution with chloroform, cocaine can be detected in the former with picric acid. Alcoholic potash decomposes the double salt, mercuric oxide being precipitated and ethyl benzoate formed.

J. W. L.

Cocaine Chromate. By W. MÜLLER (*Chem. Centr.*, 1890, ii, 818—819; from *Pharm. Zeit.*, 35, 594).—If a concentrated solution of cocaine is treated with a 4—5 per cent. solution of chromic acid, a precipitate is gradually formed of a thick, tarry nature, which finally changes to a light-yellow, amorphous precipitate of the composition $C_{17}H_{21}NO_4 \cdot H_2CrO_4 + H_2O$. In the presence of free hydrochloric acid, the chromate is precipitated almost quantitatively, and is of a lemon-yellow colour; 0.001 gram is precipitable. It is not hygroscopic, is sparingly soluble in cold water, but readily so in hot water, from which it crystallises in orange-coloured needles which darken on exposure to the light.

The precipitation in acid solution may serve to distinguish cocaine from other alkaloids. Potassium dichromate precipitates the same double salt in neutral solution; but normal potassium chromate produces no precipitate in the neutral solution; on the addition of acid, the double salt is formed. It melts at 127° . By treating it with fuming nitric acid, drying, and then adding alcoholic potash, the odour of peppermint is perceptible, which De Silva considers as

characteristic of cocaine. If the chromate is warmed with alcoholic potash, the odour of ethyl benzoate is perceptible. The chromate is insoluble in benzene, and but slightly soluble in chloroform.

J. W. L.

Oxidation of Hygrine. By C. LIEBERMANN and O. KÜHLIN† (*Ber.*, 24, 407—415).—Liebermann has already shown (*Abstr.*, 1889, 732) that the hygrine obtained from coca or truxillo leaves is a mixture of liquid bases which are very difficult to separate. He succeeded in isolating two constituents, and termed them "low-boiling hygrine," $C_8H_{15}NO$, and "high-boiling hygrine," $C_{14}H_{21}N_2O$. A crude hygrine, from which the same compounds may be separated, has been obtained in larger quantity from Peruvian cusco leaves. The low-boiling hygrine yields a *hydrochloride*, $C_8H_{15}NO \cdot HCl$, crystallising in beautiful needles if moisture be excluded, and a *hydriodide*, $C_8H_{15}NO \cdot HI$, of similar appearance; the high-boiling hygrine forms a *hydrobromide*, $C_{14}H_{21}N_2O \cdot 2HBr$, and a *hydriodide*, $C_{14}H_{21}N_2O \cdot 2HI$, also crystallising in colourless needles.

Many unsuccessful attempts were made to obtain crystallised products by the oxidation of hygrine; at length it was found that the following method yielded good results:—40 grams of hygrine is mixed with a solution of 100 grams of chromic anhydride, and 150 grams of concentrated sulphuric acid in about 600 grams of water, and the mixture boiled for 4—5 hours. After removal of chromium and sulphuric acid, the solution is boiled with baryta-water, treated with carbonic anhydride, and the remainder of the barium exactly precipitated with sulphuric acid. The filtrate is evaporated to a small bulk, and treated with freshly precipitated copper oxide; the copper salt thus formed, when purified, crystallises in pale-blue needles, readily soluble in water and alcohol, and has the composition $(C_8H_{15}NO_2)_2Cu$. It is readily converted into the corresponding acid, which may be termed *hygric acid*, $C_8H_{11}NO_2$. This forms colourless, stellate groups of needles, is readily soluble in water, alcohol, and hot chloroform, insoluble in ether and benzene, and is somewhat hygroscopic if not quite pure; after drying at 60° , it melts at 164° , but under ordinary circumstances, becomes plastic at 85° , and finally melts completely at 130° . This behaviour may possibly be due to the absorption of water from the atmosphere. It decomposes if strongly heated, evolving vapours which smell like pyridine; it reduces potassium permanganate in the cold. Its *hydrochloride*, $C_8H_{11}NO_2 \cdot HCl$, crystallises in beautiful needles, and melts at 188° ; the *aurochloride*, $C_8H_{11}NO_2 \cdot HAuCl_4$, is an oil.

Attempts were also made to prepare the calcium and barium salts, but without success, owing, probably, to the fact that the compound is the carboxylic acid of a strong base, and the acid nature of the compound is so much weakened that its salts with those metals are very unstable. The composition and general properties of the acid make it not improbable that it is a piperidinecarboxylic acid, $C_8NH_{10}COOH$. When quickly heated to 300° with concentrated sulphuric acid, it yields a mixture of pyridine and piperidine; if also the acid is boiled with an excess of auric chloride, gold is precipitated, and a mixture of pyridine and piperidine aurochlorides is obtained.

From these results, as well as from the composition of the alkaloïd, the latter cannot be a trimethylquinoline, as suggested by Hesse (*Pharm. Zeit.*, 1887, 669). It is more probably a hydroxy-allyl-piperidine, $C_8H_{10}OC_3H_5$, or has possibly the constitution

The high-boiling hygrine, on oxidation, also yields hygric acid, although in much smaller quantity, and is therefore likewise closely connected with piperidine.

H. G. C.

Cytisine. By K. BUCHKA and A. MAGALHÃES (*Ber.*, 24, 253—260).—Cytisine may be prepared by the following method more readily than by Partheil's process (this vol., p. 231):—the ground laburnum seeds are extracted with dilute hydrochloric acid, and the solution, after concentration, is made alkaline and extracted with chloroform. On distilling off the latter, cytisine remains as a pale-yellow oil which quickly solidifies to a crystalline mass, and may be obtained almost colourless by repeated crystallisation from absolute alcohol. It forms transparent, envelope-shaped crystals, melts at 156° (uncorr.), and may be sublimed; it is very readily soluble in water, alcohol, benzene, and chloroform, but insoluble in carbon bisulphide and light petroleum. Analysis and determination of the molecular weight by Raoult's method have confirmed the formula $C_{11}H_{14}N_2O$, first given by Partheil. It yields two *hydrochlorides*, the first of which, $C_{11}H_{14}N_2O \cdot HCl$, is obtained by passing hydrogen chloride into a chloroform solution of the base; the dried salt is an amorphous powder, but it crystallises from alcohol in colourless, monosymmetric prisms ($\alpha : b : c = 0.731 : 1 : 0.714$; $\beta = 107.5^\circ$), containing $\frac{1}{2}$ mol. alcohol. The *dihydrochloride*, $C_{11}H_{14}N_2O \cdot 2HCl + 2\frac{1}{2}H_2O$, is obtained by acting on the base with an excess of hydrochloric acid, and crystallises from water in small, hard, colourless crystals. The base also forms two *platinochlorides*, $(C_{11}H_{14}N_2O)_2 \cdot H_2PtCl_6 + 2H_2O$ and $C_{11}H_{14}N_2O \cdot H_2PtCl_6 + 2\frac{1}{2}H_2O$. The latter has already been described by Partheil; the former crystallises in pale-yellow, lustrous needles or plates, is sparingly soluble in water, and decomposes on heating without melting. The *aurochloride* has also been described by Partheil; the *zincchloride*, $C_{11}H_{14}N_2O \cdot H_2ZnCl_4$, forms small, colourless, transparent crystals very readily soluble in water.

On distillation with soda-lime, cytisine yields a distillate which smells strongly of pyrroline, and of pyridine and quinoline bases. Pyrroline is also formed by heating cytisine alone or with zinc-dust. Potassium permanganate converts the base into a syrupy acid insoluble in ether.

Crystals Occurring in the Nuclei of the Liver Cells. By V. GRANDIS (*Rend. Acad. Lincei.*, 6, ii, 213—218 and 230—235).—The author has previously described (*Atti. Acad. Real. Torino*, March, 1889) certain crystals found exclusively in the cell nuclei of the liver and some other organs of adult and old dogs. On account of the interference of the enveloping nuclear matter, the reactions given by

the crystals *in situ* under the microscope were untrustworthy, but the author has now succeeded in separating them, and has extracted from them a new alkaloid or ptomaine which he terms *gerontine*. Gerontine is a strongly basic compound isomeric with cadaverine; it is a heavy, yellowish liquid which resinifies on standing. It has a disgusting odour, dissolves in water, and gradually crystallises out from its solution in spherical tufts; when heated with caustic potash, an alkaline gas is evolved. The *hydrochloride* crystallises from absolute alcohol in very deliquescent, rectangular, and oblique prisms. The *platinchloride*, $C_5H_{14}N_2, H_2PtCl_6$, crystallises in tufts of pale-yellow, spindle-shaped needles readily soluble in water, but insoluble in alcohol. It blackens and decomposes at 215° . The *aurochloride* crystallises in yellow needles very soluble in alcohol and water. A compound of the hydrochloride with mercuric chloride, $C_5H_{14}N_2, 2HCl, HgCl_2 + 2H_2O$, may also be obtained: it crystallises in deliquescent, rectangular prisms and cubes, and decomposes when heated above 100° . The *picrate* forms very soluble, yellow, twinned, lenticular crystals. A *benzoyl* derivative crystallises in rectangular prisms which melt at $175-176^\circ$. With phosphotungstic acid, gerontine yields a white, granular precipitate which crystallises, on cooling, in rectangular prisms; with phosphomolybdic acid, a precipitate of yellow, hexagonal crystals is obtained, which turn first green and then blue; potassium bismutho-iodide yields a precipitate of red prisms; with potassium iodide, an amorphous, yellow precipitate; with tannic acid, a white, amorphous precipitate which turns brown after a time; with Fröhde's reagent, a transient, red coloration is obtained. From various considerations, the author concludes that the nuclear crystals consist of gerontine phosphate. S. B. A. A.

Synthesis of Proteïds. By P. SCHÜTZENBERGER (*Compt. rend.*, 112, 198—201).—The author's previous researches on the decomposition of albumin in presence of alkalis (Abstr., 1888, 971) lead to the conclusion that albumin may be broadly regarded as formed from $H_2C_2O_4 + 2NH_3 + 3C_mH_{2m+1}NO_2 + 3C_nH_{2n-1}NO_2$ with elimination of 8 mols. H_2O . This would give $C_g + {}_2H_{2g} - {}_3N_3O_8$, and if $g = 28$, the percentage composition calculated from the formula agrees closely with that of albumin.

Amido-compounds, $C_mH_{2m+1}NO_2$ and $C_nH_{2n-1}NO_2$, mixed with about 10 per cent. of urea, were finely powdered, dried at 110° , and intimately mixed with 1.5 times the weight of phosphoric anhydride, and heated in an oil-bath. At 120° , there is no change, but at 125° , dehydration takes place very rapidly, and the mixture becomes pasty, but solidifies to a compact product without any appreciable darkening. The product is dissolved in water, the solution mixed with several times its volume of alcohol, and the pasty precipitate washed with alcohol and redissolved in water. Phosphoric acid is removed by means of baryta, and the filtered liquid, when concentrated on a water-bath, yields an amorphous product, soluble in water, but precipitated as a curdy mass on the addition of alcohol. Aqueous solutions of the product are precipitated by tannin, picric acid, mercuric chloride, acid mercuric nitrate, Millon's reagent, potassium diiodide,

mercuric potassium iodide, phosphotungstic acid in presence of hydrochloric acid, phosphomolybdic acid, and lead acetate and lactic acetate. Potassium ferrocyanide gives no precipitate in a cold solution in presence of acetic acid. With caustic potash and copper sulphate, a rose-red coloration is formed. Heated with nitric acid and evaporated with excess of the acid, the product yields a yellow residue which becomes orange in contact with ammonia, and when heated decomposes suddenly, leaving a bulky mass of carbon. Its behaviour in this respect is similar to that of gelatin. When heated on platinum, the compound carbonises and swells up, evolving the characteristic odour of burning nitrogenous animal matter.

Action of Glycerol on Egg Albumin. By V. GRANDIS (*Rend. Acad. Lincei*, 6, ii, 138—145).—Berthelot found that when glycerol is left in contact with albumin, it is converted into sugar, and suggested that, in virtue of this reaction, sugar might be formed from the animal fat. The author has examined the change produced by the reaction in the albumin. Purified egg albumin was boiled with an equal volume of pure glycerol (sp. gr. = 1.25) for one-half to one hour, filtered, and the filtrate extracted with at least 10 vols. of alcohol (90°) containing a little ether. The extract is a milky liquid which in a day or two leaves a white, flocculent deposit; this dissolves in boiling water, forming a heavy, opalescent solution not coagulated by boiling, and unaffected by the addition of acetic or hydrochloric acids, or of a concentrated solution of sodium chloride. The addition of a concentrated solution of sodium sulphate or chloride, together with a drop of acetic acid, produces a flocculent precipitate soluble in the boiling liquid. Concentrated nitric acid gives a precipitate which dissolves on heating, forming a pale-yellow solution, which acquires a reddish-violet coloration on the addition of soda and a drop of copper sulphate. It is also precipitated by the other reagents for proteids. In its reactions it strongly resembles hemialbumose, but it does not appear to have the same percentage composition, approximating in this respect to antipeptone. It is probably identical with the compound obtained by Hönig (*Chem. Zeit.*, 1890, Nos. 53 and 55), but if so, its alleged solubility in alcohol and ether must be due to the use of a quantity of the solvent insufficient to precipitate it from its solutions. It appears to be formed by the direct action of glycerol on albumin, since it may be obtained without the aid of heat by leaving the two substances in prolonged contact at the ordinary temperature. Assuming that the proteid is hemialbumose, it is probable that as a first step to its conversion into sugar, the glycerol is dehydrated and converted into acetaldehyde.

When an aqueous solution of the purified proteid is treated with a quantity of alcohol insufficient to form a precipitate, and allowed to remain for about three months, a crystalline deposit of very thin, brilliant, rhomboidal, curved plates is formed. These crystals are insoluble in hot water, and in concentrated sulphuric acid and potash; they are turned yellow by iodine, but are not affected by Millon's reagent, and do not react with alloxan.

Decomposition Products of Proteids. By M. SIEGFRIED (*Ber.*, 24, 418—432).—It has been shown by Dreschsel (*Abstr.*, 1889, 1021, this vol. p. 95) that two bases may be isolated by means of phosphomolybdic acid from the products of decomposition of casein with hydrochloric acid, and that one of them when heated with baryta-water yields carbamide. The author has extended the investigation to other proteids, with the results given in this paper.

400 grams of conglutin is boiled with 1600 c.c. of 15 per cent. hydrochloric acid and 100 grams of stannous chloride for 72 hours, air being excluded, and the product after dilution to 7 litres, is saturated with hydrogen sulphide; the filtrate is evaporated, and a solution of 2500 grams of crystallised phosphomolybdic acid added, preferably to the hot solution, and the precipitate washed with a solution of phosphomolybdic acid in dilute sulphuric acid until free from chlorine.

The filtrate in addition to the decomposition products obtained by Ritthausen (this Journ., 1870, 719, 721) and Schulze (*Abstr.*, 1885, 581, 916), namely, glutamic acid, tyrosine, leucine, aspartic acid, and phenylalanine, also contains a compound which remains after separation of the foregoing substances as a syrup. On the addition of an alcoholic solution of hydrogen platinochloride, it yields a platinochloride, which is reconverted by the action of hydrogen sulphide and hydrated lead oxide into the base. This separates as a granular precipitate on the addition of ether to its alcoholic solution; it has the empirical formula $C_6H_8NO_2$, and belongs to the class of glucoproteins described by Schützenberger (*Abstr.*, 1879, 542).

The precipitate obtained with phosphomolybdic acid is boiled with baryta-water, filtered, the barium exactly precipitated with sulphuric acid, again filtered, and, after the addition of an excess of hydrochloric acid, evaporated to a syrup. By repeated precipitation with alcohol, this can be separated into a more readily soluble and a less readily soluble portion. From both fractions, however, a *platinochloride*, $C_6H_{12}N_2O_3PtCl_6$, and a double salt with silver nitrate,

were obtained; both salts have the same composition as those obtained by Dreschsel from casein. The former crystallises when pure in orange needles, but is frequently obtained as an oil. The second forms light, slender needles, but always contains small quantities of an amorphous silver salt.

These three salts may be more readily prepared in the following manner:—The precipitate obtained with phosphomolybdic acid is dissolved in hot water, decomposed with a slight excess of baryta-water, the filtrate saturated with carbonic anhydride, and heated for half an hour to boiling. Silver nitrate is then added directly to the solution until no further separation of the amorphous silver salt takes place. After remaining for 12 hours, the precipitate is separated, the filtrate evaporated to a syrup, and alcohol is added in small quantities; the silver salt of the base which yields the above platinochloride first separates as an oily precipitate, and is quite free from the salt $C_6H_{12}N_2O_3.HNO_3.AgNO_3$, which separates completely on further addition of alcohol and ether. The oily silver salt is then

converted into the platinochloride, by decomposing it with hydrogen sulphide, evaporating to a small bulk, and adding hydrogen platinochloride, alcohol, and ether.
